
(19)

This polymer is prepared in the bulk by combining rigorously dried and purified monomer in the bulk with the catalyst t-BuCH=M(NC_6H_3-i-Pr_2)[$OC(CF_3)_2Me$]$_2$ (equation 1), where M = W or Mo, in the ratio of about 1000/1 monomer

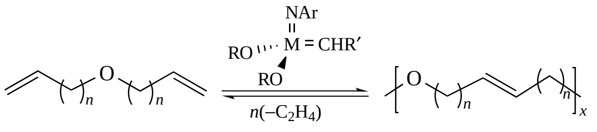
to catalyst. Polymerization occurs spontaneously, and high polymer ($M_n = 50\,000$) can be achieved by driving the polymerization via removal of ethylene with a high vacuum.

For ADMET polymerizations in general, the condensation product, ethylene, is observed immediately followed by a rapid increase in viscosity (ca. 30 min). Polymerization reactions are heated to a maximum of 60 °C (generally considered to be catalyst decomposition temperature) and continued for several hours with evacuation of ethylene until stirring is no longer possible owing to formation of the solid state. The ADMET condensation of dienes is an exceptionally clean polymerization reaction and produces a polymer containing only one type of repeat unit and condensate.

1,4-Polybutadiene containing an unprecedented high trans stereochemistry can be synthesized via the ADMET polymerization of 1,5-hexadiene.[44] The extension to other purely hydrocarbon-based homopolymers has shown that (aside from steric factors that influence the formation of the metallacycle in the mechanism) the polymerization method is both trivial and broad in scope.

Random hydrocarbon copolymers can also be produced by this new equilibrium polymerization method.[49] Copolymers containing octenylene and butenylene linkages in a statistical array based on feed ratio result from the cocondensation of the two respective monomers or by the reaction of diene with unsaturated polymer.[49] More controlled polymer structures have also been prepared by the slow addition of a diene solution to an unsaturated polymer containing active catalyst. Substituent effects were shown to dictate the polymerizability of monomers and in some cases selective polymerization of specific alkenes in the monomer resulted in what appears as perfectly alternating copolymers.[51]

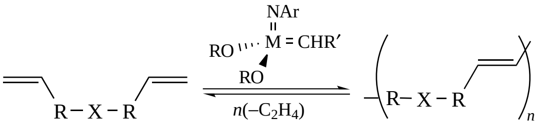
As is the case for functional ROMP monomers, the molybdenum-based catalyst used in ADMET chemistry is more tolerant to functionalized dienes than is the tungsten analog. Even so, it is evident that both types of catalysts can be used in the preparation of ADMET polymers possessing various functionalities. For example, ADMET polymers containing the ether functionality can be made (equation 20) if the oxygen atom is placed at least two methylenes apart from the metathesizing alkene ($n = 1$ or greater in the monomer).[52–54] For example, divinyl ether ($n = 0$) and diallyl ether do not polymerize via ADMET techniques, whereas di-*n*-butenyl ether and higher analogs do, to generate a new class of unsaturated linear polyethers.



(20)

M = W or Mo

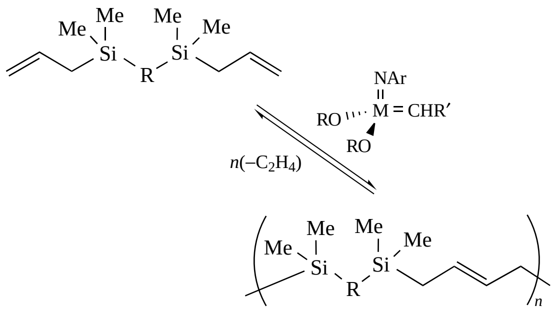
Observations of this nature have also been made for carbonyl-containing monomers (equation 21), and the structure/reactivity relationships for dienes containing esters,[55] carbonates,[56] and ketones[57] have been elucidated. As with previous work, subtle design in monomer structure significantly affects reactivity, and various new unsaturated polymers and copolymers containing these groups were prepared.



(21)

$X = -CO-, -CO_2-, -OCO_2-; R = -(CH_2)_x-$

The ADMET step condensation polymerization of carbosila- and carbosiloxa-dienes has generated a new class of unsaturated silicon-containing polymers when monomer structure/reactivity relationships, as described earlier for the polar functionalities, are obeyed (equation 22).



(22)

R = Et, Ph, $-OSiMe_2O-$, $-OSiMe_2PhSiMe_2O-$

Vinylsilane monomers do not homopolymerize owing to steric inhibition within a required catalytic intermediate, yet will specifically copolymerize with an unhindered diene, resulting in isolated units of the vinylsilane within the copolymer. Allylic silanes, however, show no resistance to homometathesis and yield novel high molecular weight, unsaturated polycarbosilanes with low glass transition temperatures and good thermal stability.

4.3 ADMET Depolymerization Chemistry

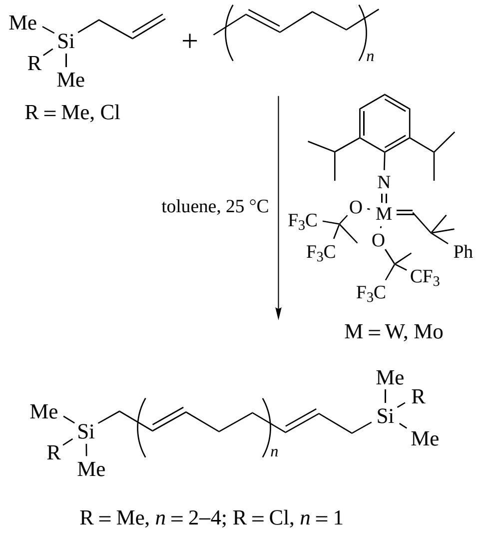
Scheme 5 suggests that every step of the ADMET polymerization cycle is in equilibrium and that, by shifting the relative concentrations of the condensate and polymer, depolymerization would result. In fact it has been shown that various unsaturated polymers can be depolymerized with excess ethylene,[50] as well as substituted ethylenes. These depolymerizations can be done either with the tungsten or the molybdenum versions of Schrock's catalyst.

Both metathesis degradation (a well documented phenomenon[58]) and metathesis depolymerization offer promise in issues related to chemically recycling discarded unsaturated polymers. However, it should be noted that ADMET depolymerization chemistry is distinguished from metathesis degradation chemistry by virtue of the fact that very specific products result from depolymerization and, in

some cases, conversions have been shown to be quantitative. The implications regarding recycling via depolymerization of polymer streams that otherwise would be discarded are clear.

Partial ADMET depolymerizations have been achieved by reaction of ethylene with 1,4-polybutadiene, 1,4-polyisoprene, polyoctenamer, polynorbornene, and poly(styrene-*b*-1,4-butadiene) to yield oligomers of these polymer structures.[50] Polybutadiene also yields 1,5-hexadiene, polyisoprene produces 2-methyl-1,5-hexadiene, and polyoctenamer generates 1,9-decadiene. Depolymerization of the block copolymer demonstrates the potential of directly forming macromers (in this case of polystyrene) from the polymers themselves. These reactions are done in inert solvents such as toluene or chlorobenzene, with a large excess of ethylene being present either at or slightly higher than atmospheric pressure. Generally the reactions are done overnight, and no purification of the products is necessary.

ADMET depolymerizations with substituted alkenes have been done as well, thereby generating perfectly difunctional telechelic molecules. As an example, 1,4-polybutadiene has been depolymerized in an inert atmosphere with a 10-fold molar excess (based on the repeat unit) of either allyltrimethylsilane or allylchlorodimethylsilane (equation 23).[59] In these examples, the chemistry can be driven to complete depolymerization to yield structures with either one, two, three, or four repeat units of 1,4-butadiene. The synthesis of perfectly difunctional oligomers by this chemistry offers significant opportunity, particularly for functional groups such as alcohols, esters, carboxylic acids, and amines.



(23)

5 A BRIEF SUMMARY STATEMENT

The past 30 years have produced a wealth of information of both theoretical and practical interest regarding the metathesis reaction. The elegance associated with delineation of the mechanistic details has permitted a high level of sophistication in the synthesis of both conventional polymers as well as previously unknown structures. The key to further advancement in homogeneous metathesis polymerization catalysis will depend upon the creation of stable catalyst structures that can be used at high reaction temperatures. Further, the design of catalysts that are effective under ambient polymerization conditions will be most welcome.

Ultimately the goal of research of this nature is to synthesize polymers possessing a high degree of structural regularity. This goal is not unreasonable, given the rapid advancements in metathesis polymerization, and it is very likely that this method of generating polymers will become as important as the chain and step polymerization schemes that pioneered synthetic polymer chemistry early in this century. We await these developments with a high level of anticipation.

1 INTRODUCTION

Across the enormous range of molecules, including natural molecules, that can act as ligands to metal ions that involve coordination via multiple donors, mixed donor systems predominate and thus represent a vast area of coordination chemistry. The necessary prerequisite is at least didentate capability, the minimum arrangement whereby two different donor atoms are coordinated. A variety of donor atoms, drawn essentially from the p-block of the periodic table, can operate; however, only a small number of atoms are commonly met as donors – predominantly N and O atoms, and to a lesser extent S, P, and heavier elements such as As, Se, and Te. There are also examples of ligands employing C, and heavier elements from group 14. Over 12 000 research papers featuring mixed donor ligands have appeared in the literature in recent decades. For this article, the focus will be on the more commonly met heteroatom donors.

Mixed donor ligands can chelate to metal ions as polydentates, where the heteroatoms bound to the metal center are usually, although not necessarily, linked together via covalent bonding with carbon atoms. The concept of di-, tri-, and tetradentate coordination is illustrated in Figure 1, where A, B, C, and D represent different nonmetals capable of forming coordinate bonds to the central metal atom with significant σ-bond character. The different donor atoms almost invariably lead to different metal-donor distances and consequently distorted geometries about the central metal ion.

A key reason for the predominance of mixed donor systems is that the common donor atoms are met in a number of different donor groups; N in amine or imine, O in alcohol and acid, for example. An example of a classical mixed donor ligand is an amino acid, with both an O and N donor atom; this clearly differs in type from the single N-donor diamine or O-donor dicarboxylate chelates (Figure 2). However, an N-atom donor chelate with one amine group and one pyridine group, or else an O-atom donor chelate with one carboxylate and one alcohol group, are effectively mixed donor ligands, although this is initially less obvious because of the common donor atoms. The two donor groups in each example are distinctly different, even though the two donor atoms are common. It is appropriate to consider such molecules as mixed donor ligands because they present chemical and structural inequivalences in the same way as different groups also containing different donor atoms. The donor groups are related but distinct, like dialects in a language; to identify this particular subclass of mixed donor ligand, where the donor atoms are common but the donor groups differ, we shall classify them as dialectical ligands (Figure 2). They contribute significantly to the family of mixed donor ligands.

For molecules of higher denticity, the presence of mixed donors increases the number of potential ligand topologies as a consequence of the way the component donors may be assembled. This is exemplified for four donor groups in Figure 3, considering a system A_3B with three type A donor groups and a single type B donor group and comparing it with the single donor analogue, A_4. The six topologies illustrated for the A_4 ligand must be expanded to 15 for the A_3B ligand, as a result of considering positional options for the B donor. 'Upgrading' to an A_2B_2 system increases options further. Of course, not all options may be structurally or synthetically practicable, nor even sought, but the enhanced diversity of ligand forms that result as a consequence of introducing mixed donors should be recognized, and is starkly illustrated in Figure 3.

Coordination of a particular mixed donor ligand to a metal ion typically leads to an increase in the number of geometric isomers possible compared with a single donor analogue. This is exemplified with mononuclear tris(didentate) octahedral complexes; a symmetrical ligand like ethane-1,2-diamine exists as a single geometric isomer, whereas a dissymmetric ligand like glycine can form fac and mer isomers. Of course, all the tris(didentate) complexes are also enantiomeric. The potential for a larger number of isomers introduced by coordination of mixed donor ligands (classical or dialectical) rather than single donor ligands should be recognized. For inert metal complexes, separation of isomers is usually practicable; however, with labile metal complexes, isomers may be in dynamic equilibrium and effectively not separable.

Mixed donor ligands present a challenge to the coordination chemist as a result of structural aspects discussed above. Further, the presence of donors of distinctly different character, such as an N-donor and an S-donor, influence the way they select metal ions, and the stability, spectroscopic, and redox properties of their complexes.

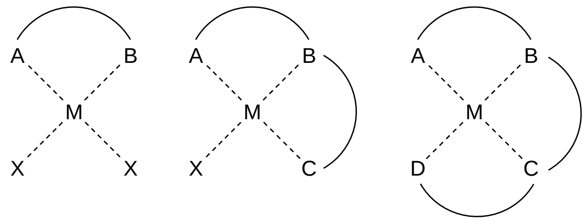

Figure 1 Types of mixed donor ligands

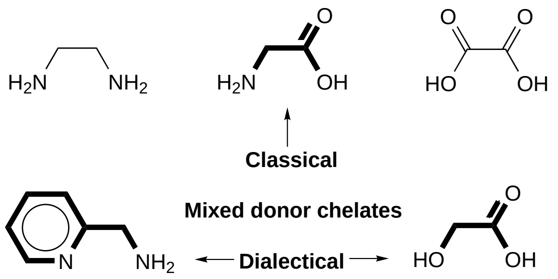

Figure 2 Classes of simple didentate mixed donor ligands

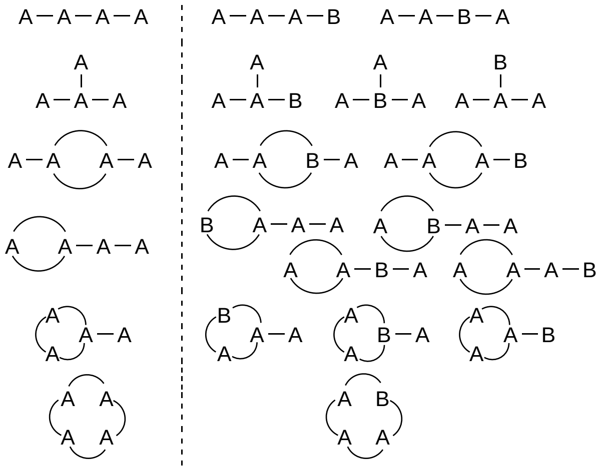

Figure 3 Some topologies for an A_3B mixed donor system compared with an A_4 system

Central to the stability and chemistry of complexes formed by mixed donor ligands are two key concepts of coordination chemistry. The first is the chelate effect, which applies to all polydentate ligands, and reflects the increase in stability of a type of complex as monodentate donor molecules are replaced by polydentates with donors linked by chelate rings. The hard–soft acid–base theory is particularly relevant to mixed donor ligands where donors of distinctly different character may bind to a central metal ion. The 'like prefers like' concept means 'hard' nonpolarizable donor atoms (N and O, for example) bond preferentially to 'hard' nonpolarizable metal ions (high-valent first-row transition metals), whereas 'soft' polarizable ligands (S, P, and As, for example) tend to bond to more polarizable metal ions (low-valent second and third transition metals). For mixed donor ligands with combined hard and soft donors, coordination to a particular metal ion will involve some mismatch, which is reflected in stability and properties of resultant coordination complexes.

The field has been the subject of several reviews of the properties, structures, and stability of numerous ligands and their complexes, including both mixed donor open-chain and macrocyclic polydentates.[1–10] Detailed reports of coordination chemistry that focus on the metal include many examples of mixed donor ligand systems.[11] The nature of this article requires that only limited references are cited herein as examples, but these include some key reviews; readers may access original work through these reviews or else by structure searching from compounds represented in line drawings that appear here.

2 CHELATING LIGANDS WITH TWO TYPES OF DONORS (A_XB_Y)

Ligands with two different types of donors represent the simplest class of mixed donor ligand in principle, but the range and structural diversity is still enormous. Practically, every combination of potential donor groups has been examined; types of donor groups incorporating the four most common donor atoms are exemplified in Table 1. Of course, metal ions play a key role in selection of donors, not only with ambivalent donor groups but also with ligands carrying a surplus of potential donors from which to select.

2.1 Didentate Ligands

Even for simple mixed donor didentate ligands, the scope is virtually limitless. Not only does any combination of two different donor groups lead to a classical or dialectical mixed donor ligand, but also some donor groups are themselves ambivalent donors because they carry two different potential donor atoms in the one group (as exemplified in Table 1), enhancing options for ligand coordination. Chelation to form three-, four-, five-, six-, and higher-membered rings has been observed; this is illustrated with examples in Figure 4, where opening out of the intraligand angle with increasing ring size is also apparent. Didentate mixed N, O, S, and Se donor ligands have been reviewed.[12]

2.1.1 N,O Donor Ligands

α-Amino acids and amino alcohols are the most common examples of N,O donor ligands (Figure 5), and have attracted attention because of potential applications as bioactive

Table 1 Common types of donor groups containing the four most common donor atoms, and examples of ambivalent donors that can bind through one of two potential donor atoms present in a group

Donor Atom	Donor Group	Example
N	Amine	–NH_2,–NHR,–NR_2
	heterocyclic N-donor	pyridine, imidazole
	Imine	HN=CR–, –N=CR–
	Amido	–N^- –CO–
O	alcohol (or alcoholate)	HO–C (or $^-$O–C)
	Carboxylate	–COO^-
	ether (aliphatic, heterocyclic)	C–O–C
	Carbonyl	>C=O
	oxyanions	–$PO_3{}^-$, –$SO_3{}^-$, . . .
S	Thiol	–SH
	thioether (aliphatic, heterocyclic)	C–S–C
	Thioacid	CSS^-
P	Phosphine	–PH_3,–PRH_2,–PR_2H,–PR_3
Ambivalent donors	thioacid (O or S)	HO-C(=S)–
	amide (N or O)	–NH-CO–
	thiophosphate (O or S)	–$PSO_3{}^-$
	sulfenate (O or S)	–S=O

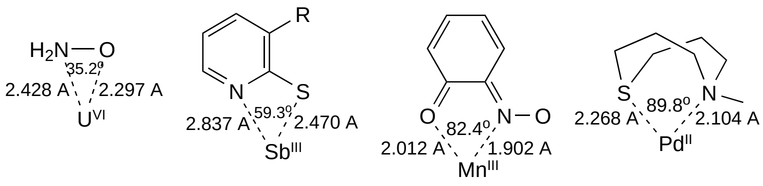

Figure 4 Complexes of mixed donor ligands with from three- to six-membered chelate rings

compounds and catalysts. The simplest member of these two classes are glycine and 2-aminoethanol (**1**; R = R′ = H; **2**, all R = H); substituents introduced in place of the R groups leads to a broad family of compounds. Whereas these two ligands form five-membered chelate rings, the analogues based on the β-amino acid 3-aminopropane (**3**) and 3-aminopropanol (**4**) form six-membered chelate rings; longer chains between donor groups leads to larger chelate rings, but stability diminishes from the five-membered rings upwards; four-membered aminoalcohol rings are rarely met and unstable. Amino acids almost invariably chelate with the carboxylic acid group deprotonated, but some examples of coordinated and protonated acid groups have appeared. In many amino alcohol complexes, both protonated and deprotonated OH groups coexist in the same compound. Monomeric aminoalcohol complexes are well known, and have been well defined by X-ray crystal structures. Polynuclear complexes of the aminoalcohols have been reviewed,[13] and often feature bridging via either deprotonated alkoxides or via hydrogen bonding between an alcohol and alkoxide.

N,O donor molecules where the carboxylic acid group is replaced by another acid group such as sulfonic or phosphonic acid may also chelate efficiently, such as aminophosphonic acids (**5**). Systems with N and O donors bound to an aromatic framework are also well represented, as exemplified by (**6**).

A key characteristic of N-hydroxide, N-oxide, and oxime ligands is the potential for formation of small chelate rings, even the uncommon three-membered chelate rings; while unusual, these have been reported for a number of mixed donor ligands.[14] N-Hydroxides such as hydroxylamine (**7**; R = R′ = H) and its N-alkylated analogues are capable of forming three-membered chelate rings, although in the presence of alternative larger-ring chelating opportunities three-membered chelate rings may not form, usually being more highly strained. Oximes are molecules with ambidentate groups that can bind to a metal ion via O or N donors, although the majority bind via nitrogen. Amidoximes (**8**), hydroxyoximes (**9**), and nitrosooximes (**10**) are well known as good chelators, and were once widely used as analytical reagents for M^{2+} complexation, the most famous being ‘cupron’ (**9**; R = R′ = Ph). Malonamide oximes are N,O didentate ligands, exemplified by the monoanion of the simplest, nitrosomalonodiamide (**11**), which binds Fe^{II} well. The oxime of acetylacetone (**12**) binds to numerous di- and trivalent metal ions. Cyanoximes (**13**), where R is an electron acceptor, can function as ligands but have not been deeply examined. The presence of the nitrile close to the

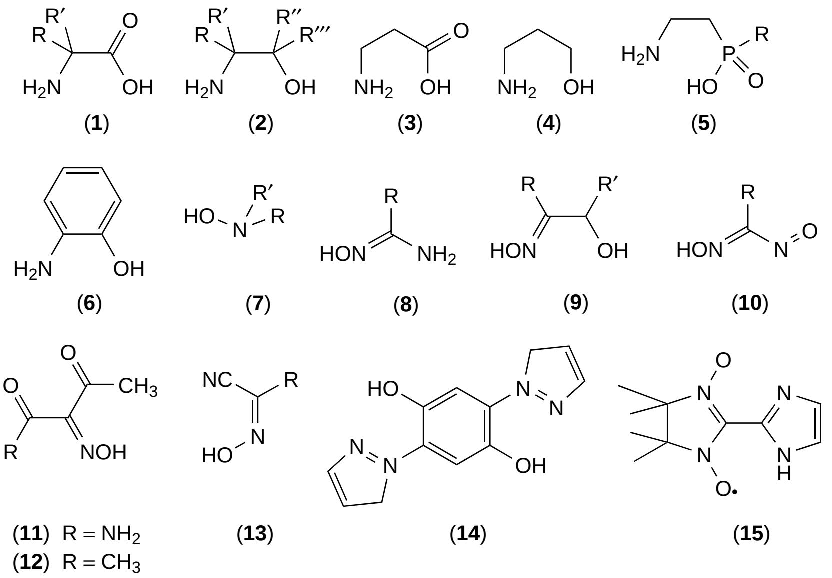

Figure 5 Didentate N,O chelates

oxime functionality leads to greater acidity (pK_a ~ 4.5–5.5) compared to other oxime-containing ligands. Cyanoximes feature in bridging arrangements, but chelation is common for transition metals.

Some N,O ligands reported are formally tetradentate, but contain two didentate compartments, each of which is constrained in such a way that it must bind to different metal ions; they may be termed bis(didentate) ligands. One example is (**14**), which as the dianion binds two $M^{II}(bipy)_2$ fragments (M = Ru, Os), for which ligand-centered oxidations lead to a bridging quinone, while fully oxidized and mixed-valence compounds also form.[15] The bridging ligand (**15**) is paramagnetic, and forms one- and two-dimensional polymeric complexes with Mn^{II} involving N,O chelation in opposite directions; some complexes formed display ferromagnetism.[16]

2.1.2 N, S and O, S Donor Ligands

Diverse examples of polydentate ligands that feature S-donors in concert with N-, O-, and also P-donors have appeared. Didentate mixed donor sulfur ligands have been reviewed.[17]

N,S donors that bind with chelate ring sizes ranging from six to three are known. Example N,S donors appear in Figure 6. One of the simplest N,S aminothiol chelates is the well known 2-aminoethanethiol (**16**). The deprotonated aminothiolate forms simple ML_2 (M = Cu, Ni, Pd) complexes, but may form polymeric compounds where the S can take on a bridging role. The black tetranuclear compound [Co_4(**16**)$_8$] (Figure 6) features the aminothiolate in simple chelate and bridging roles.[18] Chiral aminothiols and aminothioethers (**17**) derived from S-valine have appeared, and are catalysts for asymmetric addition of Et_2Zn to aromatic aldehydes.

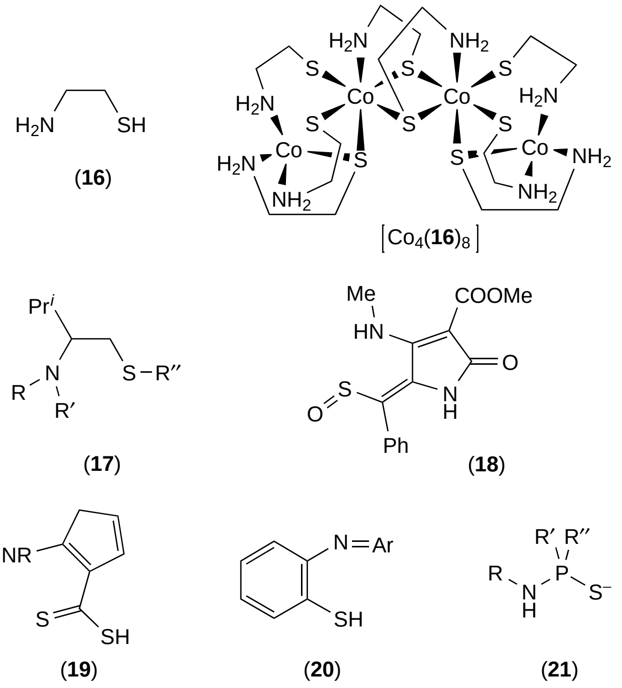

Figure 6 Didentate N,S chelates

Oxidation of the thiol donors can occur, leading to ambivalent SO_n-donors, such as (**18**), where coordination of the soft Pt^{II} is still through the soft S atom.[19] The aminothioacid (**19**) and its N-alkylated derivatives acts as an N, S chelate, forming six-membered rings with metals like Rh^{III}. The molecules (**20**) are imine-thiol chelates with donor groups attached to a central aromatic ring. Although they form apparently simple

ML_2 complexes with Ni^{II} and Pd^{II}, these complexes show both aromatic stacking interactions and helical distortions.[20] An unusual S,N-chelate, with no carbon atoms in the four-membered chelate ring set, is (**21**); it forms a 'spirocyclic' tetrahedral bis Co^{II} complex.

The N,Se donor analogues have been studied selectively. Selenocysteamine has been examined, and its complexation behavior compared with its oxo and thio analogs.[21]

O,S donor chelates include hydroxy-thiols and -thioethers, and thioether-carboxylates (thioacids), such as from (**22**) to (**24**) (Figure 7); these form similar complexes to their amine analogues. Thioacetic acids and their ethers ($RS(CH_2)_nCO_2H$; $n \geq 1$) form at least five-membered chelate rings. Monomeric complexes of 2-mercaptoethanol involve five-membered chelate rings, although these ligands often adopt polymeric structures featuring both O and S bridging. Another simple example of an S,O-chelate is the dianion of 2-mercaptophenol (**25**), which forms strong bis(didentate)metal(II) complexes.

Examples of ligands with a mixed hard–soft O,S donor set that form only four-membered chelate rings are thioacetate (**26**), monothiocarbonate (**27**), and the monothiocarbamates (**28**). Thiohydroxamic acids are long established ligands with wide analytical and biological applications;[3] N-hydroxythiohydroxamic acid (**29**) is an ambivalent ligand, which offer either O,S five-membered rings or N,S four-membered rings. Disulfide donor coordination has been closely examined. Dithiooxamide ligands are other examples of ambivalent ligands, being capable of coordinating either in the S,S or mixed donor modes.[12] Related dithiooxalate (**30**) acts as an O,S didentate chelate when bound to metals as diverse as Ag^{I}, Cu^{II}, and In^{III}.[22] The thiourea monoanion (**31**) has been observed as a chelate in a Tc^{III} phosphine.[23] Pharmacologically active carbazide (**32**; X = O), and related thiosemicarbazides (X = S), and selenosemicarbazides (X = Se) complexes feature N,X (X = O, S, Se) didentate chelation, and the chemistry of this ligand class has been comprehensively reviewed.[24] Selenosemicarbazide (**32**; X = Se, Y = NH_2) has coordination chemistry similar to its thio analog.

2.1.3 Other Didentate Donor Ligands (N,P; O,P; S,P; N,Se; O,Se; S,Se; N,Te; O,Te; N,C)

Simple chelates including soft P, Se, and Te donors with other donors are well known (Figure 8), albeit more often in complexes with heavier and or low-valent metals.

The *N,P donor* didentate ligands are excellent stabilizers of otherwise unstable oxidation states of transition metals. An interest in development of bulky, inert ligands for organometallic chemistry has seen the aminophosphines (**33**) extensively developed.[25] An iminophosphine N,P ligand (**34**) has been reported as a chelate, exemplified by binding to Ni^{II}. The 2-(diphenylphosphino)pyridine ligand (**35**) can chelate simply via a four-membered chelate ring in tetrahedral monomer such as $[Co(\mathbf{35})(NO)_2]^+$, or adopt a bridging mode in dimers (Figure 9).[26] The P,N donor aminophosphine chelate (**36**) exhibits a variety of 4-, 5-, and 6-coordination geometries in divalent metal complexes.

Most *O,P donors* such as (**37**) and (**38**) readily form stable complexes with platinum group metals. Pd complexes of the soft–soft *S,P mixed donor* ligand (**39**) are chiral and resolvable into optical isomers; an As,S analogue is also known. The bicyclo phosphine thiol (**40**) is also chiral, binding Pd^{II} as an S,P chelate.

Mixed donor didentate ligands containing selenium are less well known than their sulfur analogues. A typical example of an *Se,N donor* is (**41**), which coordinates as a didentate chelate; another is (**42**), a selective analytical reagent for platinum group metals. The monoanionic (**43**) forms neutral ML_2 complexes (M^{II} = Zn, Cd, Hg) with an overall N_2Se_2 donor set, with the imine N selected as a much better donor than the alternate ether O.[27] However, *Se,O donor* chelation is displayed by the butane-2,4-dionate analogue (**44**), which forms complexes of Pd^{II}, Hg^{II}, Pb^{II}, Cd^{II}, Co^{III}, and In^{III}. The soft–soft *Se,S donor* simple didentate ligands (**45**) and (**46**; R = H, CH_3) form complexes with Pt^{II} and Pt^{IV}, and the deprotonated ligands stabilize unusual Cu^{III} and Ni^{III}.[28]

Although tellurium chemistry has been reasonably well studied,[29] only relatively few mixed donor ligands have been described. A hard–soft *N,Te donor* didentate is (**47**). An

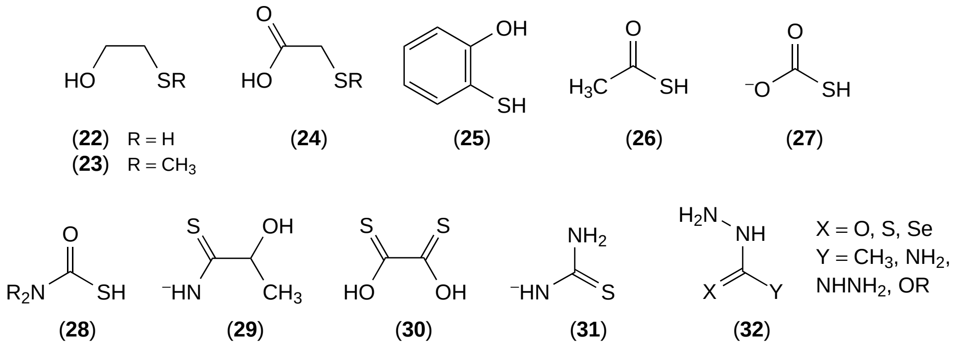

Figure 7 Didentate S,O and S,N chelates

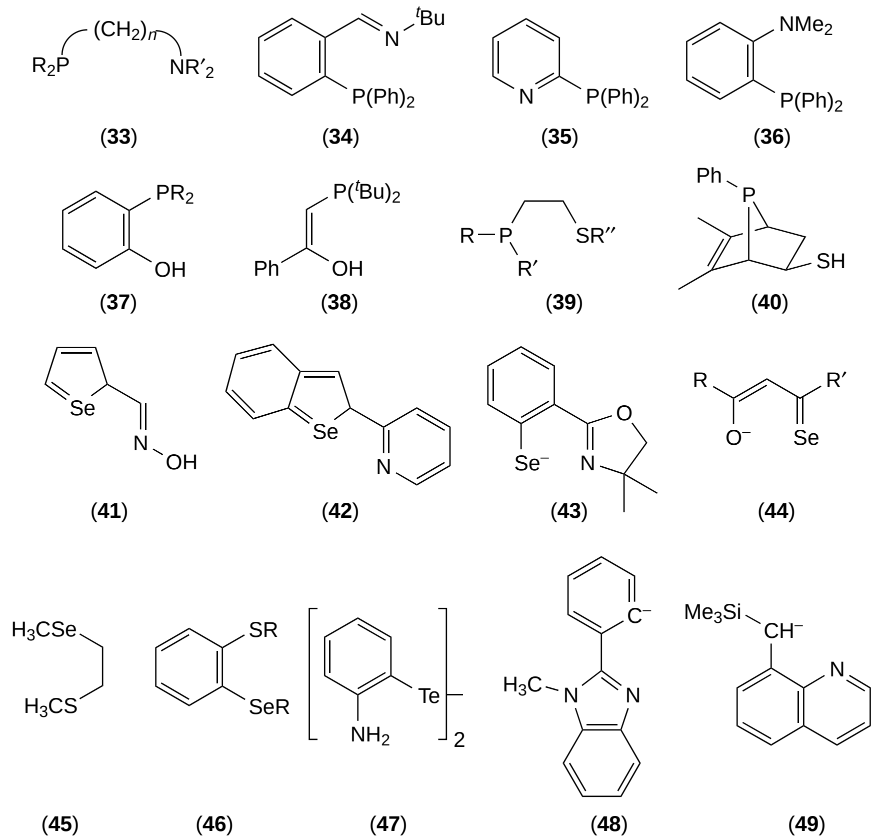

Figure 8 Didentate chelates including a P, Se, Te, or C donor

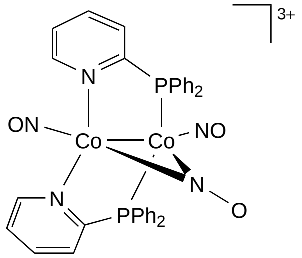

Figure 9 A didentate N,P donor bridging between two metal centers

analogue with an –OMe replacing the amine group is a potential *O,Te donor* didentate ligand.

Chelates with a N and a C donor have been recently reported. An example is (**48**), which binds octahedral Ir^{III} via an imine N as well as a carbanion.[30] Low-spin Co^{II} dialkyls that include the CoL_2 complex of the N,C chelate (**49**) form from organolithium precursor compounds.[31]

2.1.4 Ligands Derived from Nitrogen Heterocycles

Ligands that include nitrogen heterocycles as a component of their molecular structure form an important family of ligands (Figure 10), some of which have already been used as prior examples. Potentially didentate dialectical N_2 donor molecules of aromatic groups are common, exemplified by (**50**). This molecule may chelate or operate in a bridging mode, forming multinuclear complexes in the latter case.

Didentate *N,O and N,S donor* ligands where the N-donor group is aromatic in character (a pyridine, pyrazine, or imidazole, for example) or forms part of a saturated heterocyclic ring (e.g. a pyrimidine) are common. Pyridines feature heavily in ligands of this type. One simple example is 2-pyridinethiolate (**51**). This versatile electron-rich N,S ligand can bind as a monodentate, a chelate, and in bridging modes, and its coordination chemistry has been reviewed.[32,33] The restricted 'bite' of the N,S four-membered ring chelate has obvious structural effects, as observed in the *mer*-$[Co(pt)_3]$ complex, where intraligand S-Co-S angles below 73° and *trans* S–Co–S angles around 166° occur.[34] The ligand, when chelated in $[Co(en)_2(\mathbf{51})]^{2+}$, undergoes a series of stepwise oxidation reactions from thiolato (RS^-) to sulfenato ($R\text{-}SO^-$), sulfinato ($R\text{-}SO_2^-$) and sulfonato ($R\text{-}SO_3^-$) ligands, with some S,O-isomerization reactions also noted.[35] The 2-hydroxypyridine analogue, which form stable four-membered N,O chelates, is also known. The monoanionic N,O didentate ligand 2-pyridinecarboxylic acid (**52**) forms numerous complexes with five-membered chelate rings,[36] with

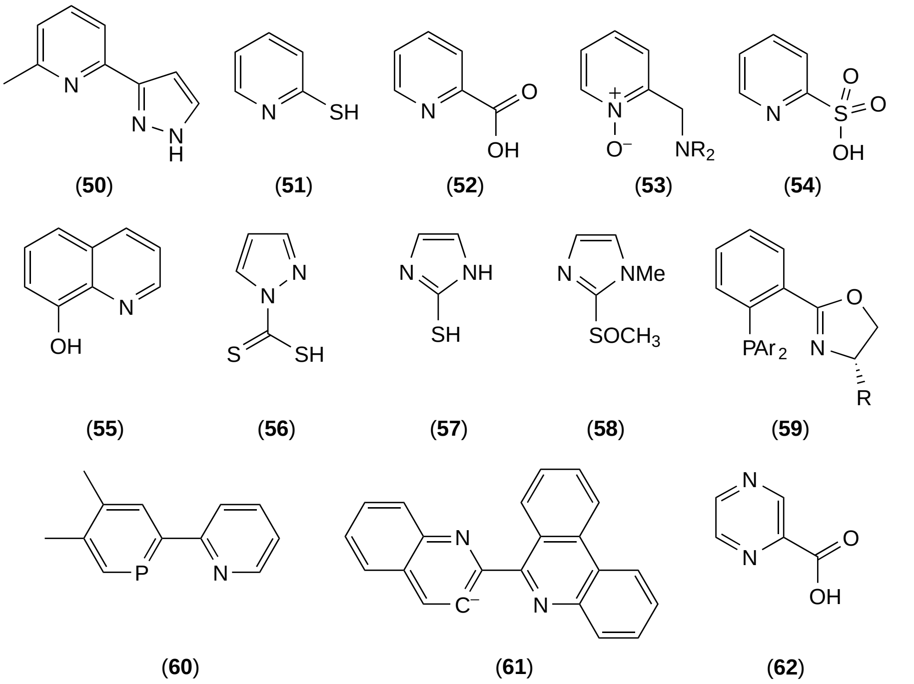

Figure 10 Didentate chelates containing N-heterocyclic donors

complexes of the neutral ligand readily isolable. Pyridine N-oxides (**53**) usually form N,O didentates with six-membered chelate rings. The sulfonate analog of picolinic acid (**54**) also acts, albeit in a polymeric Ag^{I} complex, as an N,O chelating ligand.

Quinolines substituted in the 8-position make excellent ligands and have been used as analytical reagents. The oxine (**55**) is one of the more venerable N,O didentate ligands, observed to form simple mononuclear complexes as well as clusters such as a Mn^{III} tetranuclear complex.[37] The thioxine analogue forms stable, highly colored organic-soluble complexes with five-membered N,S chelates, and a selenium analogue has also been investigated.

Other key heterocyclic rings in mixed donor ligands are pyrazole and imidazole. A review of pyrazole-derived ligands has appeared;[38] an example is 1-thiocarbamylpyrazole (**56**). Ligands with a thiol introduced at the imidazole 2-position form complexes with N,S four-membered chelate rings, as occurs for (**57**). Another example of a N,O chelate is (N-methyl-2-imidazolyl)methylsulfoxide (**58**).

The N,P phosphine-oxazoline chelate (**59**) is chiral, and complexes can act as homogeneous catalysts for asymmetric synthesis; the Ir(I) and Pd(II) complexes promote enantioselective olefin hydrogenation and allylic substitution respectively.[39] An N,P analog of the N,N didentate ligand 2,2′-bipyridine is (**60**), the soft P donor helping to stabilize low-valent metals. Further, 2,2-bipyridine derivatives such as (**61**) can bind metals such as Ir and Ru as N,C^{-} chelates with one pyridine nitrogen rotated to the opposite side, away from the metal ion.

Numerous pyrazine-containing ligands have been reported, such as (**62**), which displays N,O didentate coordination to transition metals, forming five-membered chelates.[40] Ligands with an N-heterocycle and amide groups can provide N,O chelation, but deprotonation of the amide group leads to a change in the donor set from N,O to dialectical N,N ligation. The monoamides of 2-picolinic acid at high pH demonstrate this characteristic behavior.

2.2 Tridentate Ligands

Ligands with three donor groups may bind to three sites of a metal as a tridentate ligand, although didentate chelation with one donor group pendant and unbound is also observed. Complex stability is usually enhanced by coordination of all three donor groups. Examples appear below in Figures 11, 13, and 14.

There are many examples of N_3– or O_3–donor ligands that are dialectical mixed donors. One example is (**63**), where the central pyridine group and two terminal imidazole groups can be formally considered a mixed donor set. Deprotonation of the imidazole groups causes a significant shift ($\sim$0.5 V) in the redox potential of the bis(tridentate)iron(II) complex, whereas substitution on the ring has been used to 'tune' the magnetic properties of the bis Cu^{II} complex.[41] Another example of a dialectical N_3– donor ligands is (**64**), which can form oligomeric complexes through imidazolate bridging.

2.2.1 *N_2O and NO_2 Donors*

N_2O-donors where two arms emanate from a central aromatic component are exemplified by (**65**) and (**66**). The $TiCl_2$ complex of the former is an olefin polymerization catalyst. Rather than form 1:1 complexes, (**66**) acts as a compartment ligand, forming M_2L_2 species (M = Co, Ni, Cu) where the metals, required to be closely confined, exhibit antiferromagnetic exchange.[42] 1,2-Pyrazole derivatives (**67**) are also very good N_2O-donor ligands for light transition metals,[43] forming two six-membered chelate rings. Analogues with N_2S donor sets are also known. Two types of N-donor are present in the potentially chiral N_2O donor (**68**), which forms distorted octahedral ML_2 complexes with Cu^{II} and Co^{III}, each metal isolated as a different geometric isomer.[44]

NO_2-donors often have two identical chains branching from a central amine or aromatic amine group. Examples with alcohol or carboxylic acid arms are most common. The diethanol and dipropanol amines (**69**) and (**70**),[8,9] and the well-studied 2,6-pyridinedicarboxylic acid (**71**) exemplify the class. The latter is a good chelating agent for ion chromatographic determination of first-row transition metals. ‘Uneven’ arms can be present, as exemplified in the NO_2 amidodiol (**72**), which stabilizes Co(IV) in the bis complex shown in Figure 12, formed by electrochemical oxidation.[45] EPR spectroscopy gave a characteristic 8-line hyperfine coupling pattern due to a single unpaired electron interacting with the ^{59}Co nucleus ($I = 7/2$).

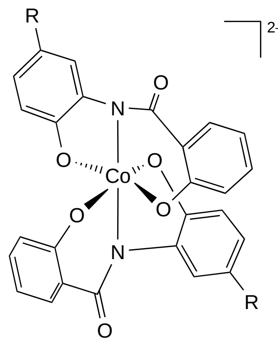

Figure 12 Tridentate bis-mer coordination of a trianionic O,N,O donor amidodiolate ligand to the rare Co^{IV}

More elaborate shapes can initiate more unusual coordination arrangements. The ligand (**73**) exemplifies types that can act as bis tridentates, forming dinuclear complexes with transition metal ions such as Cu^{II}. Amino acid derivatives containing a methyl sulfoxide group (**74**) are rare examples of ambidentate tridentate chelate ligands, offering alternative NO_2 or NOS donor sets, the latter usually found when the NH group is deprotonated.

2.2.2 *N_2S and NS_2 Donors*

Mixed N and S donor ligands (Figure 13) combine hard and soft ligand characteristics, while typically the M−N distance

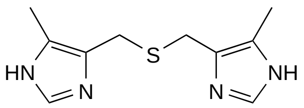
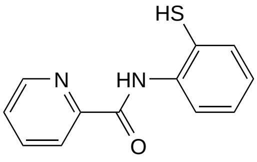
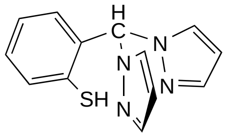
(**76**)



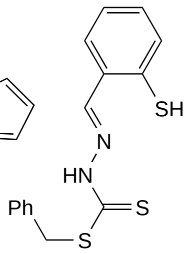
(**77**)



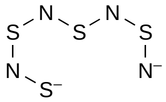
(**78**)



(**79**)



(**80**)



(**81**)

Figure 13 Tridentate chelates with (N,N,S) and (N,S,S) donor sets

is significantly shorter than the M–S distance, particularly with the lighter metal ions.

NS_2 Donor set ligands with two common branches are exemplified by the dithiol analogue of (**65**) and (**75**).[47] The former forms two six-membered chelate rings, whereas the latter forms two five-membered metallocycles. The simple N_2S donor (**76**) and close analogues tend to form oligonuclear complexes with Zn^{II} that feature thiolate bridging. Ligands (**77**) and the analogue with two methylenes in each chain form simple mononuclear complexes with Cu^{II}, featuring five- and six-membered chelate rings, respectively.[48] The unusual pyridine-amide-thiol donor (**78**) forms a very stable $[Fe^{III}L_2]^-$ complex where both amide and thiol are deprotonated.[49] Tripodal N_2S ligands of the type (**79**) have appeared, and form ML_2 complexes, of which the Fe^{III} complex was proposed as a structural model for the *nitrile hydratase* active site.[50] Complexation of (**80**) is as an NS_2 donor, employing two different types of S donors, from a thiol and a thioacid ester. Treatment of the cyclic tetrasulfur tetranitride S_4N_4 with $[PtCl_2(PR_3)_2]_2$ or $Ir(CO)Cl(PPh_3)$ leads to opening of the S_4N_4 ring to form (**81**), a pure inorganic compound that complexes as a tridentate NS_2 ligand.[51]

2.2.3 N_2C, N_2P, P_2O, P_2As, and PAs_2 Donors

Ligands with a carbon anion directly bonded to a metal ion are more common than perhaps supposed. The family of ligands (**82**) (Figure 14) invariably act as a tridentate *N_2C donor* ligand to Pt^{II}, via deprotonation of the carbon marked in the figure. The C-deprotonated N_2C pincer ligand (**83**) forms a totally flat palladacycle with sp^2 hybridization of C and both N donors.[52] A diimine tridentate (**84**) with the carbanion as a terminal rather than central donor of the N_2C ligand has been reported as a Ni^{II} complex;[53] it is an efficient catalyst of ethylene oligomerization.

Phosphorus-containing tridentate ligands are known in a number of donor sets, as exemplified by (**85**) to (**89**), which are excellent chelating agents for particularly platinum group metals. The *PN_2 donor* ligand (**85**) does not display simple coordination, forming a Cu^I complex $[Cu_2(CH_3CN)_2L_2]^{2+}$ where L chelates one metal with both N donors and donates a P donor to the other.[54] The P_2O_4 donor set in (**86**) belies its potential with a tendency to form Pt complexes with only *P_2O donor* coordination, and is a reminder that offering a particular ligand set does not ascertain all are employed. The P_2O donor ligand (**87**) forms a water-soluble Pd^{II} complex that is a catalyst for alkene hydrocarbonylation.[55] The tridentate *P_2As donor* ligand (**88**) binds with four-membered chelates in polynuclear, monovalent complexes. An example of a *PAs_2 donor*, ligand (**89**) binds via six-membered chelate rings to stabilize low-valent metal ions such as Ir^I.[56]

2.3 Tetradentate Ligands

There is a very large literature involving mixed donor tetradentate ligands and their complexes. Some example ligands appear in Figures 15–17.

2.3.1 NO_3 Donors

Linear systems with an NO_3 donor set are exemplified by simple saturated molecules, which show preferences toward lighter, higher charged metal ions, such as linear (**90**). Branched systems include tripodal ligands having different central atoms and O-donors terminating the chains, for example, (**91**) and (**92**). Their coordination chemistry is partly directed by their shape, which tends to support trigonal

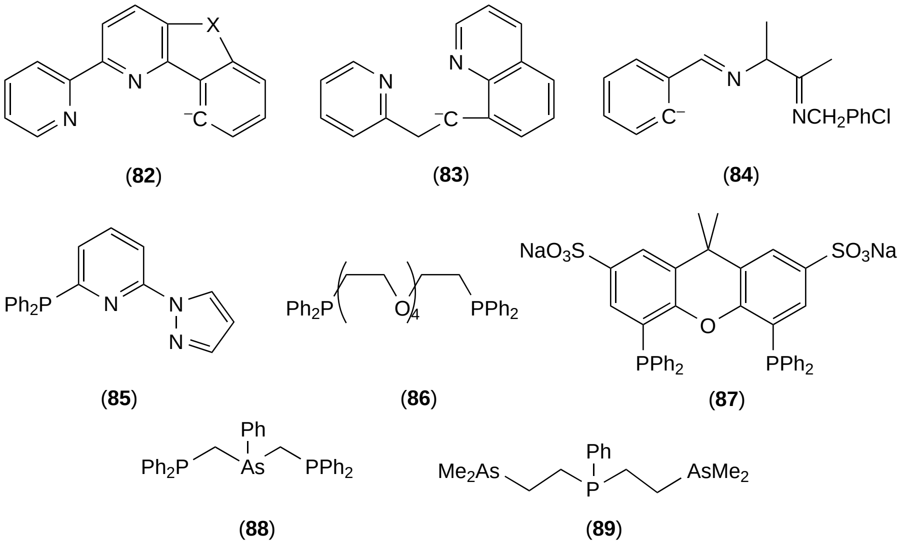


Figure 14 Tridentate ligands that contain one or more C, P, and As donors

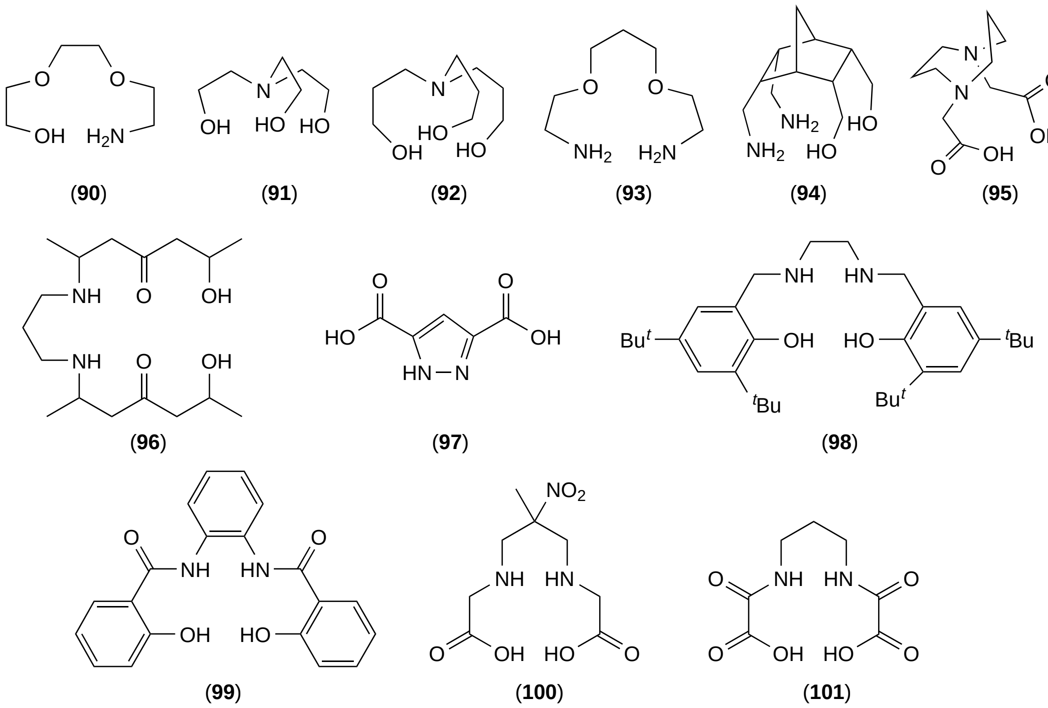

Figure 15 Examples of tetradentate ligands with N,O donor sets

bipyramidal geometries, as found in pentacoordinated Ti^{IV} complexes.[57]

2.3.2 N_2O_2

Ligands with terminal amino groups in different oxo ethers such as (**93**) and analogues with different methylene chain lengths have been studied extensively, and usually exhibit binding of all N_2O_2 donors. They are useful precursors for synthetic macrocycles, and their chemistry has been reviewed.[8,9] The topologically unusual four-strand aminoalcohol (**94**) coordinates to first-row transition metal ions, and may include bis(N_2O_2) coordination. The diacetate (**95**) of a diaza heterocycle, as a tetradentate ligand, features a central ‘butterfly’ six- and two pendant five-membered

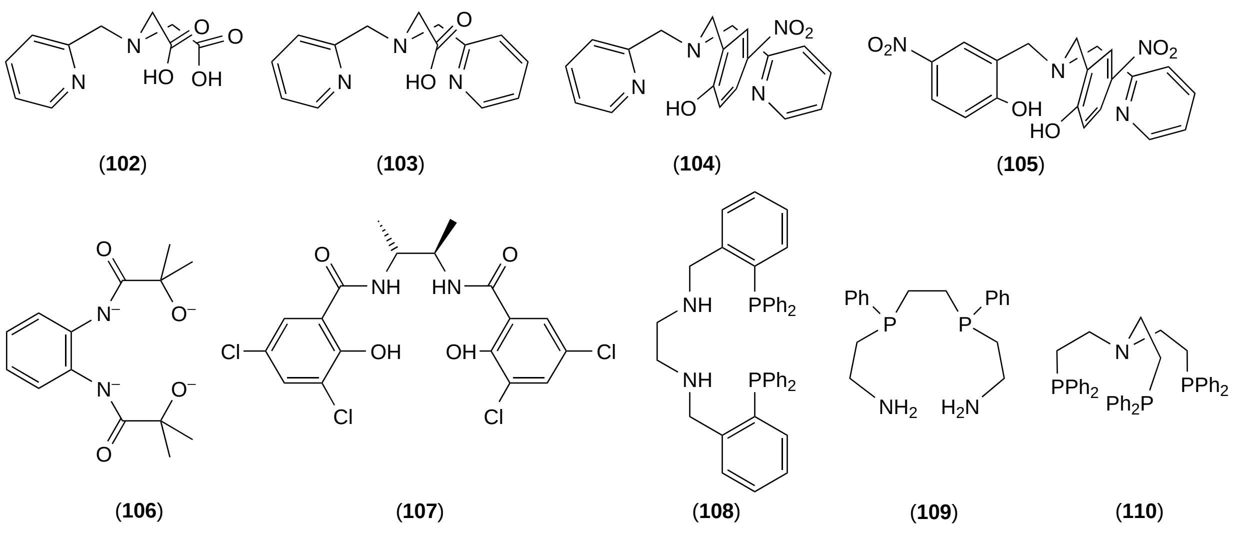

Figure 16 Tetradentate mixed donor ligands with N,O and N,P donor sets, including tripodal ligands [(**102**) – (**105**) and (**110**)]

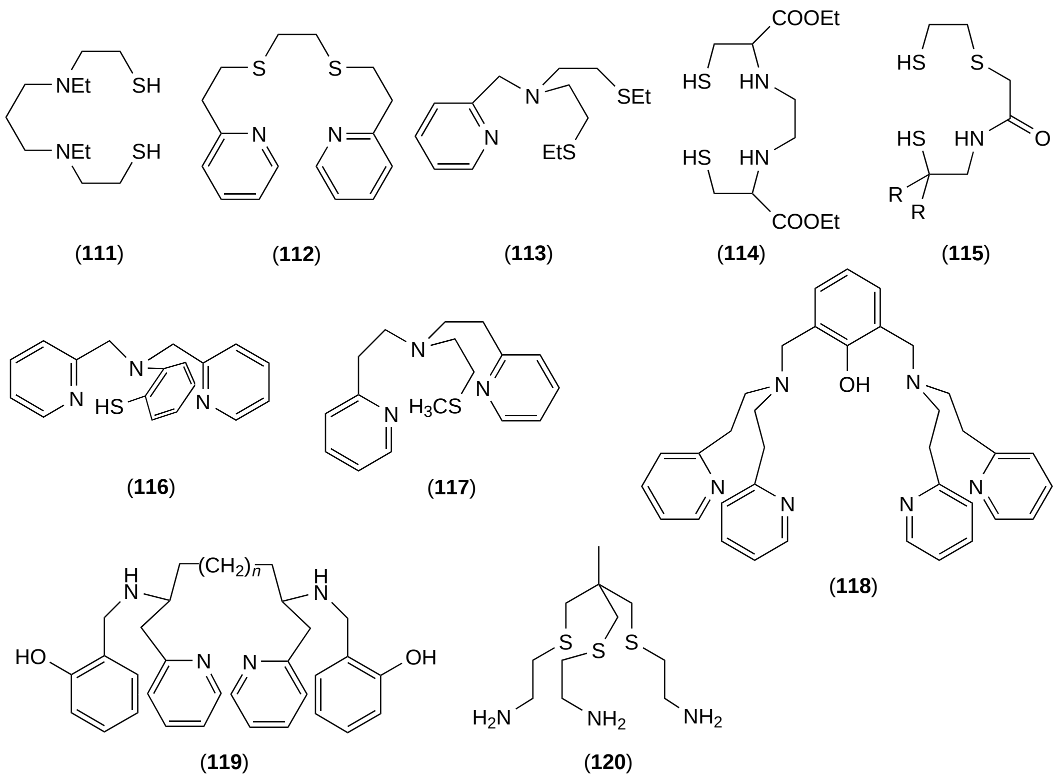

Figure 17 Mixed donor tetradentate ligands including at least one S donor, and ligands of higher denticity (5 or 6)

chelate rings. Compound (**96**) exemplifies a large series of 'compartmental' ligands, comprehensively reviewed,[58] that may house two different metal ions, one in an N_2O_2 cavity and the other in an O_4 environment. A class of N_2O_2 donor that must bind two metals in a dinuclear bis-chelate arrangement is exemplified by 1,2-pyrazole-3,5-dicarboxylic acid (**97**).

The copper complex of the diaminodiol (**98**) functions as a model for *galactose oxidase*.[59] A related diamidodiol (**99**) has been reported binding to high-valent Os and Ru, as well as in mixed [Cu{L}M(bipy)$_2$] (M = Co, Ni, Zn) compounds, some of the latter being antiferromagnetically coupled.[46] A number of diamine-diacid ligands have appeared, such as (**100**),[60]

prepared by a metal-directed template route from α-amino acids. While the amide analogue (**101**) may form simple mononuclear complexes, it may also act as a bis(didentate) bridging ligand, as in $[Mn_2^{IV}(\mu\text{-}O)_2(\mu\text{-}\mathbf{101})_2]$.[61]

Tripodal N_2O_2 and N_3O iminocarboxylate ligands such as (**102**) and (**103**) have appeared, with the vanadyl complexes acting as *halogenperoxidase* models.[62] Binuclear Mn^{II} and Mn^{IV} complexes feature linked MnL units. Related N_3O and N_2O_2 aminoalcohol ligands are known, exemplified by (**104**), which forms a mononuclear trigonal bipyramidal complex with Cu^{II}, with acetate or thiocyanate as the additional donor,[63] and (**105**), which forms a square-pyramidal Fe^{III} complex that exhibits catalytic activity as a model for *catechol-1,2-dioxidase*.

The sterically crowded ligand (**106**) forms a very rare square-planar Co^{III} complex, as shown by an X-ray crystal structure,[64] and a spin triplet (paramagnetic) ground state was also identified in the solid state. The Co^{III} complex of (**107**) catalyzes the epoxidation of norbornene with t-BuOOH or PhI as terminal oxidant,[65] catalysis driven by formation of t-BuOO radicals employing a $Co^{III/II}$ redox process.

2.3.3 N_2P_2 and NP_3 Donors

The diaminodiphospine ligand (**108**), and analogues with longer methylene chains, is a good example of the N_2P_2 donor set (Figure 16); the $Cu^{II/I}$ redox potential varies with length of the methylene chain.[66] The diimine precursor of (**108**) forms a rare low-spin and square-pyramidal iodocobalt(III) complex.[67] The linear saturated P_2N_2 tetradentate (**109**) forms *cis*-α- and *cis*-β-$[Co^{III}(L)(aa)]^{n+}$ (aa = oxalate or acetylacetonate) complexes.[68] The tripodal NP_3 ligand (**110**) shows a propensity to stabilize low-valence oxidation states of Ni and the Co triad,[69] with complexes with metal–metal bonds defined, such as the rather unusual Co-Hg-Hg-Co moiety.

2.3.4 N_2S_2, NS_3 and N_3S Donors

Linear ligands with an N_2S_2 donor set (Figure 17) may have the S donors as terminal thiols or internal thioethers. An example of the former is (**111**), which forms hexanuclear clusters with Fe^{III}.[70] The molecule (**112**) is an example of a simple N_2S_2 donor of the thioether type, and it readily forms mononuclear complexes; the diaquanickel(II) complex has been proposed as a nickel metalloprotein active site model. The copper complex of N_2S_2 ligand (**113**) forms readily, with IR, Raman, and EXAFS supporting it as a model for copper proteins. Ligands from this family, such as (**114**), may have applications in nuclear medicine, since they form robust oxotechnetium complexes.

A simple example of an NS_3 donor is (**115**), which binds to the four coplanar sites in square-pyramidal complexes. A tripodal N_3S donor (**116**) exemplifies this class of donor set, and this is known to form both mononuclear and bridged complexes. Another example of this class is the ligand (**117**), which forms a Cu^{II}(NCMe) complex which is a functional model of the CuB *dopamine β-hydroxylase* center.[71]

2.4 Higher Polydentate Ligands

Molecules with more than four potential donor groups of at least two different types are surprisingly common, with EDTA as the classical example of a hexadentate N_2O_4 donor to a wide range of metal ions. However, increasing the number of donor atoms does not necessarily increase the denticity of the coordinated ligand, and there are many examples of ligands that bind with one or several pendant, uncoordinated groups. Ligand geometry and donor location can be important in directing coordination options. For example, (**118**) can act as bis tetradentate ligands, binding two Cu^{II} ions via the bridging phenolate and the two sets of three nitrogen atoms,[72] in an arrangement that has been proposed as a model for some dinuclear copper proteins. Alternative behavior is displayed by the structurally related (**119**), which form hexadentate monomer complexes. Usually, the more flexible ligands such as $EDTA^{4-}$ and (**119**) can occupy all coordination sites efficiently.

The tripodal concept featured in (**118**), but without a central donor group, has been used to produce a range of flexible, saturated hexadenate ligands. The tripodal N_3S_3 ligand (**120**) forms robust octahedral complexes with a range of metal ions, and offer distinctive electrochemical properties compared with N_6 analogues, stabilizing lower oxidation states. Ligands with four arms emanating from a head group have also been described recently.[73]

3 CHELATING WITH THREE TYPES OF DONORS ($A_XB_YC_Z$)

Molecules carrying three different classes of potential donor groups are surprisingly common. They range from simple low-molecular weight compounds to large biomolecules; some examples of the former type appear in Figure 18. Even simple ligands with three different donor groups chelating may form a range of geometrical isomers on coordination; for example, a bis(ABC) octahedral complex will have at least six isomers. Although it is unlikely all possible isomers will form, the prospect will inevitably increase the level of difficulty of their coordination chemistry.

3.1 Tridentate Donors

This group can include dialectical donors such as N_aN_bO (formally N_2O) sets with distinctly different classes of N-donor, such as the N-pyridine, N-amine, alcohol donor (**68**). This can in principal exist as bis(tridentate) octahedral

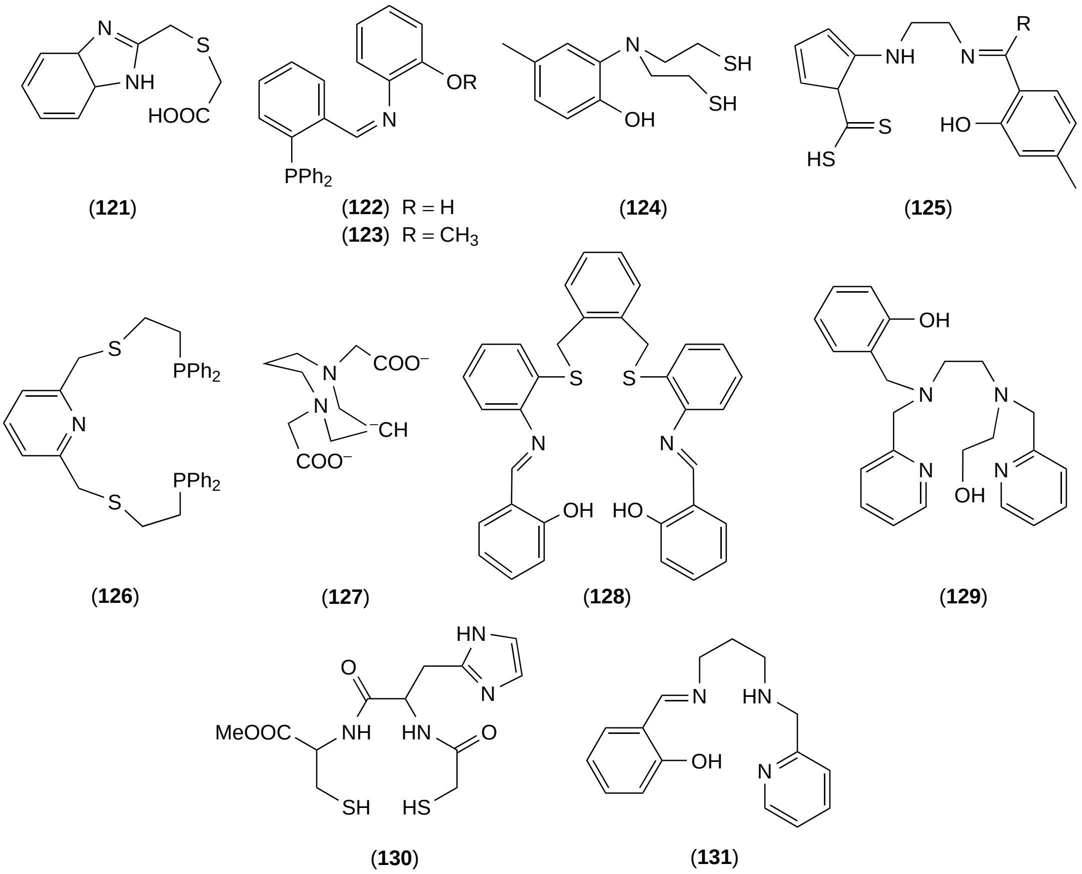

Figure 18 Ligands containing three types of potential donor atoms

complexes in any one of six geometrical isomers; the Cu^{II} and Co^{III} complexes were isolated as *trans,trans,trans* and *cis,cis,trans*(N_{py}) *fac* isomers respectively.[44] Dialectical N_3 or O_3 donor sets such as those featuring (N-amine, N-imine, N-amide) and (O-alcohol, O-acid, O-ether) are known. However, we shall subsequently restrict ourselves here to examples that are classical mixed donors with three different donor atoms.

3.1.1 NOS and NOP Donors

The relatively simple tridentate (**121**) presents the same N,O,S donor groups as biological glutamate-methionine-histidine entities. When bound as an octahedral complex, different geometric isomers have been reported, with the octahedral bis(tridentate) complexes of Cu^{II} and Ni^{II} having *trans,cis,cis*- and *cis,cis,cis*-$S_2N_2O_2$ geometries respectively.[74]

The N,O,P phosphine-imine-alcohol donor (**122**) forms simple square-planar complexes with M^{II} ions of the nickel triad. The analogous ether (**123**) acts as a terdentate ligand to Pd^{II}, with CH_3^- in the fourth site of the square-planar complex.[75]

3.2 Tetradentate Donors

A number of tetradentate donor sets featuring three different donors and of varying structural form have been reported over recent decades, and continue to evolve. The mixture of donors of different hard–soft character usually leads to no exceptional preference for a particular metal ion, so the interest in complexes of these ligands must lie in other directions, such as catalysts or biomimics. Examples will be restricted to just a very few.

A simple example of an NS_2O donor ligand is (**124**). Although capable of tetradentate coordination, variable coordination is observed, for example, as a tridentate NS_2 donor to Ni^{II}. Another N_2SO donor is (**125**), which forms tetrahedrally distorted square-planar complexes with Ni^{II}.

3.3 Ligands of Higher Denticity

A simple example of an $A_xB_yC_z$ donor ligand of higher denticity is (**126**), which carries a NS_2P_2 donor set, and binds as a pentadentate in a seven-coordinate bis(triflato)cadmium(II) complex.[76] However, mononuclear Cu^{I}, Ag^{I}, and Au^{I} complexes are four-coordinate with the ligand behaving as a P_2S_2 donor, indicative of the

coordination ambivalence of many ligands of potentially high denticity, usually reflecting metal ion preferences. An example of the rare CN_2O_2 donor set (**127**) has been structurally characterized as the aquacobalt(III) complex, with a short Co−C distance of 1.941(4) Å.[77] The $N_2S_2O_2$ donor (**128**) has been characterized binding in the hexadentate coordination mode to first-row transition metal ions. As in other sections, including dialectical ligand systems extends the example set significantly. An example is the $N_{(amine)2}N_{(py)2}O_2$ ligand (**129**); ambivalent denticity may be displayed, such as binding as a pentadentate to vanadyl with a free hydroxyethyl pendant, where only five coordination sites are readily available around the octahedral ion.

4 MULTIPLE MIXED DONOR LIGANDS

Molecules carrying more than three different classes of potential donor groups have not been extensively illustrated, although examples exist, particularly with dialectical mixed donor sets. One dialectical example of a molecule with four different donor groups all in the one molecule is (**130**), which carries imidazole, amide, thiol, and carboxylic acid groups. Its capacity to form a range of geometric isomers upon coordination has been illustrated by actual isolation of isomers of a rhenium complex. Another simple example is (**131**), which offers a pyridine, imine, amine, and alcohol group, allowing it to act as a tetradentate ligand.

At this time, low-molecular weight ligands of high denticity with a large number of different donor groups represent chemical curiosities rather than a target of concerted study, since their complexities in terms of potential isomers, variable coordination modes, and metal ion selection appear to outweigh any short-term potential usefulness.

5 COMMON FAMILIES OF MIXED DONOR LIGAND

Although the above examples have been classified in terms of donor sets, an alternative approach is to report mixed donor ligands in terms of their ‘family’ relationship – as amino alcohols or hydroxyacids, for example; or in terms of the type of complexes they form – as polynuclear systems, for example. Although these have been addressed above in another context, it is appropriate to recognize a few ligand families that are of particular importance (historically, numerically, or in applications) in coordination chemistry. The selection is not designed to be exhaustive, but merely indicative of mixed donor ligand families.

5.1 Schiff Bases

Schiff bases form one of the longest established and most prevalent of the mixed donor systems met in coordination chemistry, with almost all metal ions reported to form complexes with this class of ligand. The usually facile condensation of primary amines with ketones yields imines, featuring a C=N bond. When an aryl group is bonded to the nitrogen or carbon of the imine, it is stabilized somewhat; and this class are then known as Schiff bases (Figure 19). Synthesis by carrying out the condensation reaction in the presence of a metal ion as template is commonly employed, the metal ion both directing the reaction and stabilizing the product. Extensive reviews of the vast chemistry of mixed donor Schiff-base ligands has appeared,[78,79] including acyclic and macrocyclic systems, so only limited examples will be presented. Chirality in Schiff-base ligands has also been described, and will not be elaborated here. Schiff bases are capable of demonstrating tautomerism, probed using IR, UV, and NMR spectroscopy,[78] especially for the numerous derivatives of β-diketones or salicylaldehydes and naphthaldehydes.

Schiff bases commonly employ polyamines as reagents, the donor nature of the ligands depending both on the type of aldehyde or ketone used and the nature of primary amine or diamine. Scheme 1 illustrates some ways of obtaining Schiff bases of different denticities via 1:1 reactions of aldehydes with ketones to yield mixed N, O, S, and Se donor sets. Condensation of aldehydes and ketones with α-amino acids is also known. Where two moles of a carbonyl compounds and one mole of diamine are reacted, more elaborate Schiff bases with higher denticity result, also exemplified in Scheme 1.

Figure 19 Di-, tri-, and tetradentate mixed donor Schiff-base ligands

Employing triamines, such as NH_2–$(CH_2)_n$–NH–$(CH_2)_n$–NH_2 ($n = 2-4$), or higher polyamines rather than a diamine leads to pentadentate or higher denticity ligands. Reaction of amines with 2,6-diacetylpyridine or substituted 2,6-phenols leads to high denticity molecules including compartmental ligands.

As Schiff-base denticity increases, coordination can potentially occur in several ways, possibly leading to a number of geometric isomers. Tridentate N_2O donor Schiff bases made from salicylaldehyde (**132**) or a β-diketone (**133**) form stable complexes with transition metals where *fac* or *mer* isomerism may exist. Salicylaldehyde condenses with primary amines (RNH_2) to form didentate monobasic ligands of the form *o*-(HO)C_6H_4CH=NR. One novel example is the ferrocenylamine adduct (**134**), which forms a bis Co^{II} complex.[80] The amino acid serine derivative (**135**), as its $Co^{II}L_2$ complex, is an efficient catalyst for conversion of a number of secondary alcohols to their corresponding ketone in the presence of O_2 and 2-methylpropanal, or ethyl 2-oxocyclopentane-carboxylate, and also oxidizes hydrocarbons such as cyclohexane to cyclohexanol and cyclohexanone. In these reactions, an active Co^{III} superoxo species is implicated.[81] The biologically important aromatic aldehyde pyridoxal forms a variety of tridentate Schiff-base ligands (**136**) incorporating amino acids, and their Co complexes bind dioxygen.

One of the classical tetradentate Schiff bases is the open-chain N_2O_2 donor ligand salen (**137**), which has flexibility sufficient to permit it to form different geometric isomers on complexation. The ability of the ubiquitous salen and close analogues to bind O_2 reversibly as its cobalt complex, as in [(O_2)Co(salen)(py)], has been central to most investigations of its coordination chemistry. Complexes of the [Co(salen)] family also mediate the electrocatalytic reduction of O_2 to H_2O_2, whereas those incorporating chiral centers on the ligand backbone are useful in asymmetric synthesis.[82] Electrogenerated monovalent Co complexes of salen, salphen (**138**) and their substituted derivatives undergo oxidative additions with alkyl halides.

Pentadentate ligands, as exemplified by the N_3O_2 donor (**139**) also can exist as different geometric isomers, depending on ligand flexibility. Coordination for high denticity ligands (Figure 20) can also involve formation of unusual stereochemistries, such as that observed for the Mn^{II} complex where the pentadentate is practically planar. By way of contrast, a completely nonplanar, twisted coordination appears for the more flexible (**140**) in an oxotechnetium(V) complex.[83] Hexadentate Schiff-base complexes are not particularly common, but examples such as the N_4S_2 donor ligand (**141**) bound to Ni^{II}, exist. Schiff bases of high potential denticity may employ some donor atoms as bridging groups to form polynuclear complexes. Many potentially hexadentate Schiff bases actually form bis-tridentate dinuclear or polynuclear complexes.

Condensation of ketones or aldehydes with the methyl ester of dithiocarbazic acid produces ligands with S,N,O or S,N donor sets. An example is (**142**),[84] which acts as both a didentate and a tridentate to ReO. Nickel(II)-templated reactions of pentanedione or salicylaldehyde with aminoethanethiol produce N,O,S ligands such as (**143**) and (**144**); these form simple mononuclear complexes or else dinuclear species with thiolate bridging two Ni centers.[85] Mixed donor Schiff-base ligands including other heteroatoms such as P (**145**) and Te (**146**) have appeared.

5.2 Macrocycles

Macrocycles are traditionally considered to be ring systems with a chain size of nine atoms or higher. As ligands, they

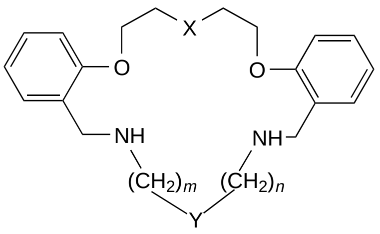
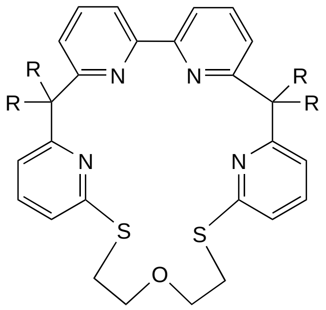
(150)



(151)



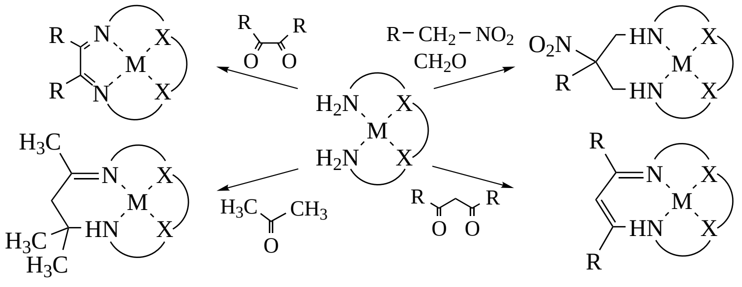
(152)

Figure 21 Macrocyclic mixed donor ligands

contain several heteroatoms within the ring that can act as donors to metals (Figure 21). Additional donors may be introduced as pendants groups attached to either N heteroatoms of the ring or to C atoms of the ring framework. The area has been widely reviewed.[86,87] Many macrocycles that feature a mix of donors in the ring have been described, and include amine, ether, thioether, and phosphine donors, in addition to heavier elements such as Se. A range of N_2X_2 donors (e.g. with X = S) are accessible through metal-templated routes, as illustrated in Scheme 2.

In particular, mixed N,O, N,S, and O,S donor sets are commonly met. The simplest examples are of the 1,4,7-donor cyclononane ring macrocycles (**147**), where examples with N_2O, NO_2, N_2S, and NS_2 donor sets complement N_3, O_3, and S_3 ligands.[88] Mixed donor sets may also be created by the introduction of pendant groups, as exemplified by the N_4O_2 macrocycle (**148**),[89] and the N_4O_4 macrocycle (**149**).[90] Coordination of both ring and pendant donors can enforce unusual properties due to steric and electronic effects within the often rigid complexes.

Macropolycycles, as distinct from the macromonocycles mentioned above, are also well explored. This can be exemplified by the macrobicyclic N_3S_3 donor (**150**), with a ligand shape that is well suited to hexacoordination of



Scheme 2

metals within the cavity, imposing effects of the soft S-donors on physical properties such as redox potentials.

Unsaturated as well as saturated systems can be prepared. Mixed donor dibenzo-substituted macrocycles of type (**151**) (with O_2N_3, O_2N_4, O_3N_2, O_4N_2, and ON_3S donor sets) have been examined to define the effect of variation of ligand structure on metal complex stabilities.[91] Ligands with heteroaromatic groups included, such as the potentially N_4S_2O donor ketal coronand (**152**), form complexes, which leads to a change in orientation of the bipyridyl unit from *anti* in the free ligand to *syn* in the complex.

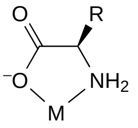
These cyclic systems are an important family of ligands; however, only brief information is presented above, as they can be explored more in the separate entry on macrocyclic ligands.

5.3 Amino Acids and Polyaminoacids

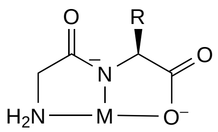
Amino acids and their peptide polymers continue to attract strong interest as ligands because of their biological importance. Detailed treatment of the wide variety of α-amino acids (typically H_2N-CH(R)-COOH), their derivatives and metal complexes is well beyond the scope of this article, so only a few aspects will be noted since comprehensive reviews exist.[92] The side chain R may participate in coordination, depending on whether it contains a coordinating heteroatom (Figure 22). For α-amino acids, the pK_a for the first ionization of the carboxylate is 2–3, whereas the ammonium group is deprotonated at about pH ~9 giving the amino form necessary for coordination. Although binding as a monodentate occurs through the amino or carboxyl group, didentate chelation via both N and O donors in a five-membered ring is most common (**153**). Complexes resulting have a rich stereochemistry, and display chirality due at least to the amino acid. In the presence of side chains carrying heteroatoms (such as occurs with histidine, cysteine, methionine, asparagine, glutamine, arginine, lysine, serine, and threonine amino acids), higher denticity is frequently observed.

Amino acids can combine by eliminating water to form di-, tri-, and higher linear or cyclic peptides, featuring –C(O)–NH–C–peptide bonds. The denticity of the ligands usually increases because of the increased possibilities for chelate formation with metal ions. At high pH, the amide nitrogen of the peptide usually is deprotonated during complexation, which leads, as illustrated by tridentate chelation of the GlyAla dipeptide in (**154**), to an increased denticity.

A large class of related polyaminoacid ligands (also called complexones) have been examined for their coordination



(**153**)



(**154**)

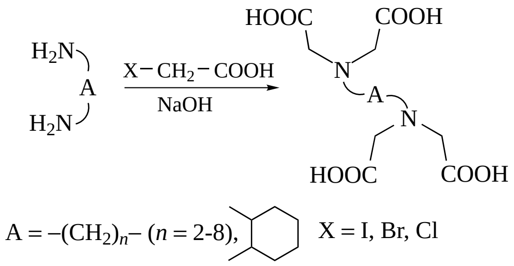
(**160**)

Figure 22 Amino acid and polyaminoacid chelates



Scheme 3

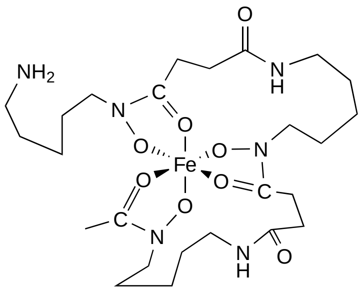


Figure 23 Enterobactin, a catechol siderophore with a dialectical (CO, NO^-) mixed donor ligand

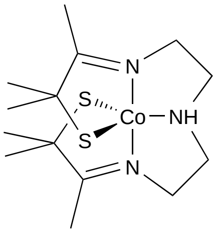

Figure 24 A five-coordinate Co^{III} complex of an N_3S_2 ligand, a proposed model for the active site of *nitrile hydratase*

and analytical chemistry, and are characterized by the presence of the iminodiacetic acid moiety, $–N(CH_2CO_2H)_2$. Complexones, usually prepared in a facile reaction of a diamine and α-halo-substituted acetic acid (Scheme 3), form very stable complexes with almost all metal ions, as detailed elsewhere.[93]

Coordination involves the formation of five- and or six-membered chelates, with polydenticity leading to highly stable and high coordination number complexes, commonly in a 1:1 M:L ratio. The high stability may relate to the flexible, saturated backbone of the ligands and the presence of sets of sterically undemanding carboxylates. Perhaps the simplest examples is iminodiacetic acid itself (**155**), which acts as a tridentate NO_2 donor ligand that forms octahedral bis complexes of *fac* or *mer* geometry. The best-known example is EDTA (**156**), a tetraprotic N_2O_4 donor acid with pK_i values ($pK_1 = 1.99, pK_2 = 2.67, pK_3 = 6.16, pK_4 = 10.26$) typical of this family of ligands, for which a correlation between pK_i and $\log K_{ML}$ has been noted. An array of analogues has resulted from varying the chain length and substituents on the chain between the amine and carboxylate (**157**) or between amine pairs (**158**), or by replacement of carboxylate with other oxoacid groups (**159**). A range of structural variations has been found for complexes of complexones of different potential denticity, leading to NO_2, NO_3, N_2O_3, N_2O_4, and N_3O_4 complexone chelation.

Related synthetic polyaminoacids, which do not feature the iminodiacetate unit but rather are composed of molecules with multiple $–NH-CH_2-COOH$ functionalities, are also common. An example is (**160**), which stabilizes the unusual square-based pyramidal geometry in Co^{III} in conjunction with an axial SO_3^{2-} ion.[94] The macrocycle (**148**) is another example, which binds octahedral metal ions with the pendants in axial sites.[89]

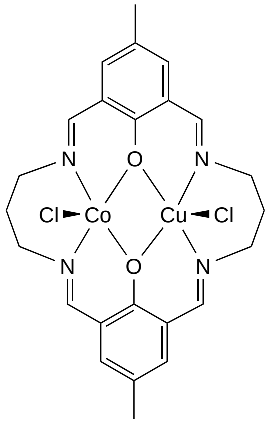
5.4 Biomolecules

Many biomolecules feature metal ions in a mixed donor set, and the area is intensively studied. As an example, the active site of the hydrogenase from *thiocapsa roseopersicina* features nickel in a mixed O,N,S donor environment. Definition of the ligand donor set in biopolymers is not always facile, however, so they tend to be overlooked as examples of mixed donor ligands. There are some small biomolecule examples extant, however. A simple example with dialectical O-donors is the ferrioxamine siderophore *enterobactin,* which features a set of three NO^-, CO chelates binding iron, (Figure 23) the former donors arising from oxidation of an original peptide amine groups.[95] Peptide complexes, of course, usually feature mixed, N,O chelation.

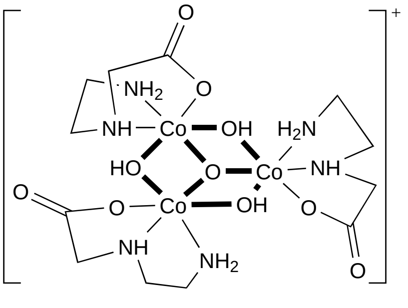
Many simple complexes have been prepared as models of active sites of biomolecules. For example, a reactive five-coordinate thiolate Co^{III} complex (Figure 24) was prepared to model the active site of *nitrile hydratase,* a Co^{III} or Fe^{III} metalloenzyme that promotes the conversion of nitriles to amides.[96] The synthesized model complex is facile in its uptake and release of azide and thiocyanate, indicating that an appropriate nonleaving group environment enhances ligand displacement sufficiently for catalytic paths in non-redox active Co metalloenzymes. Other examples have appeared earlier in this report.

6 POLYNUCLEAR SYSTEMS

Simple mixed donor ligands are commonly anticipated to form mononuclear complexes. However, many examples of polynuclear complexes that form readily through prior ligand design or via spontaneous self-assembly processes have appeared. A range of shapes, including dendrimers and helical systems, have been identified. One of the



(**161**)



(**162**)

Figure 25 Two examples of small polynuclear systems featuring mixed donor ligands

simpler, well-studied designed types are the side-by-side compartment ligands, capable of incorporating two metal ions, one in each compartment (Figure 25). Heterodinuclear complexes such as (**161**) have been made, with two different metal ions in square-pyramidal coordination geometries. Self-assembled clusters such as (**162**),[97] which features amino acid and bridging (μ_2-OH) and (μ_3-O) ligands, are well known with many metal systems. This is a burgeoning area, strongly supported by X-ray structural analysis for characterization.

7 PROPERTIES AND REACTIONS

The presence of mixed donor ligands in metal complexes can complicate or simplify chemical reactions. For example, in an octahedral $[M(NNSN)Cl_2]^{n+}$ complex where the two chloride ions are each opposite different donors means that there is a choice in the site of the first chloride hydrolysis reaction which is absent from the $[M(NNNN)Cl_2]^{n+}$ analogue, while at the same time the electronic effects of the N versus the S donor may direct which site is most reactive clearly in any case. Rearrangement reactions may be more complex, because of the greater number of potential isomers. Redox potentials may be shifted significantly and new oxidation states stabilized; for example, the N_6 versus N_3S_3 macrobicyclic Co(III) complex (**150**) show clearly different redox chemistry, with the latter stabilizing Co(I), an oxidation state not seen in the former complex. Overall, mixed donor ligands are responsible for diversifying the coordination chemistry of metal ions, and changing donor groups can be employed to 'tune' the properties and expand applications of complexes. Illustrating the broad field of reactions is beyond this review, so only one aspect peculiar to mixed donor ligands will be exemplified below.

Hemilability refers to polydentate ligands that display facile dissociation–reassociation behavior for part of their donor group set, the rest remaining coordinatively intact. Hemilability of hybrid ligands has been reviewed recently.[98] The property is observed particularly in complexes of mixed donor ligands with a mix of hard and soft donors, as exemplified by a number of studies. Reactions of bis[(benzylthio)methyl]pyridine bound to Rh^{I} as an S_2N donor ligand with MeI feature reversible release of a thiobenzyl arm and formation of a transient three-coordinate didentate N,S species.[99] The labile nature of specifically the ether donor in the Pd^{II} complex of a P,N,O-donor tridentate ligand is asserted to assist the complex in catalyzing ethylene oligomerization.[100] Solvatochromisim observed in the Ni^{II} complex of the P,O chelate $C_6H_5(CONH)(PPh_2)$ has been assigned to solvent-dependent hemilability of the amide oxygen atom, the P donor remaining intact throughout.[101] Hemilability has also been described for S,O thioether-carboxylate ligands bound to Pd^{II}.[102]

Glossary

Delocalized valency: valency not confined to single atomic center
Fourfold symmetry: rotation by 90° produces an identical arrangement
Ligand fields: the perturbation of the electronic structure of an ion or atom by the surrounding ligands
Superconductivity: electrical conductance without energy loss
Valency: the electronic structure of a compound or metal ion

Abbreviations

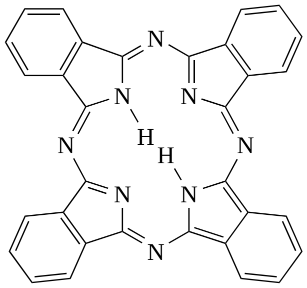
Ln = A general abbreviation for lanthanide elements; PKS model = The model developed by Piepho, Krausz, and Schatz for treating the electronic structure of mixed valence compounds.

1 INTRODUCTION

A survey of the literature[1] from 1980 to 1993 shows that over 2500 articles have been published during this period that contain 'mixed valence' or 'mixed valent' in the title. From 1994–2003, 'Mixed Valence' was in 3988 titles and there were an additional 1095 that contain 'Mixed Valent'. Four of these are reviews.[2] Thus, the 1967 statement of Robin and Day[3] that stated mixed valence chemistry represented a 'neglected class of inorganic compounds' is no longer valid. Mixed valency, the name used to describe compounds containing ions of the same element in two different oxidation states, has come of age.[4–6]

Mixed valence compounds have been used since antiquity as components in pigments such as the oxides of Fe, compounds that can produce red to black colorations in pigments. Today, biologists, as well as chemists, physicists, and geologists, study mixed valence materials. Biological systems have given us an opportunity to explore the ways in which mixed valency is used to store and transfer energy, convert light to chemical reactivity in photosynthesis, and in general utilize mixed valency in redox reactions. Physicists and chemists have been particularly involved with the high-temperature superconducting ceramics. They hold great promise for reducing energy consumption in the future for transport and use of electricity. To date, ***Superconductivity*** has been observed at temperatures above 100 K in mixed valent copper-containing oxides.

Mixed valency is not limited to consideration of individual ions in different oxidation states. Delocalized systems also exist that exhibit properties of mixed valency, as in many organometallic mixed valence compounds. For example, phthalocyanine, Pc (**1**), sandwich compounds of the lanthanides, $Ln(Pc)_2$, are best described as containing the two Pc anionic ligands in mixed valent charge states of −2 and −1 with the metal ion Ln^{3+}.



(**1**) H_2Pc

Mixed valency[5,7] benefitted from a classification scheme developed by Robin and Day,[3] which was based upon the symmetry and strength of the ligand fields about the metal ions. This scheme, which remains widely utilized today, divides mixed valence compounds into four classes. By definition, class I systems are those in which the ions of different valence are in sites A and B of very different symmetry and ligand field strength. Class I compounds have trapped valencies for the ions. Conversion from one state to the other requires substantial reorganization of the structure about both ion species. The coefficient, α, which describes the degree of mixing of the states, is zero. The energy difference between states associated with sites A and B is large. There is no symmetry operation that will take site A into site B (Table 1).

An interesting example of a class I mixed valence species is found in the intensely blue, diamagnetic (*see Diamagnetism*) anion $[(Cu^I)_4Cu^{III}(S_3CR_2)]^-$, which has been reported by

Table 1 Characteristics of the four classes of mixed valence compounds[3]

Class I	Class II	Class III-A	Class III-B
Metal ions in ligand fields of very different symmetry and/or strength, that is, tetrahedral vs. octahedral	Metal ions in ligand fields of nearly identical symmetry, differing from one another by distortions of only a few tenths Å	Metal ions indistinguishable but grouped into polynuclear clusters	All metal ions indistinguishable
$\alpha = 0$; valences very firmly trapped	$\alpha > 0$; valences distinguishable, but with slight delocalization	α maximal locally	α maximal; complete delocalization over the cation sublattice
Insulator; resistivity of $10^{10}\ \Omega$ cm or greater	Semiconductor; resistivity in the range $10-10^{7}\ \Omega$ cm	Probably insulating	Metallic conductivity; resistivity in the range $10^{-2}-10^{-6}\ \Omega$ cm
No mixed valence transitions in the visible region	One or more mixed valence transitions in the visible region	One or more mixed valence transitions in the visible region	Absorption edge in the IR, opaque with metallic reflectivity in the visible region
Clearly shows spectra of constituent ions, IR, UV, Mössbauer	Shows spectra of constituent ions at very nearly their normal frequencies	Spectra of constituent ions not discernible	Spectra of constituent ions not discernible
Magnetically dilute, paramagnetic or diamagnetic to very low temperatures	Magnetically dilute, with both ferromagnetic and antiferromagnetic interactions at low temperatures	Magnetically dilute	Either ferromagnetic with a high Curie temperature or diamagnetic, depending upon the presence or absence of local moments

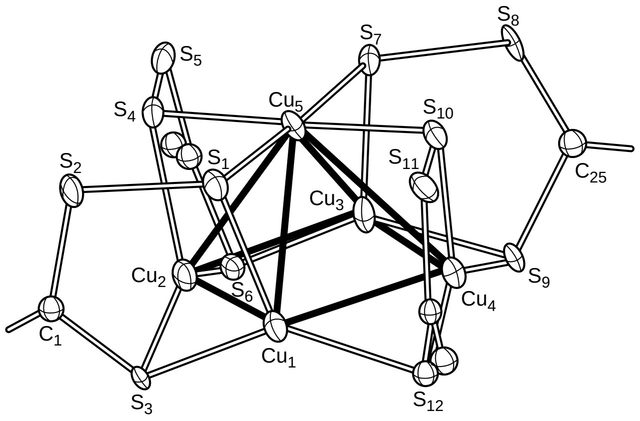


Figure 1 Molecular structure[8] of the $[Cu_8(t\text{-}Bu_2DEDS)_4]^-$ cluster (DEDS = $[S_2C(S)C(CO_2Et)_2]^{2-}$)

Coucouvanis (Figure 1).[8a] The Cu^{III} ion is in a site with fourfold symmetry, a square-planar environment that is often found for metal ions with the d^8 valence shell electronic structure of Cu^{III}. Each Cu^{I} ion is found in a site wherein the metal ion is bonded to three sulfur atoms. The Cu^{I} sites are all equivalent and related to each other by the fourfold symmetry of the complex. Hence the two types of copper ions are in very different coordination environments. This is typical class I behavior since the copper ion sites are not interconvertible by symmetry. The intense blue coloration of the complex, the spectrum of which has not been completely assigned, presumably arises because of the mixed valency of the system. It is especially interesting that D-penicillamine, a drug used in the treatment of Wilson's disease, a genetic disorder that prevents the body from removing excess copper, also produces[8b] an intensely purple mixed valence cluster anion $[Cu^{I}_{8}Cu^{II}_{6}L_{12}Cl]^{5-}$ (L = $-S-CMe_2CH(NH_2)CO_2-$) in which eight Cu^{I} atoms surround the central Cl^-, with six nearly square-planar Cu^{II} ions outside the chloride's centered cubic cluster surface (Figure 2).

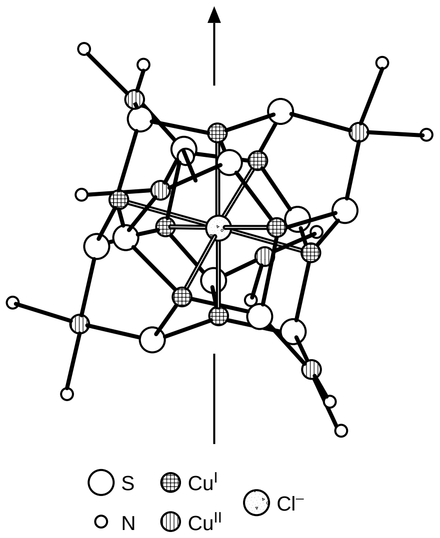

Figure 2 The Cu–Cl–N–S framework of the copper–penicillaminate cluster, showing the threefold axis through two Cu^{I} atoms and the central Cl. (Ref. 8. Reproduced by permission of Royal Society of Chemistry)

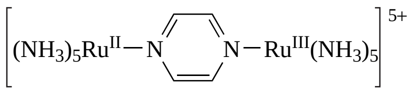
Class III mixed valence species are strongly delocalized systems (*see Delocalized Bonding*) in which the symmetry and ligand environment of the two states A and B are identical. Hence the energy difference between the two sites giving rise to electron transfer is zero and the coefficient α that describes the mixing of the states is maximal. It is possible to further divide class III into III-A and III-B, depending upon whether or not discrete polynuclear groupings of indistinguishable metal ions can be distinguished in the crystal (Table 1).

Class II compounds represent an intermediate classification in which delocalization ($\alpha > 0$) does take place but the two types of site remain distinguishable. An optical electron, the electron associated with the transition between the states represented by A and B, does not have an equal probability of being in each site. Unlike the localized class I example presented above, a class II system might have two metal ions in nearly identical octahedral environments with somewhat different metal–ligand distances in each site. Upon electron interchange, the metal–ligand distances must change as the sites interchange. Such transitions are therefore strongly dependant upon vibronic potentials (*see Vibronic Coupling*) connecting the two states.[9,10]

It is not easy to draw a clear demarcation between class II and class III behavior.[11] Indeed the Creutz–Taube ion (**2**) (*see Creutz–Taube Complex*) caused considerable concern for both experimentalists and theoreticians when it was discovered in 1969, until it was recognized[12] that it 'lay at the point where electronic coupling strengths and vibrational properties were of similar magnitude, so precluding any simple perturbation treatment'. The problem was partially solved both by decreasing and by increasing the complexity of the bridging group between the ions. For further elaboration of the complexity of electron transfer communication associated with bridging ligand structure, the recent study by Cotton[13] should be consulted. The review by Kaim[2a] also should be consulted regarding a wide variety of factors such as the medium, the charge, the nuclearity, and so on, which influence the observed coupling in mixed valence compounds. In general, class II compounds have a bonding atom or group that couples the mixed valence ions or mixed valence molecular units.



(**2**)

2 HISTORICAL OBSERVATIONS[2]

Prussian blue, $K[Fe^{III}Fe^{II}(CN)_6]$, was the first mixed valent inorganic complex to be synthesized. This deep blue colored material, first recorded in 1704, has been used in pigments and inks since early in the eighteenth century. Other double salts of Fe^{II} and Fe^{III} were described in the middle 1800s. By the late 1800s, other compounds such as the Pt^{II}, Pt^{IV} oxalates of Alfred Werner and the tungsten bronzes were recognized[11] to contain both oxidizing and reducing components. By the beginning of the twentieth century, it was recognized that most of these intensely colored inorganic species contain metal ions in two different oxidation states.

Hofmann[12] first formulated the concept of mixed oxidation states for Prussian blue and other iron-containing mixed valence species. The electronic origin of the color, of course, remained obscure until the development of quantum mechanics. Another concept, described as 'valence oscillation', was used by Hofmann and Höschele[12] following the realization that organic dyes were often found to be unsaturated species with 'valence resonance'; an example is 'cerium–uranium blue' (**3**).

$$Ce^{IV}{}_2O_6U^{IV} \rightleftharpoons Ce^{III}{}_2O_6U^{VI}$$

(**3**)

Shortly after this work, Wells[14] came to the same conclusion about valence oscillation and further suggested that enhanced electrical conductivity also resulted. Earlier studies had shown that inorganic powders that were lightly colored (white, pink, gray, and yellow) do not conduct electricity but that intensely colored ions such as the tungsten bronzes often do. As a consequence, most strongly colored inorganic salts were described during the early part of this century in terms of mixed valency. This erroneous conclusion was not satisfactorily rectified until the crystal field and ligand field concepts using wave mechanics became widely known. In fact, 'resonance' ideas continued to be used for an explanation of the colors of inorganic species, especially among chemists, for at least 20 years beyond the time of Bethe's seminal work on crystal field effects.[15]

Historically, Stieglitz[16] is credited with recognition that interactive oxidation–reduction can produce the intense colors observed in many mixed valence inorganic compounds. There was no compelling reason to continue to introduce valence oscillations to describe these inorganic substances. By 1967, when Robin and Day surveyed[3] the chemistry of mixed valence systems, and Allen and Hush independently[7] described these systems using quantum mechanics, the concepts of ligand field theory were firmly established. Robin and Day therefore developed a model based on ligand field theory that produced the classification scheme (Table 1) still used today. They introduced the idea of a molecular orbital that contained an optical electron spanning both types of site, A and B, in a mixed valence system. The electron can be completely delocalized into both sites only if the orbitals on both A and B have the same site symmetry, a class III structure. Class II compounds are intermediate between completely localized class I compounds and the class III species.

An important qualitative description of the spectral behavior of class II compounds was presented by Robin and Day.[3] This 'simple model' has found applicability to the discussion of the spectra of numerous mixed valence compounds in which some delocalization occurs. In this model, it is assumed that the ground-state wave function ψ_0 contains the function, α, which describes mixing of the wave function for site A with the wave function ψ_0' of site B. Assuming that these wave functions are linear combinations of atomic functions, ϕ_i, Robin and Day showed that the wave function describing the optical electron spanning sites A and B is given by equation (1). In this equation,

$$\psi_0 = \frac{\kappa}{N}\left[\sqrt{(1-\alpha^2)}\phi_{\mathrm{A}}^* + \alpha \sum_j c_{ij}\phi_{\mathrm{B}_j}^*\right] \tag{1}$$

ϕ_i^* represents the orbitals outside the closed-shell core for sites A and B. Since sites A and B are distinguishable, a fragment of A, ϕ_A^*, and of B, $\sum_j c_j\phi_{\mathrm{B}_j}^*$ must have the same symmetry to be mixed by the coefficient α. N is a normalization constant and κ is a product of all the closed-shell core functions. The mixing coefficient α tends to 0 for large differences in energy between the two sites.

For class I systems, $\alpha = 0$ and the mixed valence absorption bands observed generally fall at frequencies larger than 27 000 cm^{-1}, except when the system contains a colored ion as a constituent. Intervalence interactions (*see Intervalence Transfer Transition*) can provide a source for intensification of such ligand field transitions, however, in class I systems. The mixed valence electronic transition is given by equation (2), where β has the same meaning for the excited state as α does for the ground state. Hence $\alpha = \beta = 0$ for true class I behavior.

$$\frac{\kappa}{N}\left[\sqrt{(1-\alpha^2)}\phi_{\mathrm{A}}^* + \alpha \sum_j c_{ij}\phi_{\mathrm{B}_j}^*\right] \longrightarrow \frac{\kappa}{N'}\left[\beta\phi_{\mathrm{A}}^* - \sqrt{(1-\beta^2)}\sum_j c_{ij}\phi_{\mathrm{B}_j}^*\right] \tag{2}$$

For class II mixed valence systems, the absorption band that is generally observed in the visible region, 14 000–27 000 cm^{-1}, is absent in the spectra of the constituent ions taken individually. The energy of this transition is a function of the changes in the energies of the two sites, along with a term arising from the transfer of the optical electron in the electrostatic field of all the changes in the system.

Robin and Day[3] presented a particularly helpful molecular orbital description of the hypothetical $Cu^{I}Y_2X_2Cu^{II}X_3$ mixed valence system (Figure 3). This model indicates that the difference in energy between the mixed valence transitions 1 and 2 is equal in energy to the lowest energy ligand field transition in Cu^{II}. Unlike, the localized square-planar Cu^{II} complexes where three transitions occur, four are expected, 1–4, for the mixed valence system. The intensities of these mixed valence transitions are usually much larger (100–1000 times) than the ligand field transitions.

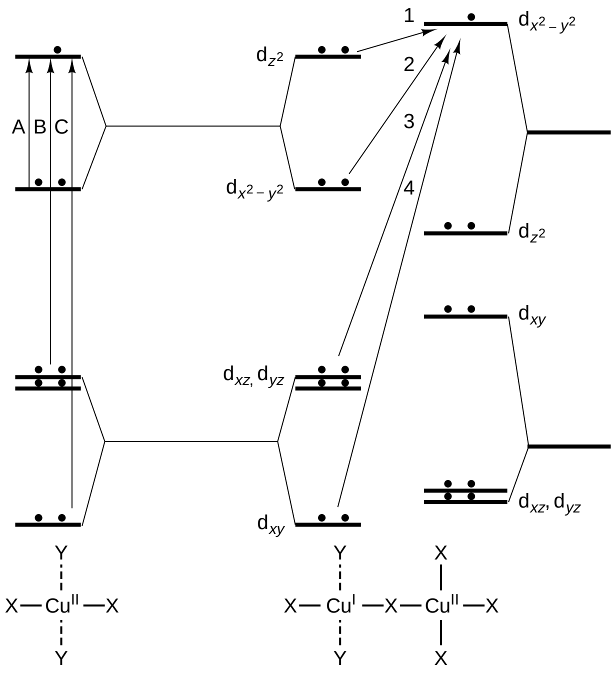


Figure 3 The molecular orbital scheme for the hypothetical class II mixed valence system $Cu^{I}Y_2X_2Cu^{II}X_3$, showing how the energy difference between the two mixed valence transitions 2 and 1 is equal to the crystal field transition A in $Cu^{II}X_2Y_2$, and so on. (Ref. 3. Reproduced by permission of Elsevier)

It is recognized that the wave function mixing required for class II mixed valence behavior is governed by the vibrational, magnetic, and electronic features of the system.[17]

3 THEORETICAL DEVELOPMENTS

Following the work of Robin and Day,[3] and Allen and Hush,[7] the first rigorous solution to the vibronic Schrödinger equation for a mixed valence system was formulated by Piepho, Krausz, and Schatz.[18] This model, based on the valence bond approach, is known as the PKS model. It is a model that has been modified[19] to include orbital vibronic constants. A fully equivalent molecular orbital model developed by Piepho[20] is easier to conceptualize, however. The Piepho model also was the first to take advantage of the concept of orbital vibronic constants[8,9] developed by Bersuker for Jahn–Teller systems (Figure 4). The Jahn–Teller theory is the basis for the PKS model.

The PKS model has been shown to be identical[19] with the MO model for one- and two-electron cases provided that the potential function connecting states is expanded to include first- and second-order terms (a Taylor series expansion).

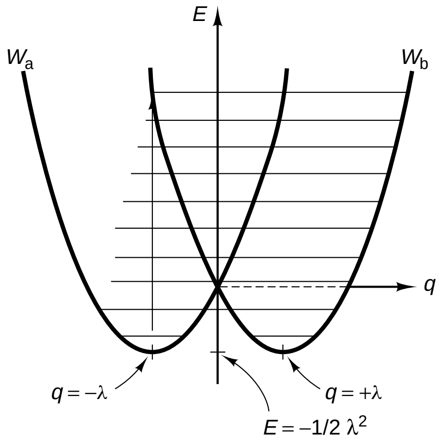

Figure 4 The potential energy surfaces in cross-section of a Jahn–Teller system utilized in the PKS model $\lambda = (8\pi^2 h\nu^3)^{-1/2} l$ (l = vibronic coupling parameter, $\nu = (1/2\pi)k^{1/2}$, k = harmonic vibrational constant). (Ref. 19. Reproduced by permission of Kluwer Academic Publishers)

Several representative examples have been presented by Schatz[19] of the results of the modified PKS model. One of these is reproduced in Figure 5 for a two-electron system.

Although the extended valence bond PKS model probably can always be shown to be equivalent to a molecular orbital model for mixed valency systems involving complex bridging ligands such as found in the Creutz–Taube ion, these systems are best treated using a MO approach. A qualitative description is now given of the MO ideas developed by Piepho.[17]

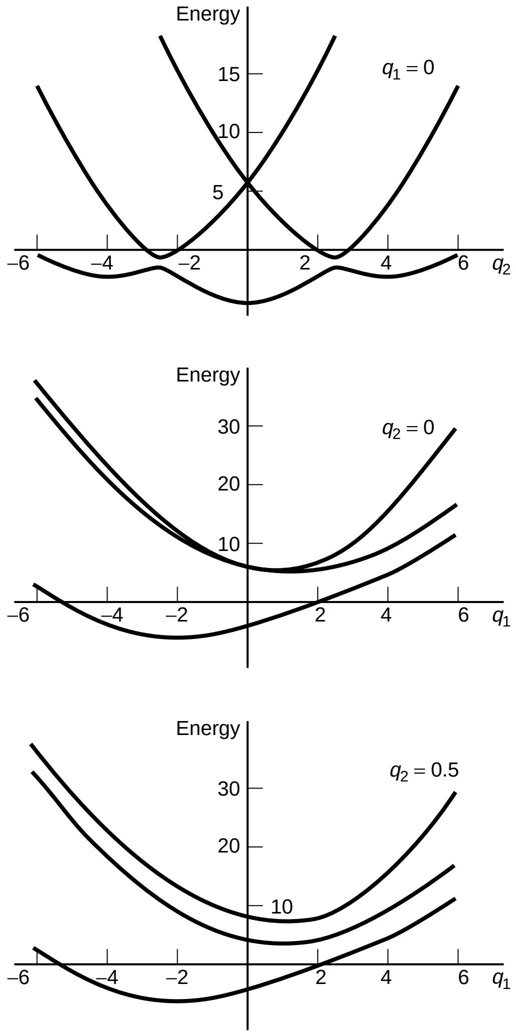

Figure 5 Potential surfaces for a two-electron system in which the covalent state is lowest ($W = -1$). See Schatz[19] for a discussion of the parameters. (Ref. 19. Reproduced by permission of Kluwer Academic Publishers)

4 MOLECULAR ORBITAL TREATMENT

The vibronic coupling model of Piepho uses standard MO theory involving MOs of the valence delocalized system. Electron coupling between the metal ion centers requires a coupling with the bridging ligand. The Creutz–Taube ion is described here with this model. A schematic diagram by Piepho[17a] for this prototypical mixed valence complex is shown in Figure 6. In this model, at least two vibronic modes are active that couple the states $\phi_1{}^{\pm} = |b_{3u}^2 b_{2g}{}^{\pm}\rangle$ and $\phi_2{}^{\pm} = |b_{3u}{}^{\pm} b_{2g}^2\rangle$. The pseudo Jahn–Teller coupling[9] of the states for a given energy splitting, Δ, leads to delocalization. However, the larger the value of Δ for a given coupling, determined by the orbital vibronic constants, the less valence trapped the system becomes. In the Creutz–Taube ion, the unoccupied b_{2u} orbital on the bridging pyrazine ligand mixes strongly with a b_{3u} metal symmetry orbital thereby producing a large splitting, Δ, of the symmetry orbitals. Hence it is not surprising that the species is valence delocalized.

In the delocalized class III limit, the band shape for electron transfer between mixed valence states is nearly entirely a result of the vibronic coupling associated with the totally symmetric, multicenter, A-bridge-B stretching mode. This mode was omitted[18] from the first PKS model and can be given by – $\langle b_{2g}|(\partial V(i)/\partial Q_2)_{Q0}|b_{3u}\rangle$, where $(\partial V(i)/\partial Q_2)_{Q0}$ is the matrix element described as the orbital vibronic constant connecting the two states. In the model[20] of Piepho, this strong coupling leads to a symmetric, relatively intense band centered approximately at Δ. Piepho[20] has suggested a number of band contours for different parameter sets. One of these (Figure 7) illustrates how the band shape contours for electronic transitions in mixed valence compounds are related to valence trapping. The parameters λ_n relate to the wavelengths associated with the orbital vibronic constants used and Δ is the energy separation between the mixed valence states. In the Creutz–Taube ion (**2**), the vibronic coupling parameter of importance, λ_1,[9] appears to be 0.70 for a

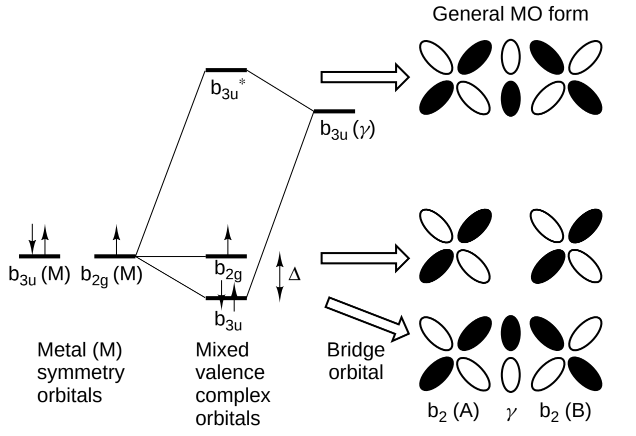

Figure 6 Schematic MO diagram for a prototype mixed valence complex in which an unoccupied b_{3u} bridge orbital interacts with a b_{3u} metal symmetry orbital.[17] (Reprinted with permission from Ref. 20. © 1988 American Chemical Society)

frequency in the 600–800 cm^{-1} range, matching the 701 cm^{-1} band observed experimentally.[14b] Figure 8 is a schematic MO diagram for the Creutz–Taube ion with sketches of the orbitals on the pyrazine bridging ligand and on the metal atoms that are important to the delocalization of the mixed valence.

5 MINERALS WITH MIXED VALENCE IONS

The colors and other physical properties of numerous oxide and silicate minerals are complex facets of mixed valence chemistry. Structural diversity and the frequency of defects complicates the understanding of the electronic properties of such minerals. However, considerable progress has been made, much of which has been described by Burns.[21]

Since biologically important mixed valence systems may have developed in living organisms from mineral systems, it is not surprising that the litany of mixed valence systems in both biology and in minerals largely encompass the same ion states: Fe^{II}, Fe^{III} (magnetite, for example); Ti^{III}, Ti^{IV} (sapphire and other minerals); Mn^{II}, Mn^{III}, Mn^{IV}; Mo^{V}, Mo^{VI}; Co^{II}, Co^{III}; Cu^{I}, Cu^{II}.

Striking examples of ligand field spectral intensity enhancement caused by mixed valency have been observed in mineral

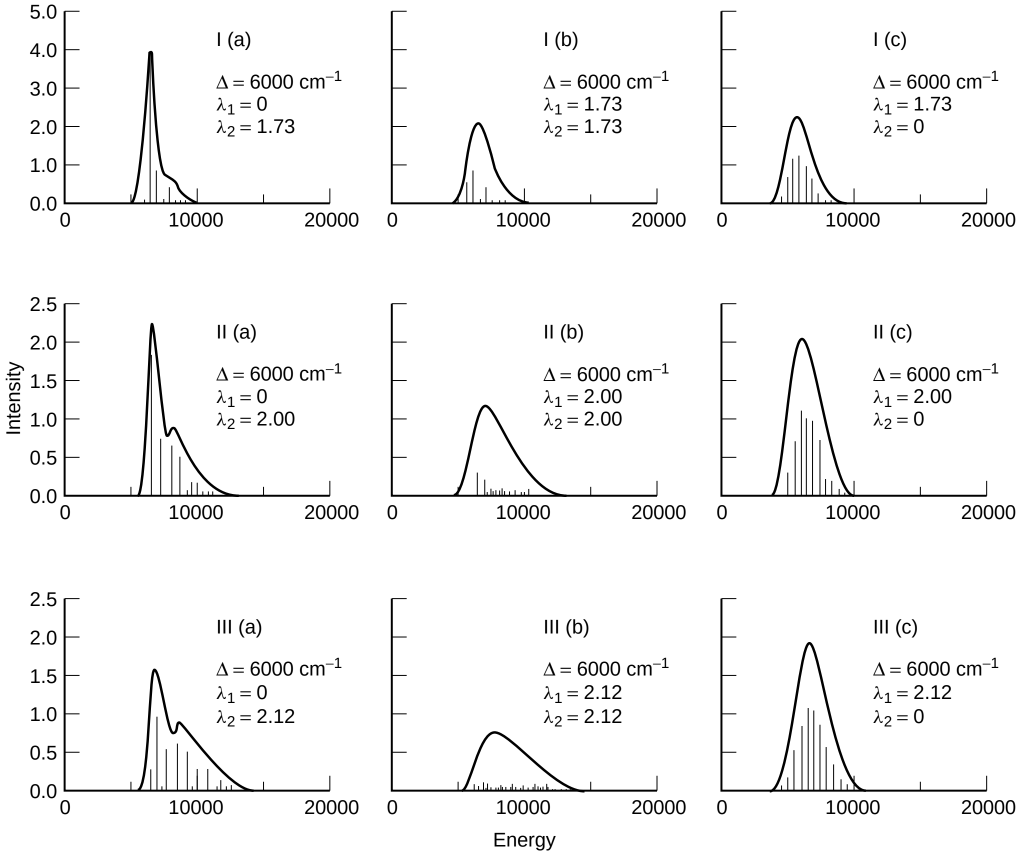

Figure 7 Calculated absorption contours at 298 K for different values of Δ and λn. (Reprinted with permission from Ref. 20. © 1988 American Chemical Society)

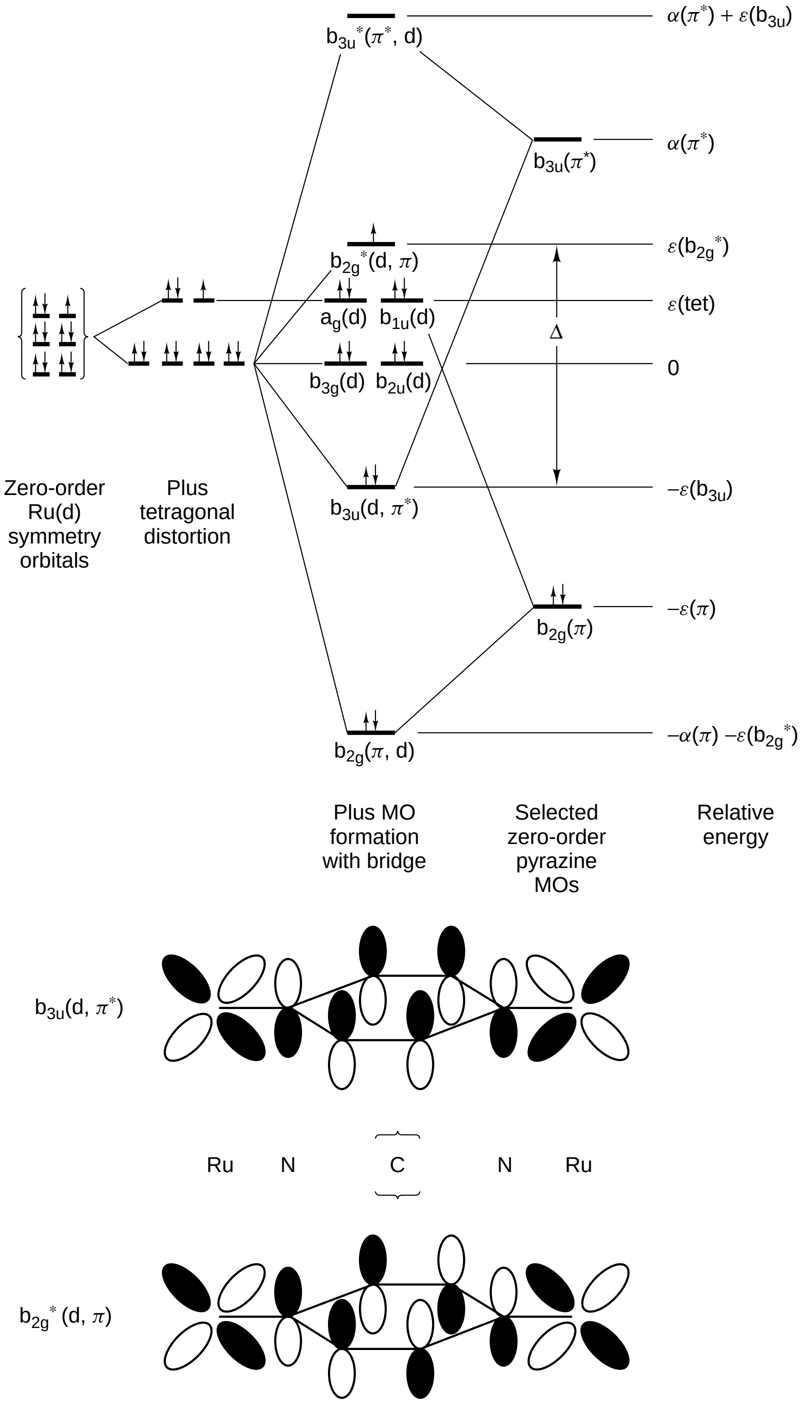

Figure 8 Schematic MO diagram for the Creutz–Taube ion and sketches of the molecular orbitals on the bridging pyrazine and the metal atoms that are important to the mixed valence delocalization.[20] (Reprinted with permission from Ref. 17b. © 1990 American Chemical Society)

studies. Recent observations made in vivianite, a mineral phosphate of composition $Fe^{II}_3(PO_4)_2{\cdot}8H_2O$, upon increasing the degree of oxidation, are shown in Figure 9. This $Fe^{II} \rightarrow Fe^{III}$ intervalence charge-transfer band is the standard against which electron interaction parameters are compared in other mineral systems.

Intervalence charge-transfer energies of various mixed valence minerals can be found in the review by Burns.[21] A few of these minerals are listed in Table 2.

Thermally activated electron delocalization also is observed in some minerals. The silicate mineral ilvanite with its Fe^{II}–Fe^{III} mixed valency has been extensively studied.

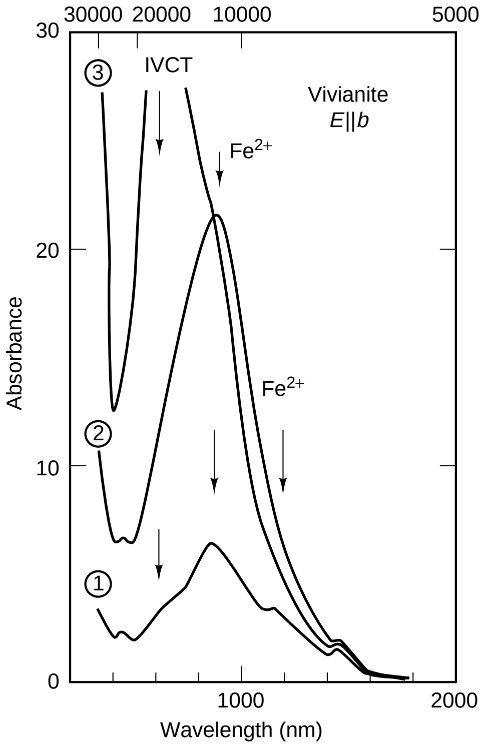

Figure 9 A $Fe^{II}-Fe^{III}$ intervalence charge-transfer band in the mineral vivianite, $Fe_3{}^{II}(PO_4)_3{\cdot}8H_2O$ upon oxidation. (Ref. 22. Reproduced by permission of Kluwer Academic Publishers)

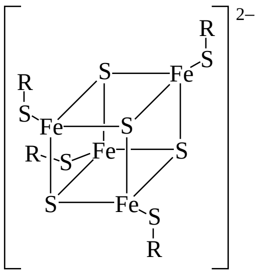
Mössbauer, magnetic, and electronic studies implicate interactions between Fe^{II} and Fe^{III} in neighboring sites. A phase change between 335 and 343 K is accompanied by thermally activated electron delocalization between 300 and 400 K. Below 120 K, ilvanite is ordered antiferromagnetically. Mössbauer studies[21] (*see Mineralogy*) have helped elucidate this mixed valence behavior.



(**4**)

6 BIOLOGICAL SYSTEMS WITH MIXED VALENCE

Mixed valency is well established in biology.[23] Clusters have been identified involving several different combinations

Table 2 Some examples from Burns[21] of intervalence charge-transfer energies in minerals

Mineral	M–M distances (pm)[a]	IVCT energy (cm^{-1})	Molar absorptivity ($M^{-1}cm^{-1}$)	Half-width (cm^{-1})

of metal ions in various oxidation states. The tetranuclear iron–sulfur system[24] and closely related Fe_2 and Fe_3 complexes[25] are associated with redox processes in proteins in which the enzyme is either mobile or fixed to a membrane. The cluster unit in the oxidized form of the ferrodoxin proteins (*see* ***Iron–Sulfur Proteins***) is made up of mixed valence $[Fe_4S_4(SR)_4]$ units that have been modeled by Holm and coworkers[24] as $[Fe^{II}{}_2Fe^{III}{}_2S_4(SR)_4]^{2-}$ (**4**) clusters. A related 'cubane' Fe_4S_4 unit also is present in the high potential iron proteins (HPIP). However, even with the structural knowledge obtained from model studies, the origin of the potential differences associated with these clusters in the proteins is not fully understood: HPIP, −150/+400 MV; ferrodoxins, −300/−600 MV. The protein apparently controls the cluster structure sufficiently well that the redox potential is different from one protein to another.

As Blondin and Girerd point out,[25] a 100 MV separation corresponds to an energy of 800 cm^{-1}. This energy difference is assumed to be associated with the vibronic trapping of the mixed valency. This energy separation is of the same order of magnitude as the Fe–S stretching vibrations required to interconvert structural states. Even in the $[Fe_2S_2]^+$ mixed valence systems with bridging S atoms, the valences are localized on a Mössbauer

timescale. Hence the trapping parameter Δ cannot be exactly zero. While this conclusion is quite reasonable in the protein environment, it is somewhat surprising that the model compounds show valence trapped class II behavior. The origin of this effect appears to be vibronic.[25]

The electronic structure of the cluster component of metalloenzymes (*see Metalloprotein*) that contain mixed valence clusters can be described using three parameters: a delocalization parameter, an electron exchange parameter, and a trapping energy parameter. As pointed out by Zener[26a] and Anderson[26b] in the 1950s and discussed by Blondin and Girerd,[25] electron transfer between magnetic ions is spin dependent. Magnetic and electronic properties are coupled in these systems. A double exchange occurs with the magnetic coupling energy, it being approximately the same order of magnitude as the vibronic coupling energy. These magnetic systems therefore become very complicated to unravel. Further, it has been shown that if double-exchange is the leading term, then the spins can be aligned parallel even with intrinsic antiferromagnetic coupling. A $[LFe^{II}(OH)_3Fe^{III}L]$ complex (L = a polydentate ligand) studied by Wieghardt,[27] in which the valences are delocalized, demonstrates the existence of parallel spins in an intrinsically antiferromagnetically coupled system. In related recent work, Wieghardt[23b] has demonstrated that in several *o*-phenylenediamine complexes of Ni, Pd, and Pt, which might otherwise be considered mixed valent, the oxidations and reductions are invariably ligand centered.

Other important mixed valence biological systems under intense study include the dinuclear Mn catalases (*see* ***Manganese Proteins with Mono- & Dinuclear Sites***) and the tetranuclear Mn site for photosynthetic water oxidation (*see* ***Manganese: The Oxygen-evolving Complex & Models***).[28] Progress here has been complicated by the lack of good models although considerable progress is being made particularly using the characterization of materials by ESR spectroscopy. In the dinuclear Mn catalase system, four oxidation states of the *thermous* enzyme are produced: $Mn^{II}Mn^{II}$; $Mn^{II}Mn^{III}$; $Mn^{III}Mn^{III}$; $Mn^{III}Mn^{IV}$. The mixed valence states are essentially inactive for H_2O_2 disproportionation. Dismukes[28] has proposed a manganese catalase mechanism involving these various oxidation state species (Figure 10). The tetranuclear Mn photosystem II (*see Photosystem I*) is even more complex and less well established although oxide bridges presumably couple mixed valence states.[29]

Other biological mixed valence systems are known but an understanding of their electronic structures is even less well

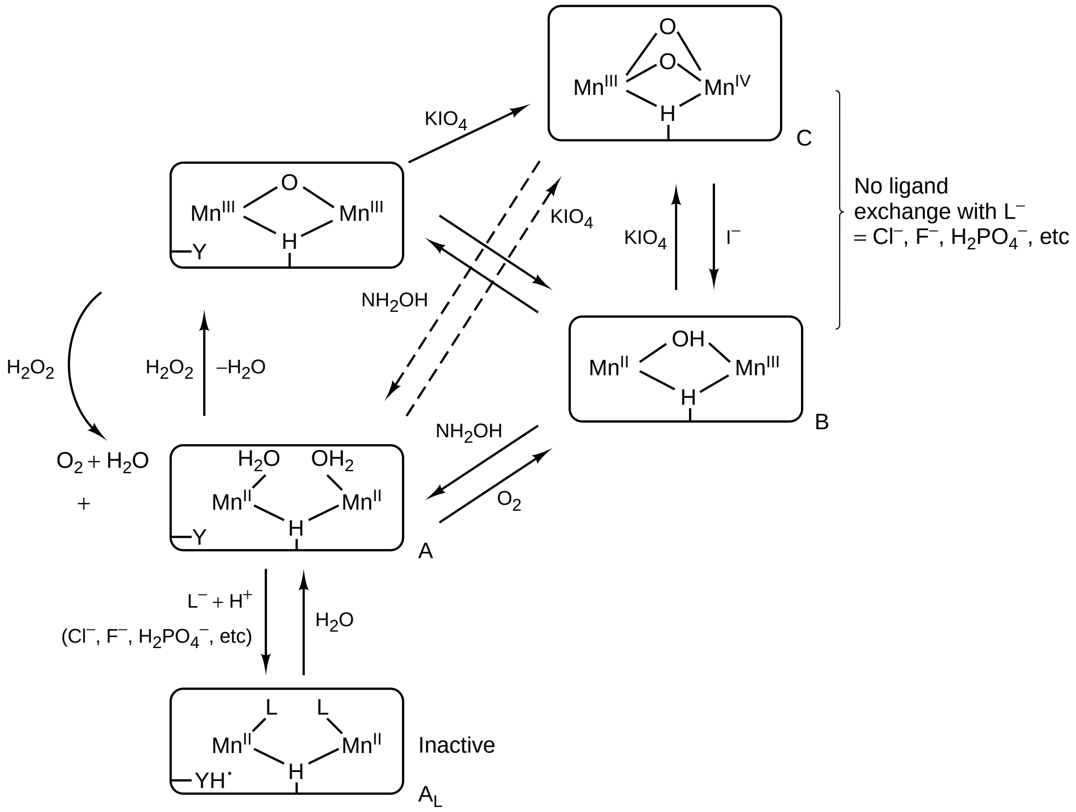

Figure 10 Proposed mechanism of action for the enzyme catalase involving mixed valence states of manganese. (Ref. 28. Reproduced by permission of Kluwer Academic Publishers)

developed than in the iron and manganese systems described above. An example involving copper has been studied by Karlin.[30]

7 CONDUCTORS AND RELATED MIXED VALENCE MATERIALS

In class I mixed valence species, electron transitions between sites are energetically difficult to accomplish. In the solid state, these materials are generally insulators. However, with class II and class III compounds, electron transfer becomes much easier so that conducting and superconducting materials are obtained (*see* ***Sulfur: Organic Polysulfanes***).

A wide range of optically interesting bronze materials such as $LiFe^{II}Fe^{III}F_6$ have been described.[31] Although architecturally and magnetically of interest, typical resistivity is high at room temperature, $10^9\,\Omega\,\text{cm}$. The factors that influence the rates of intramolecular electron transfer in solids have been discussed by Hendrickson.[32] Intramolecular electron transfer in this area is being intensely examined for possible application in molecular electronics.

Mixed valence linear chain materials have proved to be fascinating solid-state species with unusual and interesting properties. Studies range from organic metals such as TTF–TCNQ (**5**) to linear chain metal complexes. In the latter area, the three volume series by Miller[33] is an informative source of material through 1983. Since that date, superconductivity has been observed in TCNQ-type organic materials with the highest T_c found as of 1993 to be about 11–12 K.

Inorganic–organic composites are receiving close study.[34] In these compounds, as in the mixed valence copper sulfides,[35] the nonmetallic moiety is the mixed valent species. Superconductivity also is known with the sulfides in the *Chevrel Phases*.[36a] In 1991, the pure fullerene phase of carbon, C_{60} (Figure 11), was observed to become superconducting upon doping with alkali metals.[36] This organic–inorganic area is an exciting new field for investigation since conductivity

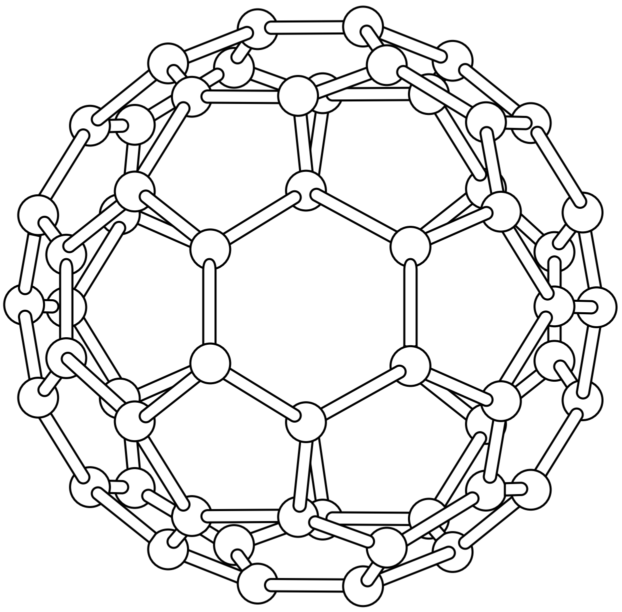

Figure 11 A sketch of the C_{60} fullerene

can be dominated by electron delocalization in the organic moieties while magnetic properties are generally associated with the metal centers.

The discovery of mixed valent oxide superconductors[37] opened up the possibility that room temperature superconducting materials may one day be obtained. Although T_c values around 10 K have been known for many years, the $YBa_2Cu_3O_7$ and $Tl_2Ba_2CaCu_2O_8$ phases have yielded superconducting critical temperatures of 75–91 K and 102 K, respectively (above the boiling point of liquid nitrogen). Evidence even has been presented for filamentary superconductivity in

specially treated $YBa_2Cu_3O_7$ films at 220 K, and reproducible resistive transitions between 160 and 200 K have been reported for films of $Y_5Ba_6Cu_{11}O_2$ subjected to He and O_2 anneals. Structural patterns from X-ray diffraction implicate copper oxide phases similar to those presented for $TlBa_{2-x}La_{2+x}Cu_2O_{9\pm\delta}$ in Figure 12. Superconductivity in another oxide, $Na_xCoO_2{\cdot}1.3H_2O$, has been related to chemical doping as observed in the high-T_c copper oxides, although the microscopic origin of high T_c in superconductivity is still under active study.[38]

8 MISCELLANEOUS MIXED VALENCE SPECIES

The Creutz–Taube ion (**2**) can be described as the prototypical mixed valent system in which a delocalized formulation best describes the electron transfer between charge centers. Bruns and Kaim[39] described another pyrazine complex that displays delocalized behavior, $[mer\text{-}(OC)_3(P\text{-}i\text{-}Pr_3)_2\ W(\mu\text{-pyrazine})W(P\text{-}i\text{-}Pr_3)_2(CO)_3]^+$. Connecting two organometallic centers with different metal valencies together by delocalized organic spacers becomes a general way to accomplish fast one- and two-electron transfer. This approach has been taken by Astruc,[22] who has described the electrochemistry of mixed valent Fe^IFe^{II} complexes of the π 'sandwich' cyclopentadiene (*Ferrocene*) type, bridged by fulvalene and by diphenyl. The $[Fe_2(Fv)(Cp)_2]^{2+}$ (Fv = fulvalene) system is one where the Fe^IFe^{II} system undergoes a two-electron reduction as measured by cyclic voltammetry. However, Astruc and his colleagues have characterized the $[Fe_2(diphenyl)(C_5R_5)_2]^{2+}$ (R = Me) complex, which, unlike the related $[Fe_2(diphenyl)(C_5H_5)_2]^{2+}$, undergoes a reversible one-electron reduction. Structural comparisons have been made (Figure 13) between the one- and two-electron reduction

species in a system giving two close one-electron transfers. The electronic energy difference between the two one-electron reductions is compensated by the energy gained in the structural rearrangement, which intervenes in the two-electron reduction product. Astruc suggests that these types of species are useful ‘two-electron transfer mediators’.

The tools used to explore mixed valency over the past few years have been able to give new understanding to these complex inorganic and organometallic systems. Various spectroscopies have been used. Of particular use for studying inorganic compounds is resonance Raman spectroscopy, which gains its very existence from the coupling of electronic and vibrational spectroscopies. In particular, Clark[40] used this tool with considerable success to explore the behavior of linear chain mixed valent species. Multiple harmonic vibrational levels (overtones) of these materials are observed to increase in number with decreasing conductivity. Excitation to the intervalence state requires less nuclear motion in the more highly conducting mixed valent species. Thus, fewer overtone bands are observed in those more highly conducting species where the conductivity obeys the relationship $\sigma = \sigma_0 \exp(-E_a/kT)$ (Table 3).

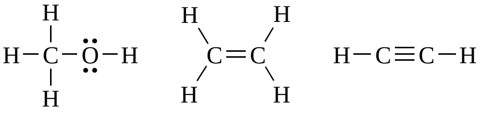
1 INTRODUCTION

Molecular orbital theory is a quantum mechanically based model used for the description of the behavior of electrons in molecules. The essence of the approach is that electronic wavefunctions are built from the commonly used s, p, d, and f hydrogen-atom based atomic orbitals and can range through an entire molecule. These molecular orbitals (MOs) can be constructed using detailed mathematical formalisms and high-speed supercomputers, or with pen and paper using rough approximations. Experimental inorganic chemists are familiar with some of the most notable historical successes of the MO approach, especially in treatments of molecular spectra, the shapes of molecules, and their magnetic character. The types of important subjects that are being treated today using MO calculations include determinations of charge distributions in molecules, details of molecular collisions, descriptions of molecular geometry in the ground and excited states, optical properties, and potential energy surface diagrams for reactions, among many other applications. Several undergraduate chemistry textbooks review MO theory from an inorganic chemists' point of view;[1–4] many other texts treat the method from a more mathematical point of view.[5–12] A large percentage of the supercomputer cpu time in the United States is expended solving electronic structure calculations, a large majority of which uses the many variations of MO theory.

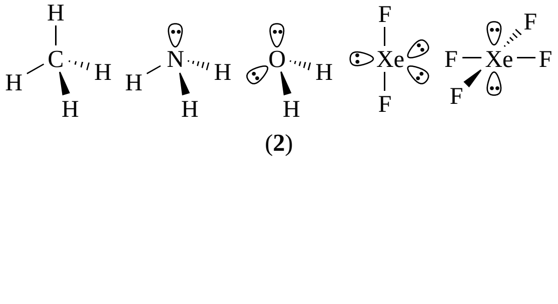
The aforementioned areas of study can be treated with a rigor that would have seemed impossible even a few years ago. This is due principally to the amazing development of efficient, graphically based software and high-speed computer hardware. As a result, rather than electronic structure calculations being in the exclusive realm of the theoretician, it is a matter of routine that experimental chemists make use of the many commercial theoretical chemistry packages for their own purposes. Though there is little chance that the chemical discipline will evolve from an experimental science into a purely theoretical endeavor, quantum chemical calculations play a growing role in chemical inquiry and chemical education.

Our current understanding of chemical bonding in molecules was developed in the late 1920s and early 1930s immediately after the quantum mechanical revolution of thought that revealed a new way of describing energy and matter. It had been known prior to the establishment of the new mechanics that covalent bonds could be described as shared electron pairs while the other electrons in a molecule were characterized as 'lone pairs' or core electrons not involved with bonding.[13,14] The arrangement of the valence electrons in the vast majority of main group compounds could be accounted for using the model that was based on the inherent stability in a 'filled octet' of electrons. Lewis dot structures that use these concepts are highly successful in rationalizing connectivity in molecules and are still used extensively in organic chemistry today (see **1**).



(**1**)

A three-dimensional extension of the same approach was developed in the 1950s as X-ray crystal structures of molecules became more easily available. The valence-shell electron pair repulsion theory (VSEPR) rules modeled the structural influence of bonding pairs and lone pairs of electrons.[15] A set of simple guidelines is used to provide the basis for a great number of structures. For example, the bond angles in the isoelectronic series CH_4 (109.4°), NH_3 (107.3°), and H_2O (104.5°) can be rationalized by attributing a larger repulsive force to lone electron pairs as compared to bond electron pairs (see (**2**)). Another particular success was the accurate model of the structure of the noble gas halides XeF_2 and XeF_4 even before their synthesis.



(**2**)

However, to go a step further and identify the physical forces that keep molecules together, as well as to develop a quantitative understanding of molecular structure, a quantum mechanical treatment was required. In 1926, Schrödinger's equation was proposed to relate the energy of a quantum mechanical system to the motions of its constituent particles and all the forces acting upon them. In a chemical system, we are ultimately interested in the mathematical representation of the kinetic and potential energies of an electron under the influence of attractive nuclear forces and the repulsive forces of the other electrons. This representation is called the wavefunction and can be expressed in a variety of ways, some of which will be described in this article. The most general form of the Schrödinger equation is:

$$\widehat{H}\Psi = E\Psi \tag{1}$$

where $\widehat{H}$ represents the Hamiltonian operator, being the sum of the kinetic and potential energy operators. Ψ represents the wavefunction of the system (also known as the eigenfunction) and E the total energy of the system (an eigenvalue). If each side of the equation is multiplied by Ψ and integrated over all space, the equation may be arranged to solve for the total energy:

$$E = \frac{\int \Psi^* \widehat{H} \Psi \mathrm{d}\tau}{\int \Psi^* \Psi \mathrm{d}\tau} \tag{2}$$

Knowledge of the physical forces that influence the total energy of a system thus reveals the theoretical underpinnings of nearly all of experimental chemistry. In fact, much of the early activity in chemical bonding theory was the result of attempts to understand the results of molecular spectroscopy experiments. The developers of what came to be called molecular orbital theory, Robert Mulliken (US) and Friedrich Hund (Germany), established a professional and personal relationship based on their common interest in the spectra of diatomic molecules especially in the influence of isotope effects. When compared to other theories of the time, a major advantage of their theoretical approach was the ability to directly apply the results to the elucidation of molecular spectra.[16]

Although equation (2) appears concise in the form above, it cannot be solved exactly for a molecular system. Electron−electron repulsions present a practical problem in the same way that they do in many-electron atoms; the repulsive interaction between two electrons is a function of the position coordinates of each electron and cannot be separated into two functions dependent on each set of coordinates individually. However, even if a complicated wavefunction that was expressed in the coordinates of all the electrons in a molecule could be developed, it would have to be reported as an extensive grid of points in 3-D space, each associated with a different potential energy with unique solutions for each and every molecule. This would clearly be an unwieldy and ineffective way of reporting electronic structure. For this reason, quantum chemists quickly learned that in order for the MO theory to be accepted by chemists at large, a judicious choice of these 'molecular wavefunctions' would need to have transferability between molecules and be easily represented, ideally in a straightforward pictorial fashion.

There are two guiding principles that direct the generation of the solutions to the Schrödinger equation. First, in order to avoid the inconvenient wavefunctions mentioned above, the method takes advantage of a technique analogous to the so-called 'orbital approximation' in atomic structure. In this approximation, a many-coordinate function is expressed as a linear combination of products of one-electron wavefunctions.

$$\Psi(\text{electron 1, electron 2, electron 3 K}) = \psi(\text{electron 1}) \times \psi(\text{electron 2})\psi(\text{electron})K \tag{3}$$

Secondly, the quality of a wavefunction in any quantum mechanical system is influenced by the variation principle, which states that a normalized, acceptable trial wavefunction will always yield an eigenvalue larger than the true energy provided that the exact Hamiltonian is used. One wavefunction is considered 'better' than another if it yields a lower energy. An alternative way expressing this idea is to say that a means of setting an 'upper bound' is easily achieved. Specifically, a trial wavefunction is designed in terms of parameters that can be varied so that the optimal wavefunction emerges when the lowest eigenvalue is attained.

These guidelines enable the chemist to use a set of common 'building block' functions for all molecules and to make small adjustments as they are warranted in accord with the variation principle. Many methods of calculating the electronic structure of molecules have been proposed since the advent of quantum mechanics but nearly all that are used today are derivatives of two approaches that were proposed in the flurry of activity after Schrödinger introduced his equation.

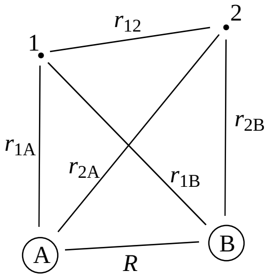
2 VALENCE BOND THEORY

The application of Walter Heitler and Fritz London's valence bond theory was the first description of the binding forces in the H_2 molecule, the simplest neutral molecule.[17] Linus Pauling and John Slater later extended the principles to larger molecules.[18,19] The key element in their proposal was the synthesis of a 'bonding' wavefunction resulting from a combination of atomic orbitals that link the two atoms in a bond. It was hugely important that this localized approach concurred with the Lewis dot model. For the simplest neutral molecule, H_2, the Hamiltonian operator may be written

$$\widehat{H} = -\frac{h^2}{2M}(\nabla_A^2 + \nabla_B^2) - \frac{h^2}{2m}(\nabla_1^2 + \nabla_2^2) - \frac{e^2}{4\pi\varepsilon_0}$$

$$\times\left(\frac{Z}{r_{1A}}+\frac{Z}{r_{1B}}+\frac{Z}{r_{2A}}+\frac{Z}{r_{2B}}-\frac{Z}{r_{12}}-\frac{Z^2}{R}\right) \qquad (4)$$

where M is the mass of hydrogen nucleus, m is the electronic mass, Z is the atomic number of the nucleus ($Z = 1$ for hydrogen), ∇_A^2 and ∇_B^2 are the kinetic energy operators for the nuclei A and B, ∇_1^2 and ∇_2^2 are the kinetic energy operators for the electrons 1 and 2, and the various distances are illustrated in (**3**).



(**3**)

In order to simplify the expression, the motion of the nuclei is neglected by implementing the Born–Oppenheimer approximation, which is justified because of the large difference in mass between the nuclei and the electrons. In fact, atomic nuclei are in constant motion, but their velocity is a fraction of the velocity of the electrons. Thus, the electrons are assumed to quickly adjust to any motion by the nuclei, essentially freezing the nuclei in space relative to the electrons, so R may be considered a constant.

The resulting Hamiltonian for H_2 can be simplified using atomic units:

$$\widehat{H} = -\frac{1}{2}(\nabla_1^2+\nabla_2^2)-\frac{1}{r_{1A}}+\frac{1}{r_{1B}}+\frac{1}{r_{2A}}+\frac{1}{r_{2B}}-\frac{1}{r_{12}}-\frac{1}{R} \qquad (5)$$

In the light of the orbital approximation, a total wavefunction for the 'system' of two separated hydrogen atoms can be written as

$$\Psi = 1s_A(1)1s_B(2) \qquad (6)$$

Each electron occupies a 1s orbital on its 'home' hydrogen, electron 1 on H_A and electron 2 on H_B. This distinction, however, is lost when the nuclear centers are brought within bonding distance of each other. At this close proximity, quantum mechanics requires that electrons be indistinguishable from one another. The simplest function in the valence bond description that accounts for this behavior is a linear combination of two possibilities (**4**).

$$\Psi = c_1\psi_1 + c_2\psi_2$$
$$\text{where } \psi_1 = 1s_A(1)\,1s_B(2) \text{ and } \psi_2 = 1s_A(2)1s_B(1)$$

(**4**)

An electron described by this new molecular wavefunction could 'belong' to either atom at a given moment while the second electron is associated with the other nuclear center. A calculation of probability density of the electron reveals that there is a buildup of electron density in the internuclear region for the bonding interaction that exceeds the density normally found at the same distance from the nucleus in the separated atoms.

Electrons described by bonding wavefunctions, that is, those that occupy bonding orbitals are more energetically stable than those electrons described by atomic orbitals in the separated atoms. Owing to the fact that an electron in this region has an attractive interaction with the two positively charged nuclei, it might appear reasonable to attribute the stability of a chemical bond to a 'classical' electrostatic attraction. However, as will be shown below, the term that describes stability of the molecule relative to the two separated nuclei is a purely quantum mechanical quantity.

This simplest valence bond description of the chemical bond can be improved (yielding a lower energy via the variation principle) using two straightforward techniques. The first considers the possibility that at a given moment both electrons can be found on a single atom. That is, the wavefunction can include ionic components written as in (**5**):

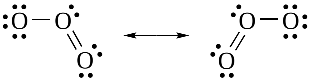
$$H_A^-H_B^+ \quad \text{or} \quad H_A^+H_B^-$$

(**5**)

This distribution of electron density can be accounted for by rewriting an unnormalized function in the form

$$\Psi = 1s_A(1)1s_B(2) + 1s_A(2)1s_B(1) + \lambda[1s_A(1)1s_A(2) + 1s_B(1)1s_B(2)] \qquad (7)$$

where λ is a weighting factor. Calculations using the variational principle have established that the optimum value for λ for the wavefunction in this form is less than one, meaning that the covalent description that places one electron on each nucleus is more important. The other improvement for a valence wavefunction is based upon the observation that, for many polyatomic molecules, a large number of Lewis dot structures may obey the filled octet prescription. This is addressed by identifying the overall wavefunction as a weighted superposition of all the electron-paired structures that obey the Lewis filled octet criterion. The structure of a molecule becomes a resonance combination of the contributing structures. A common example is ozone, O_3 (**6**).

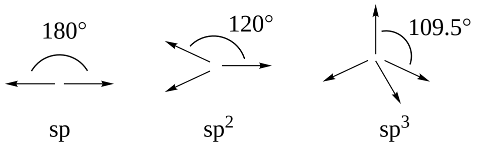


(**6**)

These adjustments rapidly increase the number of terms in the linear combination as the molecules under consideration became larger (as does the amount of time required to calculate a solution), but they all contribute toward lowering the total energy in the direction of the 'true' value.

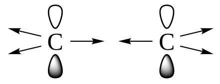
3 HYBRIDIZATION

The hybrid orbital scheme that is introduced to all student chemists was developed originally in the context of the valence bond description. Early dipole moment measurements had determined the nonlinearity of H_2O and NH_3, and the totally symmetric distribution of the C–H bonds in CH_4. It was not clear, however, how the atomic orbitals on the central atom could be responsible for the required bond angles. The tetrahedral (109.5°) geometry necessary for the nonpolar methane molecule is quite different from the 90° spacing of the lobes of the carbon 2p atomic orbitals. Pauling proposed that the bonding interactions were formed from the overlap of hybrids constructed in a hypothetical prebonding 'valence state'. The wavefunctions of the carbon 2s and 2p orbitals were combined into a linear combination of four mutually orthogonal sp^3 hybrids. Each orbital contains a mixture of 25% of each component atomic orbital (2s, $2p_x$, $2p_y$, $2p_z$), giving a total distribution of s character to p character in the ratio of 1:3. This combination of atomic functions ensures that each orbital is directed toward the corners of a tetrahedron, 109.5° apart (see (**7**)). The atomic functions can be mixed in other ratios in order to produce different angular distributions for other bonding hybrids.



(**7**)

Atomic orbitals that do not participate in the hybridization are then used for bonding with other atomic orbitals on adjacent centers as long as there is nonzero overlap of the atomic orbitals. For example, a hybridization description for the bonding in ethylene accounts for a so-called sigma (σ) framework of bonding utilizing sp^2 hybrids and a second interaction called a pi (π) interaction between pure p atomic orbitals on the carbon atoms (**8**).



(**8**)

The hybridization scheme also allows for the population of the hybrids by lone pairs. In H_2O and NH_3, nonbonding sp^3 lone pairs account for the approximately tetrahedral geometry about the central atom. A more rigorous approach rehybridizes the central atom where the correct hybridization is determined by finding the lowest energy as the character of the hybrids is varied. The N–H bond hybrids in NH_3 are more accurately described as $sp^{3.4}$, a ratio that contains more than 75% atomic p character in the hybrid, while the lone pair hybrids contain a greater percentage of s character than the tetrahedral hybrids. This process also more accurately reproduces the observed bond angles.

The valence bond hybridization description for atoms with coordination number greater than four is accomplished by the inclusion of atomic d orbitals in the linear combination of the hybrids. Six equivalent d^2sp^3 orbitals are constructed for molecules with six-coordinate 'expanded octets', for example, SF_6. This combination uses 33% atomic d character to direct the lobes of the six hybrids 90° apart in an octahedral arrangement. The use of d orbitals as a major component necessary to account for the bonding in these molecules is not required and has been discredited.[20] A detailed description of the MO treatment of hypervalent molecules will be examined later in this article. The simple valence bond picture has been extended in an approach with much wider applicability than second row main group compounds. The generalized valence bond (GVB) method (*see Valence Bond Theory*) uses Pauling's concepts as a starting point for a method that has been used to consider transition metal bond lengths, orbitals, and energies.[21]

4 MOLECULAR ORBITAL THEORY: THE $H_2{}^+$ MOLECULAR ION

Mulliken and Hund, along with important contributions from Herzberg and Lennard-Jones, developed an alternative method that does not give the localized electron pair special priority.[22–26] This approach was originally referred to as 'Hund–Mulliken' theory although the two friends never wrote a joint paper. The most significant characteristic of the method is that the electronic wavefunctions or 'molecular orbitals' (MOs) are not restricted to two nuclear centers. Thus it is viewed as a delocalized description of electronic structure because MOs are often constructed from many of the atomic centers in a molecule. It is instructive to begin with a simple system, however, in order to develop the vocabulary that is used and build the basis orbitals for larger molecules of chemical interest in the same manner that the exact one-electron hydrogen-like atomic orbitals form the basis for the orbitals in many-electron atoms. Mulliken introduced the method by looking at the simplest 'molecular' system, the hydrogen molecule ion $H_2{}^+$. The Hamiltonian for this system

in a simplified form using atomic units is:

$$\widehat{H} = -\frac{1}{2}\nabla^2 - \frac{1}{r_A} - \frac{1}{r_B} + \frac{1}{R} \quad (8)$$

where ∇^2 is the kinetic energy operator, r_A is the distance from the single electron to atom A, r_B is the distance from the single electron to atom B, and R is the nuclear–nuclear separation. Again, the Born–Oppenheimer approximation has been utilized allowing the separation of the nuclear motion from the electronic motion. In order to calculate the total energy for the molecular system, this nuclear kinetic energy term would need to be added to the electronic energy. The first three components of this operator lead to stabilization while the $1/R$ term is a repulsive term.

Mulliken proposed a different trial function than that used in the valence bond approach. In general, this function is a normalized sum of hydrogen-atom orbitals and is written in the form

$$\Psi_{MO} = c_1\phi_1 + c_2\phi_2 + K \quad \text{so that } \Psi_{MO} = \sum_i c_1\phi_1 \quad (9)$$

The procedure is called the linear combination of atomic orbitals (LCAO) approximation and can be used for molecules of any size. $H_2{}^+$ is a special case in that a wavefunction can be found that will solve the Schrödinger equation exactly, yet the MO approach will be used so that molecular orbitals can be derived. The simplest trial function for the $H_2{}^+$ system is written:

$$\Psi_{MO} = c_1 1s_A + c_2 1s_B \quad (10)$$

The $1s_A$ and $1s_B$ atomic orbitals are the building blocks (basis set) for the molecular orbitals. The wavefunction of the electron in the molecule is simply the normalized sum of the 1s atomic orbitals. In this case the function is said to be constructed from a ‘minimal’ basis set because only the atomic orbitals that contain electrons in the separated atoms are allowed to be part of the overall function. If higher energy, unfilled atomic orbitals (2s, 2p, etc.) are allowed to contribute to the LCAO description of the molecular orbital, the term ‘expanded’ basis set is used.

Both rigorous and approximate levels of theory express molecular orbitals as LCAOs, thus a short description of the AOs is commonly used. The hydrogen-like AOs that are used in the MO and VB approaches are expressed in the form

$$\Phi_{AO} = R_{n,l}(r) \cdot Y_{l,m}(\theta, \phi) \quad (11)$$

As can be seen, these orbitals are the product of a radial part R dependent on r, the distance from the electron to the nucleus, and Y, called a spherical harmonic, a function detailing the angular dependence of the atomic wavefunction. For all many-electron atoms, the radial term must be approximated because of the aforementioned problem of electron–electron repulsions.

Many theoretical methods use Slater-type orbitals (STOs) to approximate this term. STOs contain an exponential term of the form

$$\Phi(r, \theta, \phi) \propto e^{-\zeta r} \quad (12)$$

where ζ is an orbital exponent that is determined in a variational approach. The results of many calculations indicate that wavefunctions built from this form are very accurate approximations of true atomic wavefunctions. They are used quite extensively in semiempirical methods but their form is quite unwieldy for use in the complex multicenter integrals that need to be solved in rigorous theoretical methods.

Boys proposed the use of Gaussian-type orbitals (GTOs) of the form

$$\Phi(x, y, z) \propto e^{-\alpha r^2} \quad (13)$$

where α is the variational parameter.[27] The great advantage of GTOs is that they are able to be solved much more quickly than STOs in computer calculations. Unlike STOs, a single GTO does not reproduce a ‘true’ atomic orbital wavefunction with great accuracy. Investigators that use Gaussians in their basis set must use a number of GTOs that are combined to simulate the behavior of a single STO. A simple form of this basis set might be labeled ‘STO-nG’, with $n = 3, 4, \ldots$ where n is the number of Gaussian functions overlayed to mimic a single STO. These basis sets however are not very accurate for nonlinear molecules. ‘Split valence’ basis sets use sums of Gaussians to describe better less symmetric molecular environments. Multiple sets of AOs are used describe the core and valence atomic orbitals. For example, a ‘6–31G’ basis set uses a set of six Gaussians to represent the core orbitals and sets of three and one Gaussians to describe the valence functions. Another improvement involves including ‘polarization’ functions in a set of Gaussians. These functions utilize a larger angular momentum value than the electron that is being described. Thus a 2p polarization function might be added to a 1s basis set in order to depict the deformation of the orbital by the other nuclei away from what would be expected for a spherically symmetric free atom. An asterisk (*) is commonly used to refer to basis sets that use these functions so that a ‘6–31G*’ designation indicates a split valence plus polarization basis set.

Above, the equation for the total energy for a molecular system was expressed (these functions are real so the complex conjugate symbol may be dropped):

$$E = \frac{\int \Psi \widehat{H} \Psi \, d\tau}{\int \Psi^2 \, d\tau} \quad (14)$$

The numerator in this energy term can be expanded using the minimal $H_2{}^+$ basis set (**9**).

$$\Psi = c_1 1s_A + c_2 1s_B$$
$$\int \Psi \hat{H} \Psi d\tau = \int (c_1 1s_A + c_2 1s_B) \hat{H} (c_1 1s_A + c_2 1s_B) d\tau$$
$$= c_1^2 \int 1s_A \hat{H} 1s_A d\tau + c_1 c_2 \int 1s_A \hat{H} 1s_B d\tau$$
$$+ c_1 c_2 \int 1s_B \hat{H} 1s_A d\tau + c_2^2 \int 1s_B \hat{H} 1s_B d\tau$$
$$= c_1^2 H_{AA} + c_1 c_2 H_{AB} + c_1 c_2 H_{BA} + c_2^2 H_{BB}$$
where $H_{AA} = \int 1s_A \hat{H} 1s_A d\tau = H_{BB}$

(if A and B are equivalent nuclei),

$H_{AB} = \int 1s_A \hat{H} 1s_B d\tau$ and $H_{BA} = \int 1s_B \hat{H} 1s_A d\tau$

(**9**)

It is a characteristic of the Hamiltonian that $H_{AB} = H_{BA}$; therefore

$$\int \Psi \hat{H} \Psi d\tau \quad \text{becomes} \quad c_1^2 H_{AA} + 2c_1 c_2 H_{AB} + c_2 H_{BB} \qquad (15)$$

The denominator can be written in the same manner (**10**).

$$\int \Psi_2 d\tau = c_1^2 S_{AA} + 2c_1 c_2 S_{AB} + c_2^2 S_{BB}$$
where $S_{AA} = \int 1s_A 1s_A d\tau$, $S_{BB} = \int 1s_B 1s_B d\tau$,

and $S_{AB} = \int 1s_A 1s_B d\tau$

(**10**)

Now the energy E can be rewritten as a function of the variational parameters c_1 and c_2:

$$E(c_1, c_2) = \frac{c_1^2 H_{AA} + 2c_1 c_2 H_{AB} + c_2^2 H_{BB}}{c_1^2 S_{AA} + 2c_1 c_2 S_{AB} + c_2^2 S_{BB}} \qquad (16)$$

Note that the energy is a function of the coefficients of each function in the basis set.

The goal at this stage is to determine the coefficients. Mathematics provides a straightforward way for minimizing the energy by varying the coefficients, keeping in mind the tenet of the variation principle that an improvement to a wavefunction leads to a lower energy (more accurate) wavefunction. Differentiation with respect to c_1 gives

$$E(c_1^2 S_{AA} + 2c_1 c_2 S_{AB} + c_2^2 S_{BB}) = c_1^2 H_{AA} + 2c_1 c_2 H_{AB} + c_2^2 H_{BB}$$
$$E(2c_1 S_{AA} + 2c_2 S_{AB}) + \frac{dE}{dc_1}(c_1^2 S_{AA} + 2c_1 c_2 S_{AB} + c_2^2 S_{BB})$$
$$= 2c_1 H_{AA} + 2c_2 H_{AB} \qquad (17)$$

Because E is being minimized, then

$$\frac{dE}{dc_1} = 0, \text{ therefore } c_1(H_{AA} - ES_{AA}) + c_2(H_{AB} - ES_{AB}) = 0 \quad (18)$$

Similarly, differentiating with respect to c_2 gives

$$c_1(H_{AB} - ES_{AB}) + c_2(H_{BB} - ES_{BB}) = 0 \qquad (19)$$

In this case, the coefficients c_1 and c_2 for each solution are found by solving simultaneous so-called secular equations in which the factors multiplying the unknowns (c_1 and c_2) include the energy of the system E. Because our trial function has two basis functions there will be two roots for the system (hence two values of E). The set of simultaneous equations must be solved to find the roots and has a nontrivial solution only if the $N \times N$ determinant of the factors is zero (see (**11**)). Both roots of the determinant are then used to solve for the coefficients:

$$\begin{vmatrix} H_{AA} - E & H_{AB} - S_{AB} \\ H_{AB} - ES_{AB} & H_{BB} - E \end{vmatrix} = 0$$

(**11**)

$$E_+ = \frac{H_{AA} + H_{AB}}{1 + S_{AB}} \qquad E_- = \frac{H_{AA} - H_{BB}}{1 - S_{AB}}$$

(**12**)

The lower value for E is the lowest energy attainable with the trial basis set. The corresponding coefficients give the character of the most bonding orbital. It should be noted that a secular determinant must be solved whenever a linear combination of wavefunctions is optimized.

A few of the characteristics of the integrals that need to be solved in the secular determinant should be outlined. H_{AA} and H_{BB} are called coulomb integrals and are described as the energy of an electron occupying the basis orbital A or B. The resonance integral, H_{AB}, is the quantum mechanical interaction term of basis orbital A with basis orbital B. S_{AB} is the overlap integral, the quantitative measure of the volume in space where the two basis functions interact. Basis functions that have zero overlap are said to be mutually orthogonal while two functions that are exactly coincident have an overlap value equal to 1 ($S_{AA} = S_{BB} = 1$, hence the simplification in the secular determinant above). In the secular determinant for the $H_2{}^+$ system or any homonuclear diatomic system, $H_{AA} = H_{BB}$.

The two roots for the determinant give (**12**):

By substituting these into the first secular equation, it is found that for E_+, $c_1 = c_2$, and for E_-, $c_1 = -c_2$. Thus the two solutions for the Schrödinger equation can be written:

$$\Psi_+ = c_1 1s_A + c_1 1s_B \quad \text{and} \quad \Psi_- = c_1 1s_A - c_1 1s_B \qquad (20)$$

Quantum mechanics requires that the wavefunction be normalized over all space such that $\int \Psi^2 d\tau = 1$ (which is

$$\int \Psi^2 d\tau = 1 = c_1^2 \int 1s_A^2\, d\tau \pm 2c_1^2 \int 1s_A 1s_B d\tau + c_1^2 \int 1s_B^2 d\tau$$
$$= c_1^2 S_{AA} \pm 2c_1^2 S_{AB} + c_1^2 S_{BB}$$
$$= c_1^2 (2 + 2S_{AB})$$
$$\text{thus } c_1 = \pm \frac{1}{\sqrt{2+2S}} \qquad \text{where } S = S_{AB}$$

(**13**)

equivalent to stating that the probability of finding the electron in all space is equal to 1). For this system we have (**13**):

The bonding molecular orbital and the antibonding orbital are designated as:

$$\Psi_+ = \Psi_{\text{bond}} = \frac{1}{\sqrt{2+2S}}(1s_A + 1s_B) \qquad (21)$$

$$\Psi_- = \Psi_{\text{anti}} = \frac{1}{\sqrt{2-2S}}(1s_A - 1s_B) \qquad (22)$$

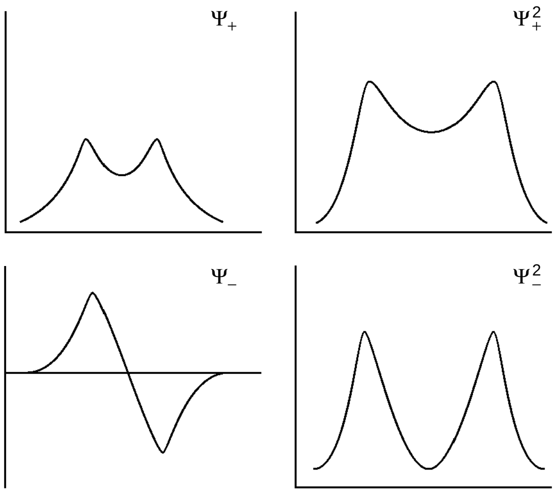


Figure 1 Value of Ψ_+, Ψ_+^2, Ψ_-, and Ψ_-^2 sketched along the internuclear axis

5 PICTORIAL REPRESENTATIONS OF ORBITALS

The combination of two atomic orbital basis functions has generated two molecular orbitals. There are a number of ways that MOs can be portrayed in a pictorial fashion to provide a connection between their functional form and their relative energies. It is easy to see why Ψ_+ is a bonding function: when the value of the function or, more importantly, the value of the function squared (the probability) is projected along the internuclear axis, a buildup of electron density is seen in the internuclear region (Figure 1). When the Ψ_- function is squared, the electron density in the internuclear region is diminished with a nodal plane of zero density bisecting the internuclear axis. An electron described by the Ψ_+ function is more stable than its energy relative to the separated nuclei, whereas an electron described by the Ψ_- function is less stable. This is illustrated in a plot of the energy of the two molecular orbitals versus interatomic distance (Figure 2). An electron occupying Ψ_+ favors a bound structure rather than the separated H$\cdots$H.

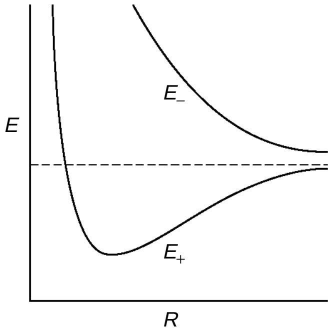

Figure 2 Plot of E_+ (bonding orbital) and E_- (antibonding orbital) as a function of internuclear distance in $H_2{}^+$

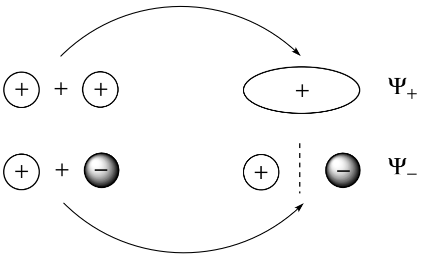
The most commonly used pictorial representation for a wavefunction is called the boundary surface and it is used to give a three-dimensional perspective of most of the electron density in an orbital. Usually these shapes are drawn so that their volume contains about 95% of the electron density in a molecular orbital. It is instructive to draw them in a process that first sketches the atomic orbitals as separated functions and then brings them together, allowing mixing to occur via the secular determinant (see (**14**)).



(**14**)

The areas of overlap suggest constructively and destructively interfering classical waves. The buildup of density in the internuclear region of the Ψ_+ orbital shows the connection of the atoms. Yet another frequently used pictorial view of a molecular orbital is as a set of contour diagrams. These are simply planar slices of the aforementioned boundary surfaces chosen to again illustrate the bonding/antibonding characteristics of a particular orbital. A plane is usually chosen so that it contains the internuclear axis (although this is not done exclusively). In larger molecules, a plane can be chosen to contain more than one nuclear center and thereby view more than one bonding/antibonding interaction within the same orbital. The sketch in Figure 3 approximates the contour plots for Ψ_+ and Ψ_-.

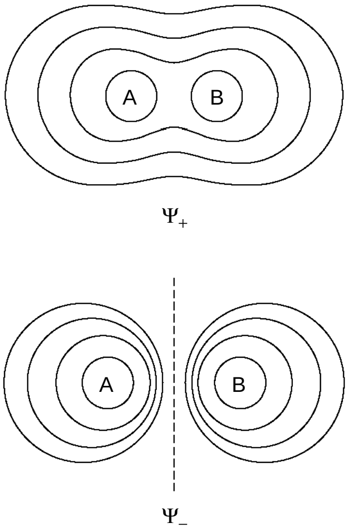


Figure 3 Contour diagrams sketched for Ψ_+ and Ψ_- for the H_2^+ molecular ion

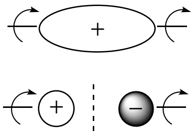
These contour diagrams illustrate the probability of finding the electron per unit volume; this quantity should be distinguished from the region in space where the electron density is greatest. In order to determine that quantity, a spatial factor needs to be included in a function analogous to the radial distribution function that is used to illustrate the highest regions of electron density in atoms. A 'circular distribution function' has been proposed and identifies a cylindrical region encircling the bond axis as the region of greatest electron density.[28]

6 MOLECULAR ORBITALS AND SYMMETRY

MO theory has developed a strong connection with mathematical group theory and the elements of symmetry. Because of the delocalized nature of the wavefunction, reference to the overall symmetry of the molecule is extremely helpful in differentiating one MO from another and provides a convenient convention for labelling. This system will eventually lead to the much more useful task of establishing a criterion for allowing MOs from separate atoms or molecules to come together in new bonding and antibonding interactions. As can be seen in the boundary surface diagrams, each of the two MOs that we have constructed is invariant to rotations about the internuclear axis. MOs with this characteristic are labelled as σ (sigma) orbitals. If the MO is antibonding with respect to the two basis functions, the label is modified using an asterisk; the antibonding overlap of two H 1s atomic functions is designated σ^* (sigma star) (see (**15**)).



(**15**)

The two energy levels associated with Ψ_σ and Ψ_{σ^*} can be used to sketch yet another pictorial representation of information derived from the secular determinant. A qualitative MO energy level diagram is sketched for the H_2^+ system in Figure 4.

H_{AA} and H_{AB} are each negative numbers while S_{AB} is positive and less than one; as a result, E_σ (formerly E_+) is lower in energy than H_{AA} and H_{BB} while E_{σ^*} (E_-) is higher in energy than the basis functions. A careful look at the denominator for each term shows that in this model the overlap term forces the antibonding orbital farther away from the basis functions energetically than the bonding orbital. Now that the atoms are within bonding distance, electrons can fill these orbitals in accord with the Pauli principle. This diagram can be used as a qualitative energy level diagram for homonuclear diatomic systems up to four electrons. Because Ψ_+ is the molecular orbital associated with the bonding interaction of the atomic orbitals, the ground state of the H_2 molecule may be described by placing two electrons in the MO with one spin up and one spin down, resulting in a molecular electron configuration, written $1\sigma^2$. The 'complete' molecular wavefunction would need to include information about spin; it is usually written as a Slater determinant in order to ensure that the Pauli principle is satisfied (α for spin up, β for spin down) (see (**16**)).

$$\Psi_{MO} = \frac{1}{\sqrt{2}}\begin{vmatrix} \psi_\sigma\alpha(1) & \psi_\sigma\beta(1) \\ \psi_\sigma\alpha(2) & \psi_\sigma\beta(2) \end{vmatrix}$$

$$\Psi_{MO} = \psi_\sigma(1)\psi_\sigma(2)\left[\frac{1}{\sqrt{2}}[\alpha(1)\beta(2) - \alpha(2)\beta(1)]\right]$$

(**16**)

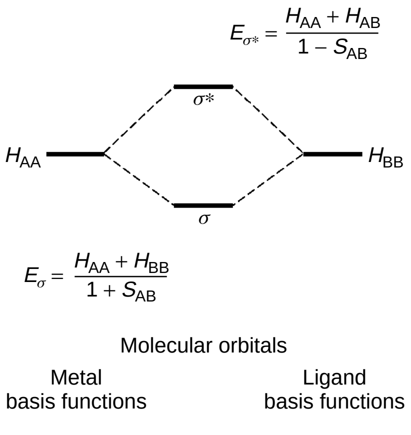


Figure 4 Molecular orbital energy level diagram for H_2^+

The spatial and spin parts can be viewed separately for our purposes, however, because the Hamiltonain that is being used yields energy values that are independent of spin. The unnormalized spatial part of the function is used frequently to avoid clutter:

$$\Psi_{MO} = \frac{1}{2(1+S)}[1s_A(1) + 1s_B(2)][1s_A(2) + 1s_B(1)] \quad (23)$$

The next two electrons are placed into the σ^* antibonding orbital using a molecular (*Aufbau Principle*). Note that the diagram suggests that this will be an unfavorable configuration because of the net instability of the whole molecule. The instability of diatomic helium He_2 can be rationalized with this diagram because two electrons are required to occupy the highly destabilizing Ψ_- energy level. Recent experimental and theoretical work has confirmed, however, that long-range Van der Waals attractions are responsible for a He_2 dimer with a internuclear separation of 55 Å, much longer than a standard chemical bond owing to the overlap of atomic orbitals.[29]

7 IMPROVEMENTS TO THE WAVEFUNCTION

The model that is outlined above is generated from a one-electron Hamiltonian and is only an approximation to the true wavefunction for a multielectron system. As suggested earlier, other components may be added as a linear combination to the wavefunction that has just been derived. There are many techniques used to alter the original trial wavefunction. One of these is frequently used to improve wavefunctions for many types of quantum mechanical systems. Typically a small amount of an excited-state wavefunction is included with the minimal basis trial function. This process is called configuration interaction (CI) because the new trial function is a combination of two molecular electron configurations. For example, in the $H_2{}^+$ system a new trial function can take the form

$$\Psi = c_1\psi_1 + c_2\psi_2 \quad \text{where} \quad \psi_1 = \psi_\sigma(1)\psi_\sigma(2) \quad \text{and} \quad \psi_2 = \psi_{\sigma^*}(1)\psi_{\sigma^*}(2) \quad (24)$$

where ψ_2 represents the functional form of the antibonding orbital populated by two electrons. (It can be shown that a singly excited state of the type $1\sigma^1 1\sigma^{*1}$ yields a value $H_{AB} = 0$). If the solution of a secular determinant and its component integrals yield a nonzero coefficient for the so-called doubly excited state, the overall energy will be lowered to a more accurate value. Therefore, the linear combination given in

$$\Psi_{CI} = c_1\psi_1 + c_2\psi_2 = c_\sigma\psi_\sigma(1)\psi_\sigma(2) + c_{\sigma*}\psi_{\sigma^*}(1)\psi_{\sigma^*}(2) \quad (25)$$

is the CI ground state. It would be incorrect to interpret this result as proposing that all H_2 molecules spend an amount of time in this doubly excited state; rather, the small addition of this particular orbital's functional form to the original trial function produces a more accurate reproduction of the true wavefunction's behavior than the first function alone.

It is instructive to examine the differences between the original function and the new one. The minimal basis, unnormalized wavefunction for H_2 can be written as (**17**).

$$\begin{aligned}\Psi_{MO} &= c^2[1s_A(1) + 1s_B(1)][1s_A(2) + 1s_B(2)]\\ &= \underbrace{c^2[1s_A(1)1s_B(2) + 1s_B(1)1s_A(2)}_{\text{covalent term}}\\ &\quad \underbrace{+\, 1s_A(1)1s_A(2) + 1s_B(1)1s_B(2)]}_{\text{ionic term}}\end{aligned}$$

(**17**)

The first two terms are exactly the wavefunction for the valence bond description while the last two terms are the type of ionic components that were described earlier. In the MO wavefunction, these ionic terms are given much more weight (50%) than in the valence bond wavefunction. This is exactly the improvement that the configuration interaction procedure makes. If the CI wavefunction described above is expanded as in (**18**)

$$\begin{aligned}\Psi_{CI} &= c_\sigma[1s_A(1)1s_A(2) + 1s_A(1)1s_B(2) + 1s_B(1)1s_A(2)\\ &\quad + 1s_B(1)1s_B(2)] + c_{\sigma*}[1s_A(1)1s_A(2) - 1s_A(1)1s_B(2)\\ &\quad - 1s_B(1)1s_A(2) + 1s_B(1)1s_B(2)]\\ \Psi_{CI} &= (c_\sigma - c_{\sigma*})[1s_A(1)1s_B(2) + 1s_B(1)1s_A(2)]\\ &\quad + (c_\sigma + c_{\sigma*})[1s_A(1)1s_A(2) + 1s_B(1)1s_B(2)]\\ \Psi_{CI} &= c_1\Psi_{valence} + c_2\Psi_{ionic}\end{aligned}$$

(**18**)

the VB description and the MO description are seen to approach each other. The wavefunctions are formally the same for this simple system. In practice, when considering larger systems, huge numbers of ionic terms in the valence approach and many excited state terms in the MO description would need to be included in order for this convergence to reappear. As time has gone on, however, the MO description with configuration interaction added has come to be the more popular method of choice. The minimal basis set of atomic 1s orbitals has provided a justification for the stability of a chemical bond; however, the use of a CI wavefunction is necessary to approach exact total energy values.

Another technique that is used is to simply increase the number of basis orbitals in the Slater determinant. This is easily done by including a larger number of the hydrogen-like atomic orbitals in the trial function. If the entire $n = 2$ set of atomic orbitals (2s, $2p_x$, $2p_y$, $2p_z$) is included in a linear combination with the 1s orbital for each atomic center, when

the atoms are brought together in a bonding interaction the trial function becomes

$$\Psi = c_1 1s_A + c_2 2s_A + c_3 2p_{x_A} + c_4 2p_{y_A} + c_5 2p_{z_A} + c_6 1s_B + c_7 2s_B + c_8 2p_{x_B} + c_9 2p_{y_B} + c_{10} 2p_{z_B} \quad (26)$$

As a result, the secular determinant for this function becomes a 10 by 10 matrix, the solution of which is not trivial; however, the value of the lowest energy term, E, gives a more accurate value which is in accord with the variational principle. The use of still larger basis sets will push the value even lower.

Yet another means of generating more accurate wavefunctions in terms of reproducing the experimental value for bond dissociation energies is to explicitly include the interelectronic distance r_{12}. A calculation that included this term as well as polarization functions and CI reproduced the H_2 experimental bond dissociation energy to seven significant figures.[30] However, beyond the problem of being too computationally intensive for molecules of larger size, this technique does not have the advantage of transferability to other molecules. Thus, in the next section our focus will be on standard MO principles using a minimal basis set.

8 HOMONUCLEAR DIATOMIC MOLECULES

The solution of the many types of coulomb, exchange, and overlap integrals in the 100-term matrix described above will be detailed below, but at this point two valuable principles will allow the neglect many of the terms and yet develop a good qualitative idea of what the resultant molecular orbitals look like as well as their relative energy ordering. The first of these principles is that atomic orbitals must have significant overlap with each other if they are going to contribute to the same molecular orbital. In the expanded basis, in addition to the s−s σ overlap that has already been illustrated, there are two other types of σ interactions: two p orbitals may overlap end-on to produce a bonding/antibonding interaction, or s and p orbitals centered on adjacent atoms may have a nonzero overlap (Figure 5).

Other types of bonding are also present. If the z-axis is the internuclear axis, the p_x and p_y atomic orbitals can have a side-to-side nonzero overlap with the p_x and p_y orbitals on the adjacent atom (Figure 6). These bonding/antibonding interactions are labelled π and π^*, respectively. In general, these side-to-side π-type overlaps are smaller than σ-type overlaps. Note that the nodal plane of the atomic functions that contains the internuclear axis is maintained in the molecular wavefunction. There is an additional nodal plane, however, bisecting the internuclear axis in the π^* molecular orbital. This is the nodal plane that identifies the antibonding character of this type of orbital. Orbitals that combine to give bonding/antibonding MOs are often said to 'have the right symmetry' to interact. An example of a pair of orbitals that do not have the right symmetry to interact (or rather, do not contribute to the same MO) is the side-on overlap of a p orbital with an s orbital (Figure 7). This interaction has a net zero overlap because any constructive bonding interaction of the s orbital with the upper lobe of the p orbital will be exactly compensated for by a negative interaction with the lower lobe of the p orbital.

The second criterion for a significant interaction in the secular determinant is that the contributing orbitals must be near in energy to each other. For example, though a $2s_A-1s_B$ overlap may be nonzero, the much lower energy of the $1s_B$

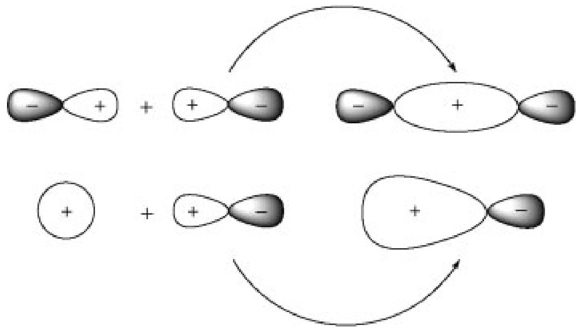

Figure 5 Boundary surface diagrams for p−p and s−p σ molecular orbitals

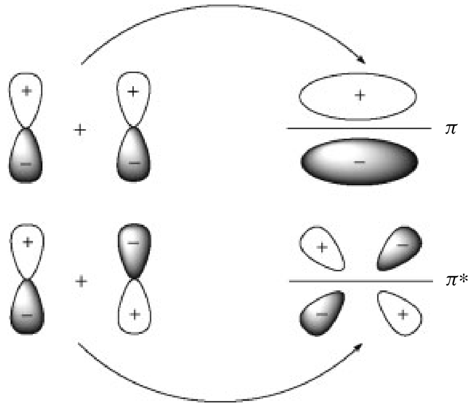

Figure 6 Boundary surface diagrams for π/π^* molecular orbitals

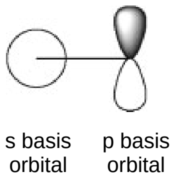

Figure 7 Boundary surfaces for nonbonding s−p interaction

orbital will cause a very small H_{AB} value and the resultant bonding orbital will be overwhelmingly 1s in character while the antibonding orbital will have almost exclusively $2s_A$ character (Figure 8). The conclusion that can be made from these criteria is that when the 10×10 matrix is solved, each MO that is constructed will contain significant character of only a few functions in the AO basis.

Even though the one-electron H_2^+ Hamiltonian has been used to derive all 10 molecular orbitals (only one of which is even half-filled in H_2^+), a MO diagram built from the expanded basis will enable us to draw quite accurate boundary surfaces and relative energy separations for all the second row homonuclear diatomics. (This has been verified by the more rigorous approaches that are detailed later.) The figures sketched in Figure 9 show the MO diagrams that result from the 10×10 secular determinant.

Tie lines are drawn between the MOs and the AOs that have the largest coefficients in each linear combination. As expected from the criteria detailed above, each set of 1s and 2s orbitals is split into σ and σ^* molecular orbitals, although the 1s functions are so stable that they are called core orbitals and make no contribution to the bonding in the molecule. However, there are two possibilities for the ordering of the p orbitals. In general, p_π overlap is poorer than the p_σ overlap between adjacent atoms; using this criterion, the p_σ bonding orbital should appear below the p_π bonding orbitals; likewise the p_{σ^*} orbital will appear above the $p_{\pi*}$ as seen in Figure 9(a). This model for ordering assumes that the 2s atomic basis orbitals are too far removed in energy to mix significantly with the 2p functions. It turns out that this model is accurate for highly electronegative atoms such as oxygen and fluorine, where the 2s orbitals are particularly stable because of their higher penetration into the highly stable regions close to the nucleus. When the 2s and 2p atomic functions are closer in energy, for those atoms of average or low electronegativity, the interaction term H_{AB} and overlap terms S_{AB} allow mixing of 2s and 2p basis functions to the same molecular orbital as shown in Figure 9(b). This effect

Figure 8 Molecular orbital energy level diagram for 2s–1s. There is virtually no interaction

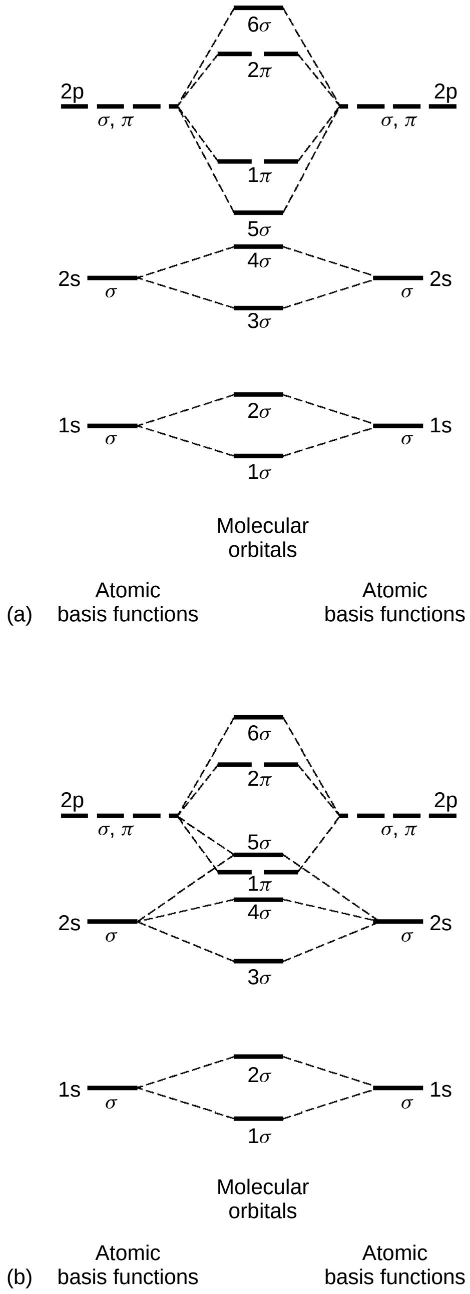

Figure 9 Molecular orbital energy level diagram for homonuclear diatomics: (a) without s–p mixing, (b) with s–p mixing

is called s–p mixing and leads to a small stabilization of the $2s_{\sigma^*}$ MO and a destabilization of the $2p_\sigma$ molecular orbital. Because of this mixing, the orbitals are no longer pure s or p, thus labelings such as $2s_\sigma$ or $2p_\pi$ are no longer allowed. Each MO is identified as simply σ- or π-type with each of these sets numbered with integers from the lowest energy to the highest energy.

Now that the orbitals are arranged with respect to energy, a molecular electron configuration may be predicted. Electrons

fill lower energy orbitals first, two electrons at a time. If the level is doubly degenerate, the electrons are placed in separate orbitals first. The bond order (B.O.) of a molecule is an accounting of the number of electrons that contribute to bonding minus the number of electrons that destabilize the molecule by filling antibonding levels. In a mathematical form:

$$\text{B.O.} = \frac{(\text{\# of bonding electrons} - \text{\# of antibonding electrons})}{2}$$

Extensive mixing between many basis orbitals can make this assignment difficult and of limited predictive value, but for diatomic molecules bond order correlates well with experimentally determined bond lengths and strengths. In Table 1, higher bond order values are associated with large dissociation energies and short bond lengths.

Working across the first row of the periodic table, the Li_2 molecule has a total of six electrons and a $1\sigma^2 2\sigma^2 3\sigma^2$ configuration, giving four electrons in bonding MOs and two electrons in antibonding MOs for a bond order of one. Be_2 has two additional electrons that must occupy the $4\sigma^2$ orbital, giving a bond order of zero and the prediction that the species is unstable. Spectroscopic investigations indicate that B_2 has two unpaired electrons (a triplet state) whereas C_2 has no unpaired electrons (a singlet). This fits nicely with the strong mixing model for low electronegativity atoms that places the 3σ level above the 1π. In molecular nitrogen, N_2, a bond order of three is calculated. This accounts for the largest homonuclear diatomic dissociation energy and the shortest bond length of the second-row diatomics.

There is still significant 2s–2p mixing in N_2, as is evidenced by the results from photoelectron spectroscopy (PES). In a procedure that revisits the classic photoelectric effect, UV radiation irradiates the sample of interest, and a detector measures the kinetic energy of the electron that is ejected from the molecule. The kinetic energy of the electron is the difference between the energy of the original photon and the energy required to ionize that particular electron. The peaks in Figure 10 correspond to the energy ordering of the orbitals

Table 1 Bond orders of second-row homonuclear diatomic molecules with bond lengths and energies

Molecule	Bond order	Bond length (pm)	Bond energy (kJ mol^{-1})
H_2	1	74.2	458
He_2	0	–	–
Li_2	1	267.2	105
Be_2	0	–	–
B_2	1	159	289
C_2	2	134	630
N_2	3	109.8	941
O_2	2	120.7	494
F_2	1	141.8	153
Ne_2	0	–	–

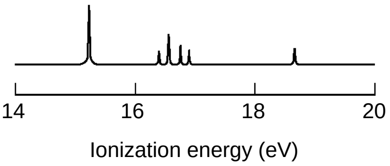

Figure 10 Sketch of photoelectron spectra (PES) of N_2

in the MO diagram. Use of higher energy radiation identifies the ionization energy of nitrogen 1s orbitals as approx 400 eV. This verifies the earlier prediction of the high stability of the 1s atomic orbitals and the assumption that they are too localized to take part in bonding for the second-row diatomics. PES thus demonstrates that MO theory provides an accurate description of electronic structure.

For oxygen, O_2, each of the 2π levels is occupied by a single electron with their spins matched in accord with Hund's rules. The bond order is now reduced to two, with an accompanying increase in bond length and decrease in bond strength. The two unpaired, parallel spin electrons account for the paramagnetic behavior of molecular oxygen, as evidenced by its attraction to a magnetic field. The prediction of the paramagnetic behavior of oxygen was one of MO theory's chief accomplishments and a motivation for its acceptance as a distinct improvement over the valence bond method.

The 2π antibonding level is filled in F_2, yielding a bond order of one. Finally, the complete occupation of the molecular orbitals with 20 electrons in the Ne_2 dimer is overall destabilizing; this element, like the rest of the noble gases, prefers to exist in the form of isolated atoms.

9 HETERONUCLEAR DIATOMICS

Similar qualitative MO diagrams for heteronuclear diatomic molecules identify some new bonding combinations and rationalize physical characteristics and chemical reactivity of these species. The key difference in the character of the MOs that result from the secular determinant is that much more mixing of multiple AOs occurs. This is a result of the differing electronegativities of the atoms. Comparable AOs, for example, the 1s on atom A and the 1s on atom B, may not have any interaction at all due to the high electronegativity of atom B. The MO diagram for HF is shown in Figure 11.

The fluorine 1s orbital is several eV more stable than the F 2s. It has essentially no interaction at all with the H 1s orbital. Of the 10 electrons in the system, the first two are in this low-energy core orbital. The next two electrons are placed in the 2σ orbital that includes some of the H basis function and therefore has a slight degree of bonding character. This bond is considered to be highly polarized toward fluorine because of its high F 2s character. The 3σ orbital has more

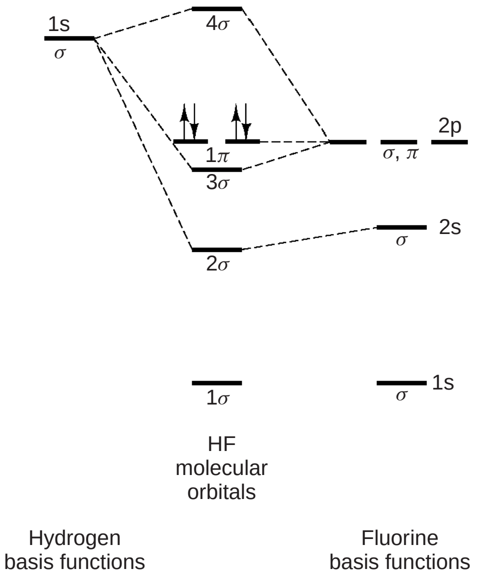

Figure 11 Molecular orbital energy level diagram for HF

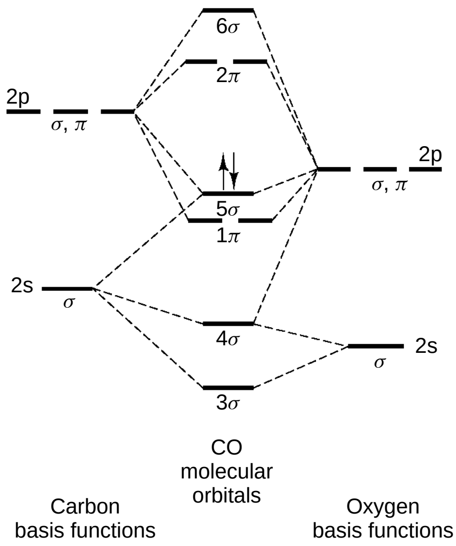

Figure 12 Molecular orbital energy level diagram for CO

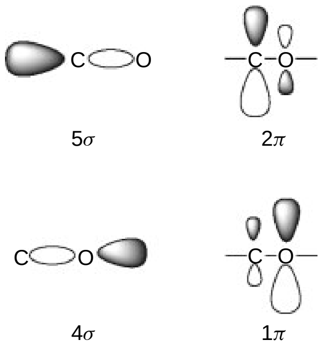

Figure 13 Sketch of boundary surfaces for CO valence orbitals

F 2p character than F 2s character and is also bonding with respect to the H orbital. This set of orbitals (2σ, 3σ) illustrates a central feature of the MO approach. Whereas a simple Lewis structure or valence picture would draw a localized electron pair interaction between two orbitals, the MO picture attributes some bonding character to two separate molecular orbitals. This simple MO diagram illustrates the difficulty of determining a meaningful definition for bond order in a polyatomic molecule. No single MO completely represents the bonding between two atoms.

The F 2p_x and F 2p_y atomic orbitals (a doubly degenerate set) are each filled with two electrons and come across as unperturbed 'molecular orbitals' in a π symmetry set. This type of orbital is said to be nonbonding as its entire character (electron density) remains on the fluorine center.

The heavy weighting of the MO coefficients toward the F atom is observed experimentally in dipole moment measurements. For HF, the value is 1.91 D toward the fluorine atom. Finally, the unoccupied 4σ orbital is predominantly H 1s in character and is populated in excited states of the molecule where the measured dipole is much less.

The MO sketched in Figure 12 is that for the ubiquitous inorganic ligand, carbon monoxide, CO. The chief difference between this diagram and that for the homonuclear diatomic molecules encountered above is that the oxygen atomic basis orbitals are significantly lower in energy than their carbon counterparts. There are 14 electrons in the molecule, making CO isoelectronic with N_2. The σ and π labeling system is still applicable and identifies the atomic functions that are allowed to combine using symmetry criteria (Figure 13). The molecular electronic configuration is $1\sigma^2 2\sigma^2 3\sigma^2 4\sigma^2 1\pi^4 5\sigma^2$ (the 1σ and 2σ levels are essentially core O 1s and C 1s orbitals, respectively, and are not shown in the diagram). The 3σ orbital shows fairly good bonding overlap, has mostly C 2s and O 2s character and is polarized heavily toward oxygen. The 4σ orbital has large amounts of 2p_z mixed in with the 2s for each atom and can best be described as weakly bonding but primarily a lone pair on the oxygen atom. The doubly degenerate 1π levels are π-type bonding levels again polarized toward the more electronegative oxygen atom. The highest occupied molecular orbital (HOMO) is essentially nonbonding and is mostly comprised of the C 2s and C 2p_z basis functions. It can be viewed as essentially a lone pair on the carbon atom. Coincidentally, this accounting of three bonding orbitals, one lone pair centered on carbon, and one lone pair on oxygen, coincides with the Lewis dot structure.

It is the 5σ 'lone pair' that enables the molecule to act as a Lewis base and donate electron density to an acceptor orbital of the appropriate energy and symmetry on another atom or molecular fragment. Later in this article the donation of electron density from the 5σ orbital to transition metal d orbitals will be discussed. The distribution of the polarization

of the filled MOs (some toward carbon, some toward oxygen) is responsible for the small measured dipole of CO (0.1 D toward the oxygen atom).

10 THE SELF-CONSISTENT FIELD APPROACH

Until this point, the consideration of electron–electron repulsion terms has been neglected in the molecular Hamiltonian. Of course, an accurate molecular Hamiltonian must account for these forces, even though an explicit term of this type renders exact solution of the Schrödinger equation impossible. The way around this obstacle is the same Hartree–Fock technique that is used for the solution of the Schrödinger equation in many-electron atoms. A Hamiltonian is constructed in which an 'effective' potential of the other electrons substitutes for a true electron–electron repulsion term. The new operator is called the Fock operator, $\widehat{F}$. The orbital approximation is still used so that $\widehat{F}$ can be separated into i (the total number of electrons) 'one-electron' operators, $\widehat{F}_i$ (**19**).

$$\hat{F}(1, 2, 3, K, i)\,\Psi\,(1, 2, 3, K, i) = E\,\Psi\,(1, 2, 3, K, i)$$

$$\hat{F} = \sum_i \hat{F}_i$$

$$\hat{F}_i = -\frac{1}{2}\nabla_i^2 - \sum_{\mathrm{A}} \frac{Z_{\mathrm{A}}}{r_{i\mathrm{A}}} + \sum_j^{n/2} (2J_{ij} - K_{ij})$$

$$\text{where } J_{ij} = \int \psi_i(1)\psi_i(2)\frac{1}{r_{i2}}\psi_j(1)\psi_j(2)\mathrm{d}\tau$$

$$\text{and } K_{ij} = \int \psi_i(1)\psi_j(2)\frac{1}{r_{i2}}\psi_j(1)\psi_i(2)\mathrm{d}\tau$$

(**19**)

The Fock operator determines three sets of information for each electron i: (1) the kinetic energy term of the electron ($-1/2\nabla^2$), (2) an attraction term with each nucleus, A, ($-\Sigma Z_{\mathrm{A}}/r_{i\mathrm{A}}$), and (3) the interaction of the electron with all the other electrons in the molecule. This average force is treated by the $(2J_{ij} - K_{ij})$ term and can be described as the potential felt by a single electron in the 'field' of the other $i - 1$ electrons in the molecule. A few words about the components of this last term in the Fock operator are in order. J is called the coulomb operator and is identified as the classical repulsion between electrons. The exchange integral K is due to the quantum mechanical effect of spin correlation, an intrinsic property of the electron that keeps apart electrons of the same spin. This operator has a stabilizing effect on the energy of the system.

The matrix elements in the secular determinant now rapidly increase in complexity because a single H_{AB} value (now F_{ij}) can be composed of hundreds or thousands of coulomb and exchange integrals for even a modest organic molecule using a minimal basis set. In addition, a new difficulty arises in the actual solution of the integrals because the new 'average potential' operators are dependent on the wavefunctions (hence, the electron density) of the other $n - 1$ electrons. The procedure to solve the quandary is the Hartree–Fock–Roothaan (HFR) self-consistent field (SCF) method. An initial guess is given for the wavefunctions, usually a linear combination of all the basis Slater or Gaussian orbitals, which is used to build the Fock operator which then operates on all of the original wavefunctions to give new molecular orbitals. These MOs are utilized in a 'new' Fock operator which is used to calculate better molecular orbitals. In practice, the variational parameters are the coefficients of the STOs or GTOs and their orbital exponents. They are varied in order to find an energy minimum as prescribed by the variational principle. When this iterative process reaches a point at which the new MOs differ little from their input MOs within some selected tolerance, the calculation is said to be converged.

The so-called 'Hartree–Fock limit' is the energy that is approached in the limit of an infinite number of basis functions using the Fock operator form above. A true 'full' Hartree–Fock calculation would not expand the wavefunctions into a LCAO basis set and therefore would need to be solved numerically in order to achieve the exact Hartree–Fock limit. This limit is not the true upper limit to the energy of the exact Hamiltonian that the variational principle aims for because of the approximation that uses the average potential field. This gap in energy is referred to as the 'correlation energy' and can be treated in a number of ways. The typical way is to expand the basis set even further using excited states (the CI technique applied to molecular orbitals). The size of the molecules that can be treated by calculational approaches that use these large expanded basis sets (usually with Gaussian functions) is ever increasing with the advent of easily accessible computational capacity and speed.

As a group, these calculations are called (*Ab Initio Calculations*) (roughly translated: from the beginning) because all interaction integrals are explicitly calculated and no experimental data are used to adjust F_{ij} or S_{ij} values. These rigorous approaches can achieve remarkable accuracy in the calculation of bond lengths and angles for organic and inorganic molecules. Explicit treatment of the correlation energy problem is required in order to assure quantitative precision in orbital or total energy calculations. These techniques will be summarized later in this section; however, some important steps in the development of current electronic structure methods were the advancements put forth by many inorganic chemists in the later part of the 20th century. Several excellent sources detail the procedures used in ab initio calculations, the history of their development as well as the accuracy of computation versus experiment.[31–38]

For many years however, the chief problem in the application of ab initio methods to many problems of interest

for the inorganic chemist was that many chemical systems were simply intractable using these rigorous means owing to the sheer number of integrals that need to be solved. Many 'semiempirical' theories have been developed in order to shorten the process and yet derive valuable and accurate information. Occasionally, adjustments are made in the form of the operators to simplify the calculations. Other approaches set criteria for neglecting some terms in the now massive secular determinants, while still others do both. For example, when a coulomb integral of the type written earlier is expanded in the LCAO approximation, integrals of this type result:

$$\iint \phi_A(1)\phi_B(1)\frac{1}{r_{12}}\phi_C(2)\phi_D(2)\mathrm{d}\tau_1\mathrm{d}\tau_2 \qquad (27)$$

The most difficult of these to calculate are the multiple center integrals that contain atomic orbitals of as many as four atomic centers (in the case when A, B, C, and D are atomic orbitals on different nuclei). Since these centers may be quite distant from each other in the molecule, most of the terms of this type are quite small. The zero differential overlap (ZDO), complete neglect of differential overlap(CNDO), moderate neglect of differential overlap (MNDO), intermediate neglect of differential overlap (INDO), and partial retention of diatomic differential overlap (PRDDO) approaches differ in the types of integrals that are ignored.[39–41] An INDO approach labelled INDO/1 or ZINDO has found wide utility with particular success in answering structural and spectroscopic questions in transition metal systems. Of note, a relationship between second order nonlinear optical characteristics and electronic structure in organometallic chromaphores has been examined.[42–44] Certain types of 'differential overlap' within the coulomb and exchange integrals are set to zero where the differential overlap of electron (1) is defined as $\phi_A(1)\phi_B(1)\,\mathrm{d}\tau_1$. This procedure is not the same as setting the overlap integrals, S_{AB}, within a secular determinant equal to zero, an approximation which will be covered below.

An alternative SCF approach frequently used to study orbital interactions in inorganic and organometallic systems is the method of Fenske, Hall, and coworkers.[45,46] A simplified Fock operator is used to eliminate the need for calculating the more difficult multicenter integrals. Coulomb and exchange terms are estimated using the point-charge and Mulliken approximations.[47] The explicit use of CI is eliminated by using Slater's average of configurations.[48] Studies using approximate methods should be approached with some caution; in assessing the justification by any calculational approach of the use of the total energy in a structure or reactivity argument, it should be noted that any procedure that changes the Hartree–Fock Hamiltonian, whether by eliminating terms or approximating them, eliminates the applicability of the variational principle in choosing one structure or mechanism versus another.

Yet another way of treating electron correlation is found in the density functional theory (DFT) of Hohenberg, Kohn, and Sham.[49–53] Though it is not strictly a version of molecular orbital theory, this approach has been hugely influential in inorganic chemistry especially in its highly precise geometry optimizations and in its accurate description of the thermochemistry of reactions principally in the calculation of absolute activation energies. Simply, DFT focuses on the electron density in the molecule, $\rho(\mathrm{r})$, rather than a many electron wavefunction. It is based on the idea that the total energy of the molecule is conveyed as a 'functional' of $\rho(\mathrm{r})$, that is, a function of the electron density that of course is dependent on the coordinates of the electrons as are molecular orbitals. Other marked similarities among the wavefunction-based methods and DFT is that some of the same orbitals are used as building blocks and that SCF methodologies are used that require the solution of closely related Fock matrices. A chief difference is found in the DFT version of the exchange term K_{ij} in the Fock operator. The 'exchange correlation energy' term in DFT does not have an exact expression but is approximated in a variety of ways. Most versions of DFT use a 'gradient correction' term that is a sum of local and exchange terms weighted to fit the properties of well-known molecules. Unfortunately, there is no systematic way to improve the functionals to achieve an arbitrary level of accuracy like those seen in ab initio methods that are bond by the variational principle. Still, a crucial advantage for DFT methods is that they provide highly accurate results at a cost significantly less than computationally intensive perturbation theory methods.

11 THE HÜCKEL AND EXTENDED HÜCKEL METHODS

By far, the theoretical approaches that experimental inorganic chemists are most familiar with and in fact use to solve questions quickly and qualitatively are the simple Hückel method and Hoffmann's extended Hückel theory.[54–56] These approaches are used in concert with the application of symmetry principles in the building of symmetry adapted linear combinations (SALCs) or group orbitals. The ab initio and other SCF procedures outlined above produce MOs that are treated by group theory as well, but that type of rigor is not usually necessary to achieve good qualitative pictures of the character and relative orderings of the molecular orbitals.

Hückel's treatment of delocalized electrons in conjugated organic systems was introduced just as MO theory was being developed. Many approximations are made and the first of these is to separate the σ framework of bonding away from the π framework orbitals. Electrons occupying the σ bonds are in localized two-electron bonds that the hybrid description would label as sp^2–$sp^2\sigma$ bonds. The π electrons are not perturbed by the σ framework because their energies are too far apart and of the wrong symmetry to interact. Thus only the out of plane $2p_z$ orbitals are used as basis functions for the wavefunctions of these electrons. The allyl system is a good

first example (Figure 14 and equation 28):

$$\Psi_\pi = c_1\phi_1 + c_2\phi_2 + c_3\phi_3 \quad (28)$$

where ϕ_1, ϕ_2, and ϕ_3 are carbon $2p_z$ orbitals. This system yields the secular determinant given in (**20**):

$$\begin{vmatrix} H_{11}-ES_{11} & H_{21}-ES_{21} & H_{31}-ES_{31} \\ H_{12}-ES_{12} & H_{22}-ES_{22} & H_{32}-ES_{32} \\ H_{13}-ES_{13} & H_{23}-ES_{23} & H_{33}-ES_{33} \end{vmatrix} = 0$$

(**20**)

The appeal of the Hückel approach is that no integrals need to be solved. If we make the assumptions that (a) the diagonal terms $H_{11} = H_{22} = H_{33} = \alpha$ are equal, (b) the off-diagonal H_{ij} values for adjacent atoms (all carbon) are set to a single value, β, while nonadjacent H_{ij} values are set to zero, and (c) the overlap is simplified such that $S_{ii} = 1$ and $S_{ij} = 0$, the secular equation becomes much less complex. The 3×3 determinant is written as in (**21**):

$$\begin{vmatrix} \alpha - E & \beta & 0 \\ \beta & \alpha - E & \beta \\ 0 & \beta & \alpha - E \end{vmatrix} = 0$$

(**21**)

To solve the determinant the matrix must be expanded so that three roots give three energies for the system, that is, N AOs give N MOs (**22**):

$$\alpha - E \begin{vmatrix} \alpha - E & \beta \\ \beta & \alpha - E \end{vmatrix} - \beta \begin{vmatrix} \beta & \beta \\ 0 & \alpha - E \end{vmatrix} = 0$$

$$(\alpha - E)^3 - (\alpha - E)\,\beta^2 - (\alpha - E)\beta^2 = 0$$

let $x = \alpha - E$

$$x^3 - 2\beta^2 x = 0$$

$$x(x^2 - 2\beta^2) = 0$$

$$\text{gives} \quad x = 0, \pm\sqrt{2}\beta$$

(**22**)

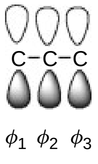

Figure 14 Basis set orbitals for the allyl system in Hückel calculations

Substituting the energies into the secular equations and then solving the equations to get the wavefunctions (and accounting for normalization) gives (**23**):

$$\alpha - E = 0, \pm\sqrt{2}\beta$$

$$\text{thus } E = \alpha, \alpha \pm \sqrt{2}\beta$$

(**23**)

Qualitative drawings of the orbitals are sketched with the relative coefficients represented by the size of the basis orbital in the overall molecular orbital (Figure 15). The α value is set to a relative zero of energy while the β values are derived from experimental data. For our purposes, this value is around 75 kJ mol^{-1}.

Even this very approximate procedure uncovers the inherent stability of a delocalized system that is not obvious in this single example. The solution of the 2×2 determinant for a system of two p_z orbitals, such as the p system in ethylene, yields two MOs with energy values of $\alpha + \beta$ (bonding) and $\alpha - \beta$ (antibonding). This means that the energy for two electrons in the allyl system $(2\alpha + 2\sqrt{2}\beta)$ is more stable than two electrons in the ethylene π system. Thus, the

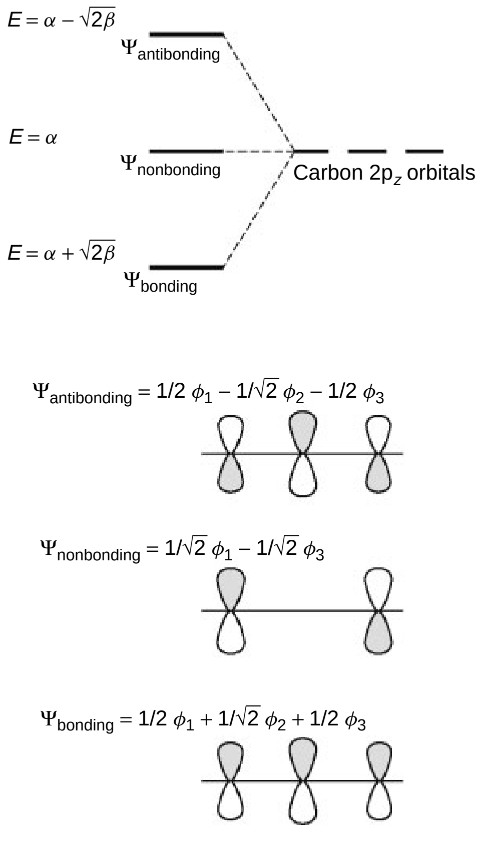

Figure 15 Hückel π-system energy level diagram, energies, and wavefunctions for the allyl system

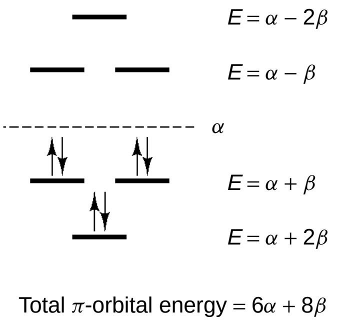

Figure 16 Hückel π-system energy level diagram and energies for C_6H_6

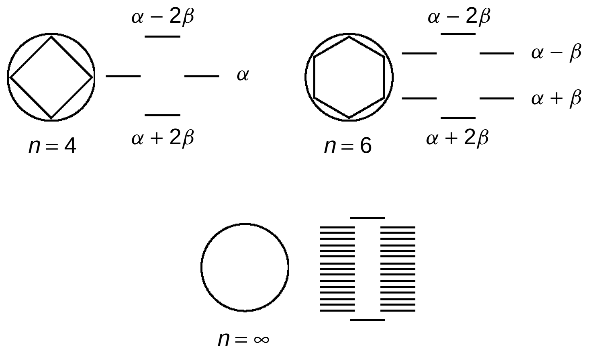

Figure 17 Hückel π-system energy level diagram progression, $n = 4, n = 6, n = \infty$

delocalization energy for two electrons in the allyl system is 0.828β.

In benzene, solution of the 6×6 secular determinant using the same procedure gives the energies shown in Figure 16. Each carbon atom supplies one electron to the energy level diagram, giving a π electron energy for benzene of $6\alpha + 8\beta$. If delocalization is ignored and the system is treated as three isolated double bonds, the Hückel approximations give a p electron energy of $6\alpha + 6\beta$. The delocalization energy is 2β. Unfortunately, α and β values differ from system to system which restricts the method's predictive value.

An interesting general result is derived using the Hückel model for a ring system of N p orbitals. For a ring of N atoms, the orbital energies using the Hückel approximations fit the algebraic formula

$$E_j = \alpha + 2\beta \cos\left(\frac{2j\pi}{N}\right) \tag{29}$$

where j runs from 0, $\pm1, \pm2\ldots$ to $\pm N/2$ (N even) or $\pm$ $(N-1)/2$ (N odd). The relative spacings of the orbitals can be reproduced by inscribing an N-fold regular polygon in a circle of radius 2β with a point at the bottom of the circle (Figure 17). The lowest lying MO is thus always singly degenerate and accommodates two electrons. The remaining orbitals occur in doubly degenerate pairs and may be filled with four electrons.

Using this approach, if this approximation is extended to the infinite limit of n basis orbitals, the resultant energy level diagram would be a tightly packed 'band' of doubly degenerate MOs that are delocalized around the whole ring (except for the lowest bonding orbital and half the highest antibonding orbitals). Bands of orbitals are tightly packed groups of delocalized 'molecular' orbitals and may be empty, filled, or partially filled depending on the number of electrons contributed by the basis set orbitals. The number of nodes increases going from lower energy to higher energy. This process of making bands is the first stage in the MO treatment of solids.[57–59]

Though clearly useful for many applications in organic chemistry, the simple Hückel theory has little utility in inorganic chemistry. Hoffmann's extended Hückel theory is able to treat s, p, and d basis sets while evaluating all overlaps. Slater-type basis functions are used in a LCAO expansion of the molecular orbitals but as in the Hückel approach the integrals in the Hamiltonian are not explicitly evaluated. The H_{AA} terms, the basis orbital energies, are estimated using spectral data and are called valence state ionization potentials (VSIPs). The off-diagonal terms are determined using a modified version of the Wolfsberg–Helmholtz formula:

$$1.75\left(\frac{H_{AA} + H_{AB}}{2}\right) S_{AB} \tag{30}$$

where S_{AB} is the calculated orbital overlap.

Whenever overlaps are explicitly calculated, atomic charges can be assigned in a straightforward manner. For a particular orbital interaction, $\Psi_1 = c_1\phi_1 + c_2\phi_2$, the total electron density in that molecular orbital is as shown in (**24**).

$$\int \Psi_1^2 d\tau = c_1^2 \int \phi_1^2 d\tau + 2c_1c_2 \int \phi_1\phi_2 d\tau + c_2^2 \int \phi_2^2 d\tau$$
$$= c_1^2 + 2c_1c_2 + c_2^2$$
$$\text{if } \phi_1 \text{ and } \phi_2 \text{ are normalized and } S_{12} = \int \phi_1\phi_2 d\tau$$

(**24**)

The popular Mulliken population analysis assigns the electron density of the MO that 'belongs' to A as the coefficient of that atomic orbital on center A squared plus half the 'overlap population':

$$\text{density on center A} = c_A^2 + c_{12}S_{12} \tag{31}$$

The even splitting of the overlap is arbitrary and works reasonably for covalent bonds. However, it is a

poor approximation in more polar interactions and many theorists have proposed alternative ways of calculating distributions of density (although none nearly as simply). Extended Hückel theory has been quite useful for predicting the ground-state conformations of transition metal systems.[60,61]

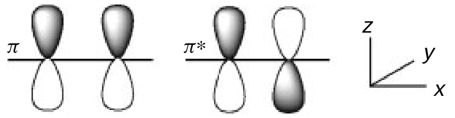

Figure 18 π/π^* orbitals in a homonuclear diatomic molecule. Both orbitals are unchanged upon operation by the σ (*xz*) reflection plane; π is antisymmetric upon operation by an inversion center, π^* is symmetric upon operation by an inversion center

12 GROUP THEORY AND MOLECULAR ORBITAL THEORY

Until this point only a limited connection to the relationship between 'symmetry' and molecular orbitals has been established. Symmetry concepts provide a good tool for building energy level diagrams and drawing the shapes of orbitals.[62–64] In order to extend the process of drawing qualitative MO diagrams and using them to predict some physical observables for molecules larger than diatomics, a more thorough consideration of symmetry must be undertaken. We have used the terms sigma and pi to label orbitals that are symmetric (σ) or antisymmetric (π) with respect to a 180° rotation about the internuclear axis. As might be expected, more complex molecules may contain other symmetry elements. For example, rotations other than 180°, reflections through planes, inversions through a center of symmetry, or mixtures of these enable quite precise labeling of MOs with respect to their behavior when operated on by a symmetry element. The framework for the classification of MOs by symmetry is called group theory. Detailed proofs for all the techniques illustrated here can be found in other sources.[65]

There are five general types of symmetry elements that are used to classify objects. The first is the identity element, E, in which nothing at all is done. All objects are unchanged under operation by the identity element; however, this element contains important information and is necessary for decomposing large basis sets into smaller units of interacting orbitals. Rotations about an axis are labelled C_n where the degree of rotation is $360°/n$. A C_2 axis is a 180° rotation (exactly that used for the σ, π designations in diatomics). A 120° rotation is done about a C_3 axis, while a 90° rotation is coupled with a C_4 axis. Reflections (σ) are associated with planes that act as mirrors exchanging one side of the plane with the other. Atoms that are contained in the planes are unchanged. Inversions (i) exchange the positions of two points through a point, the inversion center. Improper rotation axes (S_n) combine an n-fold rotation followed by a reflection through a plane perpendicular to the rotation axis.

All objects can be categorized by the list of symmetry elements that they contain. The complete list of symmetry elements for a given molecule identifies its point group classification. The use of the term 'point' refers to the fact that all the planes, axes, and inversion points intersect through a single point that may or may not be the location of an atom in a molecule. This classification is distinguished from that used for crystallographic space groups of repeating unit cells in two or three dimensions. There are approximately 47 chemically important point groups. Some have very little symmetry; the C_s point group contains the identity element and a mirror plane. Others have much more, that is, the tetrahedral group T_d has a total of 24 separate elements: the identity element, eight different C_3 axes, three C_2 axes, six S_4 axes, and six σ planes. The identification of a molecule as belonging to one particular point group or another does have chemical utility. For example, a molecule is nonpolar if its list of symmetry elements contains a mirror plane or rotation axis perpendicular to the principal axis. Also, a molecule is chiral if no improper rotation axis is present.

Most chemists are interested, however, in the connection between the symmetry operations and the classification and construction of molecular orbitals. A first step to this end is that within a point group designation there can be different responses to the individual symmetry elements. A π bonding orbital in N_2 (point group $D_{\infty h}$) changes sign upon operation of i while the π^* antibonding orbital remains unchanged (Figure 18). Each of these orbitals, however, is unchanged upon reflection in a plane that bisects the orbitals lengthwise (*xz* plane).

The entire list of information that details all the responses to all the symmetry elements in a point group for a basis set of atomic or molecular orbitals is called a reducible representation. Reducible representations, however, are not useful in determining the criteria for deciding which orbitals will participate in bonding/antibonding interactions. These representations must be factored (reduced) into smaller groups. It can be shown with a little effort that a total wavefunction for a molecule, and in turn the set of all the molecular orbitals for a molecule in a certain point group, can be expressed as a simple sum of irreducible representations. There are a only a limited number of irreducible representations for each point group.

12.1 H_2O

A detailed description of each irreducible representation is found in a character table. The table for the C_{2v} point group (that for H_2O) is shown in Figure 19. It shows that there are only four symmetry elements in this point group ($E, C_2, \sigma_v(xz)$, and $\sigma_v(yz)$), each a member of a different

C_{2v}	E	C_2	$\sigma_v(xz)$	$\sigma'_v(yz)$	
A_1	1	1	1	1	z
A_2	1	1	−1	−1	
B_1	1	−1	1	1	x
B_2	1	−1	−1	−1	y

Figure 19 Character table for C_{2v} point group

class. (By convention, the planar water molecule is found in the *xz* plane.) Occasionally, a point group will contain multiple numbers of the same symmetry element. In ammonia, there are three mirror planes that are grouped in the same class because their effect on a basis set (representation) is the same regardless of which particular symmetry element is used. In the C_{2v} point group, there are four irreducible representations, with the names A_1, A_2, B_1, and B_2. The letters A and B are used for singly degenerate representations (one-dimension) while E and T (not used in the C_{2v} point group) are used for doubly and triply degenerate representations, respectively. The full names (including subscripts) have precise definitions; however, for most purposes they simply serve the same function as the σ and π labels did for the diatomic MOs.

The numbers in the table, the characters, detail the effect of the symmetry operation at the top of the column on each representation labelled at the front of the row. The mirror plane that contains the H_2O molecule, σ (*xz*), leaves an orbital of b_1 symmetry unchanged while a C_2 operation on the same basis changes the sign of the wavefunction (orbital representations are always written in the lower case). An orbital is said to span an irreducible representation when its response upon operation by each symmetry element reproduces the same characters in the row for that irreducible representation. For atoms that fall on the central 'point' of the point group, the character table lists the atomic orbital subscripts (e.g. x, y, z as p_x, p_y, p_z) at the end of the row of the irreducible representation that the orbital spans. A central s orbital always spans the totally symmetric representation (all characters = 1). For the central oxygen atom in H_2O, the 2s orbital spans a_1 and the $2p_x$, $2p_y$, and $2p_z$ span the b_1, b_2, and a_1 representations, respectively (see (**25**)). If two or more atoms are symmetry equivalent such as the H atoms in H_2O, the orbitals must be combined to form symmetry adapted linear combinations (SALCs) before mixing with functions from other atoms. A handy mathematical tool, the projection operator, derives the functions that form the SALCs for the hydrogen atoms.

(**25**)

After all the basis orbitals have been labelled by their symmetry behavior, a qualitative molecular orbital diagram may be drawn (Figure 20).

Three orbitals of a_1 symmetry interact in H_2O (a fourth, the O 1s is so low in energy that it is not able to interact and is unperturbed in the diagram). The $2a_1$, largely O 2s in character, has a slight stabilization owing to the combination with the higher energy a_1 orbitals but is essentially nonbonding. The $3a_1$ MO contains a mixture of the O 2s and $2p_z$ as well as the H a_1 SALC. It shows moderate bonding character with a significant amount of electron density pointing away from the bonding region. The $4a_1$ is an antibonding mixture of the entire a_1 basis set. The O $2p_x$ and the H b_2 SALC form a strongly interacting bonding/antibonding set. The O $2p_x$ is the highest occupied molecular orbital (HOMO) in H_2O; it spans the b_1 basis and has no other orbitals to interact with so retains its full atomic character as a nonbonding lone pair.

The Lewis structure idea of equivalent lone electron pairs in water is at odds with the MO diagram. The $2a_1$ and $1b_1$ MOs can be identified as lone pairs but are not equivalent with respect to energy or atomic character and are quite unlike the 'rabbit ear' lone pairs drawn using the VSEPR approach. Though these conclusions are made from qualitative MO diagrams based on symmetry principles and work quite well, it must be noted that quantitative values for the energies and atomic coefficients for the MOs must be generated from a secular determinant using one of the approximation methods detailed above.

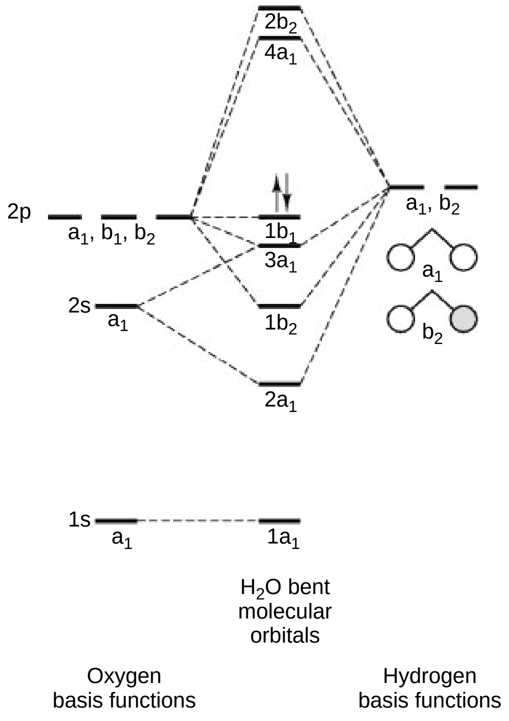

Figure 20 Molecular orbital energy level diagram of bent H_2O

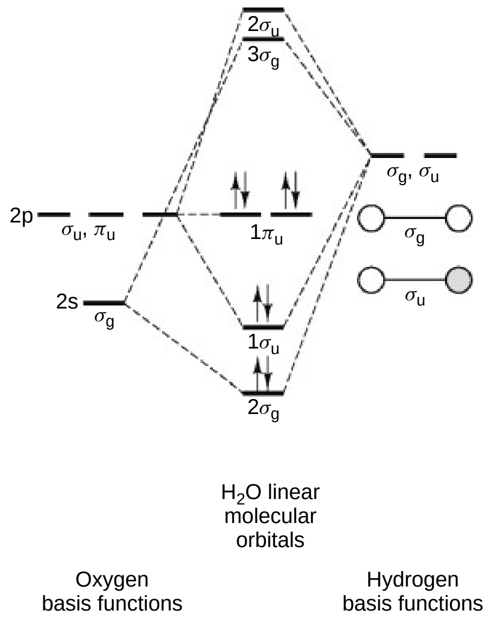

Figure 21 Molecular orbital energy level diagram of linear H_2O

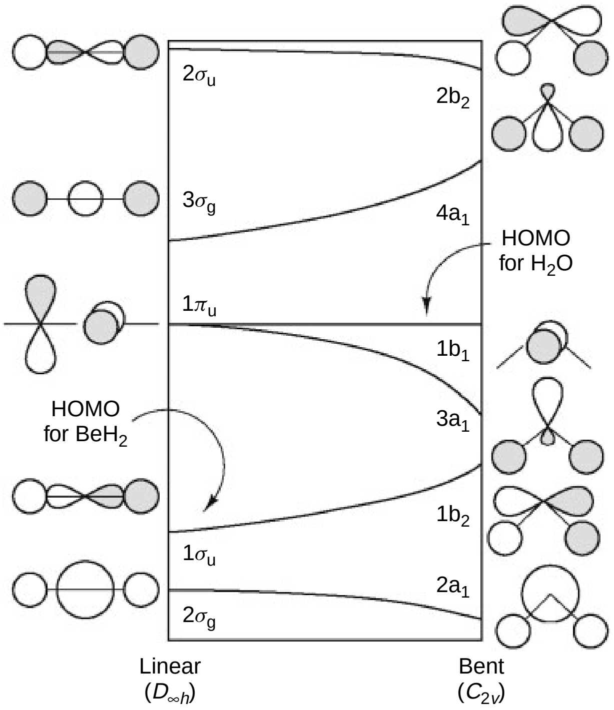

Figure 22 Walsh diagram for AH_2 system

In order to illustrate a powerful predictive application of this qualitative MO approach, it is instructive to generate the energy diagram for the water molecule in a linear geometry. The point group symmetry for the linear arrangement ($D_{\infty h}$) results in changes for the labelling of the same basis orbitals that were used in the bent geometry (Figure 21).

The identical H 1s SALCs are labelled σ_u and σ_g. The O 2s now spans σ_g while the O 2p set spans σ_u ($2p_x$) and a degenerate π_u set ($2p_y$ and $2p_z$). The σ_u and σ_g sets form bonding/antibonding MOs as shown, but there are now two nonbonding p orbitals that cannot interact with orbitals of appropriate symmetry. Using the aufbau method for H_2O (10 electrons total), this linear arrangement is less stable than a bent geometry because the O $2p_z$ orbital is not allowed to take part in any stabilizing interactions with the hydrogen orbitals whereas it makes a contribution to the $3a_1$ bonding orbital in the bent structure. Even though the bonding character of this orbital is not particularly strong, the stabilization does control the geometry in H_2O.

Some of the information contained in each MO diagram can be reexpressed in a comparative pictorial form called a Walsh correlation diagram (Figure 22).[21] The MOs and their relative energy spacings for the linear form are reproduced on the left side of the diagram, while the MOs for the C_{2v} bent geometry are reproduced on the right. Lines are drawn between the MOs that 'correlate' in the two point group designations. The $2\sigma_g$–$2a_1$, $1\sigma_u$–$1b_2$, and $2\sigma_u$–$2b_2$ connections are straightforward, but the $1\pi_u$ orbitals of the linear molecule lose their degeneracy upon a bending distortion. The O $2p_y$ orbital is unaffected (as it is out of the plane of the molecule) and becomes the unperturbed $1b_1$ MO in the bent geometry, but the O $2p_z$ is of a_1 symmetry and can mix with orbitals of like symmetry (the former $2\sigma_g$ in the linear arrangement) to acquire some bonding character, thus stabilizing the orbital. This same correlation diagram can be used to predict the geometries of AH_2 molecules with other electron counts as well. BeH_2 places only four electrons in the valence orbitals, filling the bottom two orbitals in the diagram. The relative stability of the $1\sigma_u$ MO in the linear arrangement, when compared to the $1b_2$ MO in the bent geometry, rationalizes the linear structure observed for BeH_2.

12.2 AH_3

The Walsh diagram for AH_3 systems is shown in Figure 23. BH_3 has six valence electrons and has a planar geometry. This preference is driven by the population of the degenerate 1e' set of MOs, which have better overlap in the planar geometry as illustrated. NH_3, on the other hand, has eight valence electrons to place in valence MOs and prefers the pyramidal C_{3v} geometry because of the very high stability of the $3a_1$ orbital in that arrangement. As for any qualitative interaction diagram, a calculation must be carried out to determine quantitatively preferences in geometries and actual bond angles.

12.3 CH_4

A symmetry analysis of the basis orbitals for methane (T_d point group) identifies the representations for the central

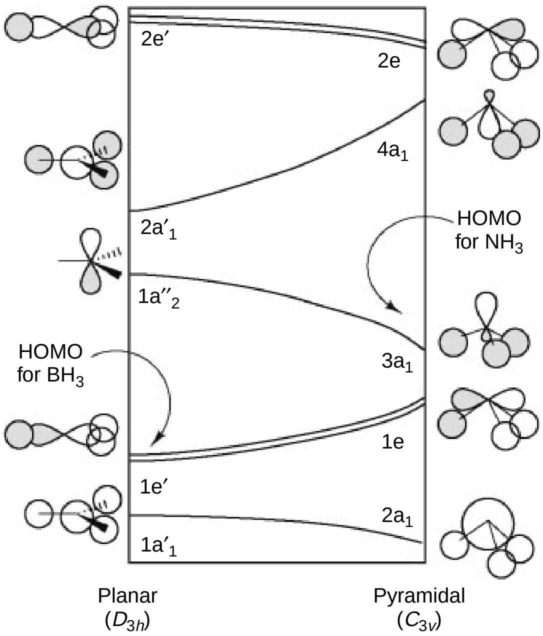

Figure 23 Walsh diagram for AH_3 system

carbon basis orbitals as C 2s (a_1) and C 2p (t_2). The four symmetry equivalent H 1s orbitals are reexpressed as a_1 and t_2 SALCs. The a_1 H combination interacts strongly with the C 2s orbital and a triply degenerate t_2 set forms bonding/antibonding combinations with the C 2p orbitals (Figure 24).

The MO diagram shows that the eight valence electrons in methane all occupy orbitals with bonding character, two in the a_1 orbital and a total of six in the t_2 set. Because the carbon basis orbitals and the SALCs for the hydrogen basis set are so close in energy, these bonding interactions are particularly strong. An interesting outcome of the MO description is that

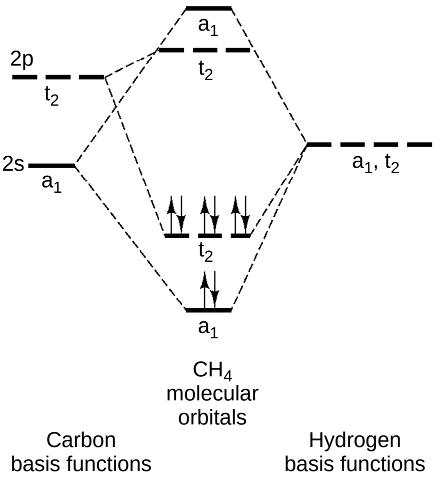

Figure 24 Molecular orbital energy level diagram for CH_4

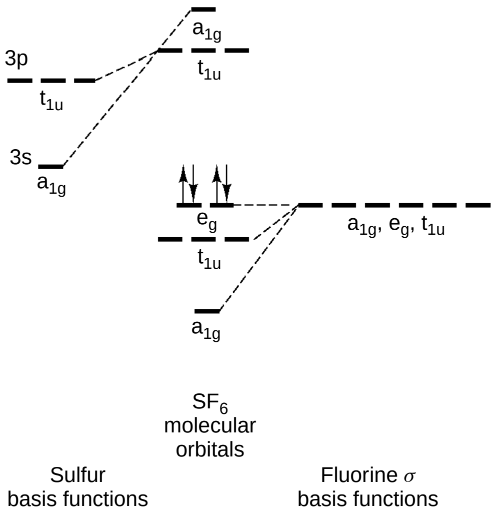

Figure 25 Molecular orbital energy level diagram for 'hypervalent' SF_6

although the four bonds have equivalent lengths and strengths there are two types of bonding electrons, each with different ionization energies. Photoelectron spectroscopy verifies that the t_2 set has an ionization potential of 15 eV while the a_1 electrons require 23 eV to be ejected. The spectrum also displays a roughly 3:1 intensity of the peaks, consistent with the predicted populations.

12.4 SF_6

As a last example of bonding in a main group system, let us revisit the SF_6 'hypervalent' molecule. A symmetry analysis of the atomic orbitals in this system indicates that a minimal basis set of the 3s and 3p orbitals on sulfur and one σ-type donor SALC from each fluorine atom is sufficient to account for the stability of this molecule (Figure 25). The other SALCs on fluorine do not contribute to the bonding and are omitted from the figure.

The 10 atomic orbitals in the basis set yield a set of 10 molecular orbitals. There are 12 valence electrons available (six from S, one each from the F SALCs) that are assigned to the available orbitals giving a molecular electron configuration of $a_{1u}^2 t_{1u}^6 e_g^4$. The delocalized character of the MO allows for the construction of six 'bonds' from only eight 'bonding' electrons. Sulfur atomic d orbitals are not necessary to account for the stability of the molecule; however, rigorous calculations with an expanded basis set do indicate that a slight population ($\approx$0.25 electrons total) of the d orbitals does lower the calculated energy.

12.5 Transition Metal Systems

The group theory analysis of molecular orbitals holds an important historical role in the understanding of absorption

spectra of transition metal complexes. In principle, rigorous calculations should be able to provide accurate energies for the filled and unfilled molecular orbitals; however, the basis sets that are required to perform an ab initio SCF determination of orbital energies were simply beyond the capabilities of the computer technology in the 1950s and 1960s. This difficulty was the primary motivation behind the development of the many approximate methods (many by inorganic chemists), reviewed earlier in this article.

A symmetry analysis is usually performed to identify the orbitals that interact, then secular determinants are solved to generate energies and coefficients. Octahedral coordination complexes of the type ML_6, (M = transition metal, L = ligand) are representative of the systems that are treated in this way. The metal is typically a d^6–d^8 transition metal (Cr, Fe, etc.) while the ligands fall into three categories: (1) σ-donor ligands, such as NH_3 or H_2O, that have a lone pair that donates electron density to the metal center using σ-type overlap; (2) π-donor ligands that have filled orbitals with local π symmetry with respect to the M–L axis as well as low-energy σ orbitals; the halide ions (F^-, Cl^-, Br^-, I^-) are typical of this category of ligand; (3) π acceptors like CO that have low-lying π^* orbitals that can accept electron density from d orbitals of appropriate symmetry. Figure 26 illustrates the energy level diagram for π donors and Figure 27 illustrates the levels for π acceptors with a first row transition metal (a MO diagram for a σ donor can be easily generated by eliminating the π basis functions from one of the other diagrams). The most important transition

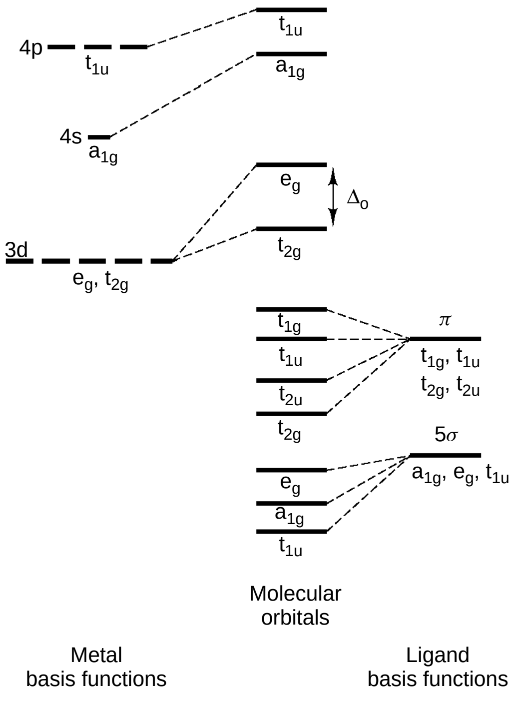

Figure 26 Molecular orbital energy level diagram for first-row transition metal with π-donor type ligand

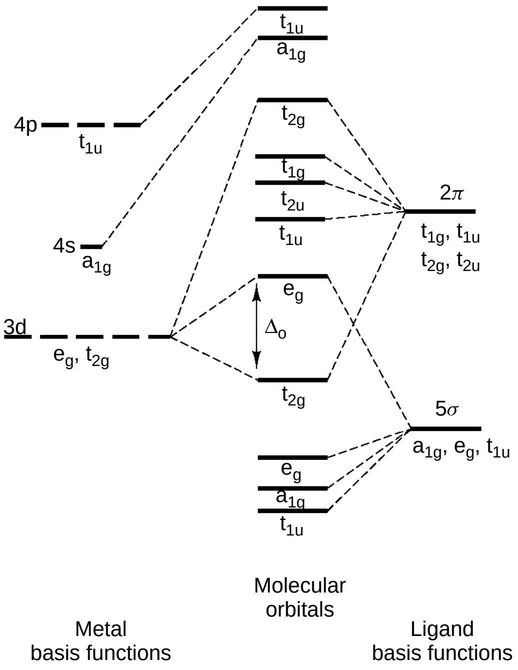

Figure 27 Molecular orbital energy level diagram for first-row transition metal with π-acceptor type ligand

in the visible absorption spectra for these complexes is labelled with Δ_0 in each of the diagrams.

π-Donor ligands (the halides) have completely filled valence orbitals that interact with all of the atomic orbitals on the metal. The ligand SALCs are generally lower in energy than the important d levels; as a result, the majority of the character of the bonding interactions (t_{2g}, e_g) lies on the ligands. The antibonding interactions are principally of metal d character and are of course destabilized relative to the d basis orbitals. An important distinction among the ligands can be made when comparing the σ-only ligands (NH_3, H_2O) to the π-donor ligands. The triply degenerate t_{2g} set of metal d orbitals will be unperturbed by σ-donors. Thus the Δ_o gap is generally smaller for π donors than for σ donors. If the gap is small enough, electrons may preferentially singly occupy the e_g levels rather than expend the energy necessary to pair in the same t_{2g} orbital, giving up to as many as five unpaired electrons in a single molecule. Ligands of this type are called high spin.

In π-acceptor ligands, low-energy basis orbitals again destabilize the metal e_g set, but now the t_{2g} set is stabilized by the accessible π^* ligand basis orbitals. This opens up the Δ_o gap, resulting in relatively larger transition energies. Ligands with this character are called low-spin because the electrons will pair in the t_{2g} levels before entering the e_g set. This variation in Δ_o is assembled in the (*Spectrochemical Series*), which is generalized: π donor $<$ σ donor $<$ π acceptor.

As mention earlier in this article, recent progress in computational chemistry has had a tremendous impact on

our understanding of the theoretical underpinnings of larger chemical systems of interest. Several important recent reviews have detailed the application of ab initio MO and DFT methods to the reactions of main group and transition metals.[28] The field of theoretical chemistry has now reached a fully mature stage in theory and application. Chemists are now able to use electronic structure calculations as a reliable, practical tool for the study of the structure and function of important molecular units and provide important evidence for the rational design of new chemical systems.[66–68]

1 INTRODUCTION

Molybdenum compounds play a significant role in industrial catalysis, in particular, in alkene metathesis, ammoxidation, epoxidation, hydrodesulfurization, hydroformylation, and in chemical and photooxidation processes.[1,2] Molybdenum is also an essential trace element encountered in a wide variety of enzymes. These enzymes are responsible for the growth and health of organisms, and the cyclic of nitrogen, sulfur, and carbon in the bio−geo-spheres.[3–5]

During the last decade of the twentieth century, the inorganic and coordination chemistry of molybdenum has expanded substantially. Among the major developments in this period have been (1) the introduction of a versatile range of polydentate ligands, including the tripodal tris(amido), triamidoamine, and tris(pyrazolyl)borato species which have enabled the stabilization of novel species and chemistry; (2) continuing development of the chemistry and catalytic applications of a range of complexes containing oxo and imido ligands (*see*, e.g. ***Oxidation Catalysis by Transition Metal Complexes***; ***Hydrodesulfurization & Hydrodenitrogenation***), (3) increased activity and substantial sophistication in the chemical modeling of molybdo-enzymes structure, function, and spectroscopy (*see*, e.g. ***Molybdenum: MPT-containing Enzymes***), (4) a substantial growth of interest in the electro-optical and nonlinear optical behavior of molybdenum compounds, and (5) the development and rationalization of major areas of cluster chemistry, including the assembly of mesoscopic polyoxoanions and rational construction of chalcogenide-containing clusters.

Molybdenum coordination has recently been comprehensively reviewed in *Comprehensive Coordination Chemistry*, particularly in the areas of mononuclear complexes,[6] polyoxometallate synthesis, structure, and reactivity[7,8] (*see also* ***Polyoxometalates***), and in chalcogen-containing cluster complexes.[9]

2 HALIDE AND CYANIDE COMPLEXES

Most synthetic routes to Mo^{III} complexes utilized *mer*-$[MoX_3(solvent)_3]$ species, the general preparations of these species having been reviewed.[6] A complex containing a cyano-Mo^{III} complex, $[Mn^{II}L]_6[Mo^{III}(CN)_7][Mo^{IV}(CN)_8]_2\cdot 19.5\ H_2O$ (L = N_5-donor ligand) has been described.

Reduction of $K[MoF_6]$ with KI in anhydrous HF afforded the molybdenum(IV) salt $K_2[MoF_6]$, while reduction of $[MoOCl_3]$ or $MoCl_5$ with TlCl at 350 °C afforded $Tl_2[MoCl_6]^{2-}$. The salts $[ECl_3]_2[MoCl_6]$ were also prepared in reactions of $MoCl_4$ with ECl_4 (E = Se, Te). All the hexahalide Mo^{IV} anions had octahedral geometries. Complete loss of ether from $[MoCl_4(OEt_2)_2]$ afforded amorphous $MoCl_4$ and this adduct was an important and versatile precursor for most halo-molybdenum(IV) chemistry.

Liquid $[MoF_6]$ is a powerful oxidising agent and its reduction with KBr in anhydrous HF or I_2 in acetonitrile afforded molybdenum(V) salts of $[MoF_6]^-$. Molybdenum pentachloride in the gas phase was shown to be monomeric and has C_{4v} symmetry, but is unstable with respect to $[MoCl_6]^-$.

Salts of molybdenum(VI) fluoride, $[MoF_7]^-$ were prepared by reaction of $[MoF_6]$ with F^- under appropriate conditions. These anions have capped octahedral structures in agreement with theoretical predictions. Radiotracer experiments using

^{18}F established that there is rapid and complete intermolecular fluoride exchange between $[MoF_7]^-$ and $[MoF_6]$.

3 COMPLEXES WITH O-DONOR ATOMS

3.1 Molybdates and Oxomolybdenum Complexes

Dioxo-Mo^{IV} complexes are very rare and almost invariably adopt trans-octahedral structures. Examples include matrix-isolated *trans*-$[MoO_2(CO)_4]$, *trans*-$[MoO_2(CN)_4]^{4-}$, and *trans*-$[MoO_2(dppe)_2]$.

Careful crystallographic and spectroscopic studies have shown that the 'green' bond-stretch isomer of *cis,mer*-$[MoOCl_2(PMe_2Ph)_3]$ is in fact a binary mixture of blue *cis,mer*-$[MoOCl_2(PMe_2Ph)_3]$ and yellow *mer*-$[MoCl_3(PMe_2Ph)_3]$, and this area has been thoroughly reviewed.[10–12] The separation of conformational isomers of *cis,mer*-$[MoOBr_2(PMe_2Ph)_3]$ has been achieved.

The complicated and difficult reactions of ethanol with $MoCl_5$ have been unravelled, the products being found to depend on stoichiometry and temperature. Unstable monomers containing the molybdenyl Mo^{3+} core were detected, for example, $H[MoOCl_4]\cdot 2EtOH$ and $[MoOCl_3(HOEt)]$, which have square-pyramidal structures with an apical oxo group. In the absence of other ligands, these species eliminated HCl, ultimately forming $[(Mo_2O_2Cl_4)\mu\text{-}(OEt)_2\mu\text{-}(HOEt)]$. Addition of ethene, CO, or $OPPh_3$ (L) to $[MoOCl_3(HOEt)]$ afforded $[MoOCl_3L(HOEt)]$ which also eliminated HCl, giving dinuclear species.

Dinuclear fragments, linear polymers, and clusters were found in solid-state materials such as $KMoOCl_4$, $E_2[MoOCl_4]_2$, $[ECl_3][MoOCl_4]$ (E = Se or Te), and $[Te_{15}X_4][MoOX_4]_2$ (X = Cl, Br).

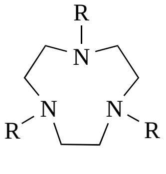
Complexes of the type $[MoOX_4L]^-$ were generated by ligand association or displacement reactions affording numerous salts, where X = halide and L = H_2O, THF, DMF, or NCMe. Ligand exchange at molybdenum centers also afforded a general route to the species $[MoOCl_3L_2]$, which usually adopted a mer structure.

The tetrahedral molybdate(VI) ion, $[MoO_4]^{2-}$ is stable and inert under basic conditions but was readily protonated on acidification.[13] The first protonation afforded $[HMoO_4]^-$, and the second resulted in an increase in coordination number, giving $[MoO_3(OH_2)_3]$, $[MoO_2(OH)_2(OH_2)_2]$, or $[Mo(OH)_6]$. Subsequent protonation produced $[MoO_2(OH)(OH_2)_3]^+$ and $[MoO_2(OH_2)_4]^{2+}$, these last species being observed only at very low Mo concentrations ($<10^{-4}$ M). At higher concentrations, condensation leads to polyoxomolybdate formation (see Section 7.2). The existence of six-coordinate dioxo-Mo^{VI} species has been supported by EXAFS studies and by the isolation of $[MoO_2X_2(OH_2)_2]$ (X = Cl, Br).

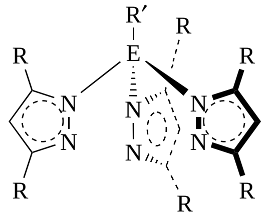
The intensely yellow/red tetrahedral thiomolybdates, $[MoO_xS_{4-x}]^{2-}$ ($x = 0$–3) were formed by the reaction of $[MoO_4]^{2-}$ with H_2S or sulfiding reagents in basic solutions. These salts are interesting because of their roles in Cu–Mo antagonism in ruminants, and their potential as treatments for Wilson's disease. Several alkylammonium salts of $[MoS_4]^{2-}$ have been reported, which has facilitated the study of the nonaqueous chemistry of this dianion.

Reaction of the hydroxylamido complexes $[MoO_2(ONR_2)_2]$ (R = Et, Bz) with $B(C_6F_5)_3$ gave the pseudo-octahedral species $[MoO\{OB(C_6F_5)_3\}(ONR_2)_2]$.

The colorless $[MoO_3(R_3tacn)]$ was obtained from MoO_3 and R_3tacn (**1**) in hot water or by oxidative decarbonylation of *fac*-$[Mo(CO)_3(R_3tacn)]$ using HNO_3 or H_2O_2/THF. The crystal structure determinations of several of these species as solvates confirmed their octahedral geometries.[1] In aqueous protic media, $[MoO_3(R_3tacn)]$ (R = H, Me) underwent quasi-reversible reduction ($2e^-$, $4H^+$) to $[Mo(O)(OH_2)_2(R_3tacn)]^{2+}$, which underwent further reduction affording di- and trinuclear species. A variety of related trioxo species have been reported, for example, $[MoO_3(Bu^t_3tch)]$ and $[MoO_3L]^-$, L = Tp^-, Tp^*, Tm^*, (**2**); tpa (**3**). A number of these complexes crystallized as aqua solvates and exhibited extensive networks of H-bonding.



(**1**)

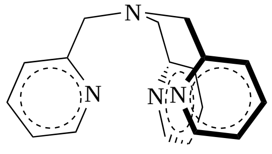


(**2**)

Tp^-, E = H, R′ = R = H

Tp^{*-}, E = H, R′ = H, R = Me

Tpm^{*-}, E = H, R = Me

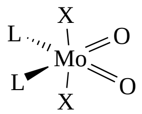


(**3**)

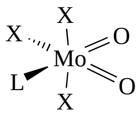
Many dioxo complexes of Mo^{VI} are used in oxidation catalysis as enzymes, and in metal oxide surface modes as sensors and drugs. These have been prepared by ligand addition, exchange, and/or metathesis using *cis*-$[MoO_2]^{2+}$ precursors such as $[MoO_2X_2]$, $MoO_2X_2L_2$ (X = halide; L = H_2O, DMSO, $OPPh_3$, etc.), or $[MoO_2(acac)_2]$. The oxo groups were invariably cis and usually had four- or six-coordination. The four-coordinate species $[MoO_2X_2]$ are tetrahedral and X is almost always a π-donor ligand, for example, $[MoO_2S_2]^{2-}$. Five-coordination in dioxomolybdenum(VI) chemistry is rare but examples included trigonal

bipyramidal $[MoO_2(OSiPh_3)_2(PPh_3)]$ and square-pyramidal $[MoO_2(bdt)X]$ (bdt = benzene-1,2-dithiolate; X = $OSiPh_3$, $SC_6H_2Pr^i$-2,4,6).

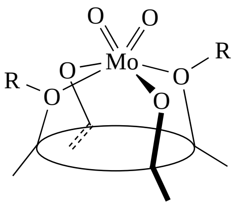
The majority of dioxo-Mo^{IV} complexes have distorted octahedral geometries, with the weakest π-donor ligands (L) being trans to the oxo ligands, whereas stronger π-donor ligands (X) are mutually trans and cis to the oxo groups, for example, *cis,trans,cis*-(**4**). Exceptions included $[MoO_2Cl_2(tmeda)]$ and $[MoO_2Cl_2(Me_4cyclam)]$ where steric demands of the N-ligands enforced the electronically unfavorable cis,cis,cis geometry (**5**).



(**4**)



(**5**)



(**6**)

3.2 Alkoxide, Aryloxide, and Catecholate Complexes

3.2.1 Alkoxide Complexes

Distorted octahedral species $[Mo(OCH_2CH_2O)_3]$ and $[Mo(OC_2Me_4O)_3]$ were formed in the reactions of nitrido-Mo^{VI} complexes with 1,2-ethanediol and 2,3-dimethyl-2,3-butanedione in basic media. Reaction of $[MoO(OEt)_4]$ with $MeOCH_2CH_2OH$ afforded liquid $[MoO(OCH_2CH_2OMe)_4]$ which solidified on standing to afford the distorted octahedral complex of the same formula.

Reaction of Ag_2MoO_4 with Ph_3SiCl afforded tetrahedral $[MoO_2(OSiPh_3)_2]$ which reacted with PPh_3 to give the trigonal bipyramidal $[MoO_2(OSiPh_3)_2(PPh_3)]$. Six-coordinate species of the type $[MoO_2(OSiPh_3)_2(N–N)]$ (N–N = phen, Me_4phen, 4,4′-Me_2bipy, 5,5′-bipy) were also reported. Both $[MoO_2(OSiPh_3)_2]$ and $[MoO_2(OC_6H_3Bu^t_2\text{-}2,6)_2]\cdot 2HOC_6H_3Bu^t_2$-2,6, obtained by reaction of $[MoO_2Cl_2]$ with $LiOC_6H_3Bu^t_2$-2,6 were stabilized by significant π-donation from the OR^- ligands. Octahedral $[Mo(OTeF_5)_6]$ has been synthesized and its structure determined crystallographically.

3.2.2 Aryloxide Complexes

Paramagnetic *trans*-$[Mo^{IV}(OPh)_4(PMe_3)_2]$ was obtained from reaction of $[Mo(PMe_3)_6]$ with an excess of phenol in benzene. Red–purple-$[Mo^{IV}Cl_2\{O_2(OR)_2^{Bu}cal\}]$ was formed in the reactions of $[MoOCl_4]$ with 1,3-dialkyl-*p*-*t*-butylcalix[4]arenes in hexane. A generalized structure for calixarenes is shown in Figure 1.

Only one dioxomolybdenum(VI) monocalixarene complex, (**6**) (R = Me) has been reported. The dioxomolybdenum(VI) bis-calixarene complexes $[Mo(O_4^{Bu}cal)\{O_2(OH)_2^{Bu}cal\}]$ and $[Mo_2(O_4^{Bu}cal)_2]^{2-}$ were formed in the reactions of $[MoCl_4L_2]$ (L = OEt_2, SEt_2) with $(HO)_4^{Bu}cal$ and NEt_3 in toluene. The octahedral geometry of $[Mo(O_4^{Bu}cal)\{O_2(OH)_2^{Bu}cal\}]$ was defined by alkoxide O-donor atoms from tetradentate $O_4^{Bu}cal$ and bidentate $[1,2\text{-}O_2(OH)_2^{Bu}cal]^{2-}$. This complex reacted with HCl to give *cis*-$[MoCl_2(O_4^{Bu}cal)]$. Oxo-calixarene complexes are of interest as models of heterogeneous metal oxide catalyst surfaces, centers that may be capable of supporting organometallic transformation, and as building blocks for supramolecular species.

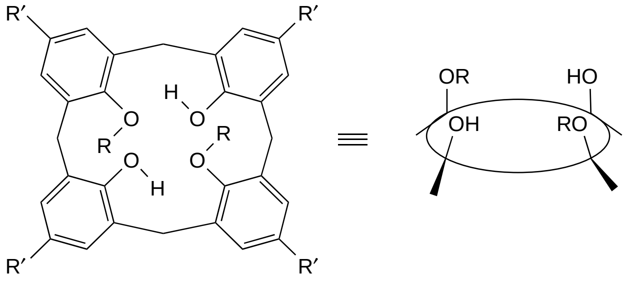


Figure 1 Calixarene ligands

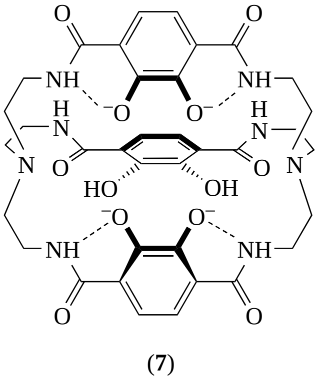
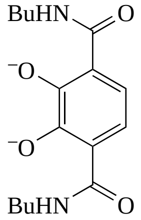
3.2.3 Catecholate Complexes

Reaction of $[MoOCl_3(dme)]$ with 9,10-phenanthrenequinone (O–O) afforded the quinone-stabilized Mo^V species $[MoOCl_3(O–O)]$. Related semiquinone, $[Mo^VCl_4(O–O^-)]$ and Mo^{VI} complexes containing arenediolato ligands have also been prepared.

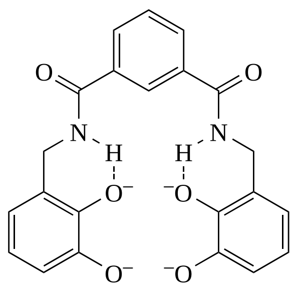
A range of siderophore-like complexes containing dioxomolybdenum(VI), including $[MoO_2(btrencam)]^{2-}$, $[MoO_2(bta)_2]^{2-}$, and $[MoO_2(bdax)]^{2-}$ have been prepared, (btrencam, (**7**); bta, (**8**); bdax, (**9**)). The *cis*-MoO_2^{2+} group in $[MoO_2(btrencam)]^{2-}$ was accommodated outside the macrobicyclic cavity by two catecholate units H-bonded to adjacent amido NH groups, while the third catecholate group was protonated and directed away from the octahedral Mo^{VI} center.



(**7**)



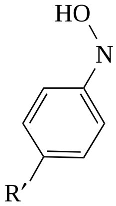
(**8**)



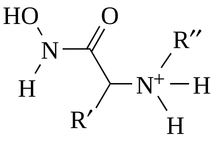
(**9**)

Molybdate binds to the aminochelin siderophore of *Azotobacter vinelandii*, and quenches the fluorescence of attached Ru(bipy)-chromophores, this affording a sensitive probe for the oxoanion.

Hydroxamic acids and their amino acid derivatives formed a series of dioxomolybdenum(VI) complexes of the type *cis*-$[MoO_2(hdx)_2]$ and $[MoO_2(hdxamc)_2]$ (hdxH, (**10**); hdxamcH, (**11**)), which are attractive as models for siderophores and for the development of metal-chelating drugs.



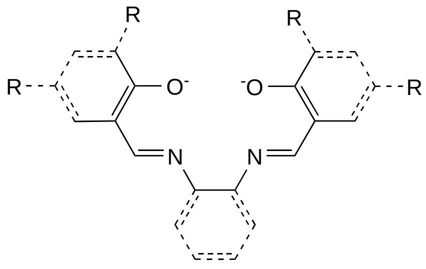
(**10**)



(**11**)

3.2.4 Peroxide Complexes

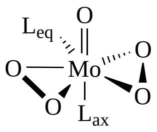
Reaction of $[MoCl_4(NCMe)_2]$ with a variety of Schiff base ligands, LH_2 in the presence of a base in THF afforded *trans*-$[Mo^{IV}Cl_2L]$, where L is as shown in Figure 2.[1] These Mo^{IV} complexes have octahedral structures although the equatorially disposed N_2O_2 ligand exhibited slight tetrahedral distortion.



Acen: rings absent
Salen: phenolato rings present, dimino rings absent
Salphen: all rings present, R = H
$Bu^t{}_4$salphen: as salphen, R = Bu^t

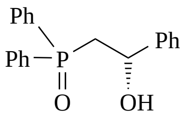
Figure 2 Tetradentate Schiff base ligands

Peroxide complexes of molybdenum(VI) are intermediates in industrially important epoxidation reactions. The so-called 'Mimoun-type' complexes $[Mo^{VI}O(O_2)_2L_{ax}L_{eq}]^{0/n-}$ (**12**) generally exhibit pentagonal-bipyramidal structures, with an axial oxo group trans to L_{ax} and L_{eq}, and two peroxo groups in the equatorial plane. These complexes are effective reagents for the selective oxidation of alcohols to aldehydes, amines to nitroso compounds, sulfides to sulfoxides and then to sulfones, phenols to *o*-quinones, and in the sulfoxidation of thianthrene-5-oxide.[14]

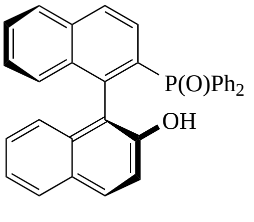


(**12**)

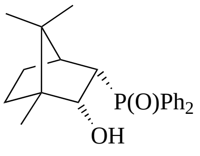
Chiral ligands such as (*R*)/(*S*)-(**13**), (*R*)/(*S*)-(**14**), and (*R*,*R*,*S*)/(*R*,*S*,*R*)-(**15**) form 'Mimoun-type' complexes $[MoO(O_2)_2L]$ and $[MoO(O_2)_2L(OH_2)]$, the structure of $[Mo(O_2)_2(\mathbf{C})][(OH_2)]$ revealing that the phosphoryl donor occupied the equatorial position (L_{eq}). Enantioselectivity in the stoichiometric epoxidation of prochiral olefins was marginal ($<10\%$) except in the case of the complex containing (**14**), where e.e.s of up to 39% were noted. An efficient biphasic catalytic epoxidation system based on $[MoO(O_2)_2(OPR_3)]$ (R = *n*-dodecyl) has been developed.



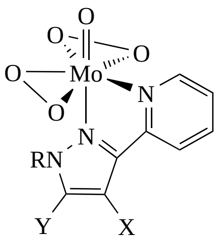
(*R*)-(**13**)



(*S*)-(**14**)

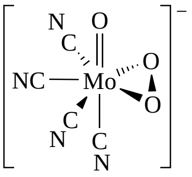


(*R*,*R*,*S*)-(**15**)

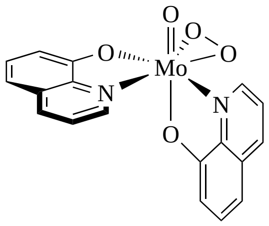


(**16**)

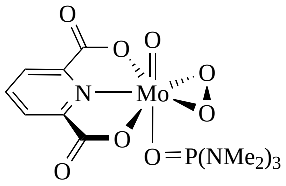
Complexes containing 2-(pyrazol-3-yl)pyridines (R = alkyl; X/Y = H, C, Br, Me, NO_2, CF_3, Ph), (**16**), were effective



(**17**)



(**18a**)



(**18b**)

epoxidation catalysts. Such complexes were also photoactive, producing both singlet and triplet O_2 on irradiation.

Oxo-monoperoxo Mo^{VI} complexes are relatively uncommon. $[MoO(CN)_5]^{3-}$ reacted with O_2 giving $[MoO(O_2)(CN)_4]^{2-}$ (**17**), which was also formed by autoxidation of $[MoO(CN)_4(pz)]^{2-}$. An ill-defined species $[MoO(O_2)_2{\cdot}2quinH]$ was formed by reaction of MoO_3 with 8-hydroxyquinoline in 30% H_2O_2, but this converted to pentagonal-bipyramidal $[MoO_2(quin)_2]$, (**18a**), on recrystallization. This species was a catalyst precursor for the autoxidation of methylbenzenes. An X-ray structural determination of $[MoO(O_2)(pdc)\{OP(NMe_2)_3\}]$, (**18b**) (pdc = pyridine-2,5-di(carboxylate)), revealed that it had pseudo-octahedral geometry with a symmetrical sideways-bound (κ^2) peroxido group cis and orthogonal to the Mo=O group. Related oxaziridine complexes [MoO(ONAr)(hmpa)] were effective catalysts for the oxidation of aryl amines to nitroso compounds by H_2O_2.

4 COMPLEXES WITH SULFUR, SELENIUM, AND TELLURIUM DONOR ATOMS

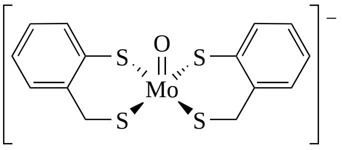
4.1 Thiolato Complexes

Diamagnetic molybdenum(IV) thiolato complexes of the type $[MoO(SR)_4]^{2-}$ were prepared by BH_4^- reduction of corresponding Mo^V precursors, by thiol exchange with $[MoO(SC_6H_4Cl\text{–}4)_4]^{2-}$, or by reaction of $[MoOCl(PPh_2Me)_3]$ with HSC_6F_5 in the presence of NEt_3. X-ray crystallographic examination of a selection of these oxo-Mo^{IV} complexes established that the coordination sphere had expanded slightly with respect to their oxo-Mo^V analogues.

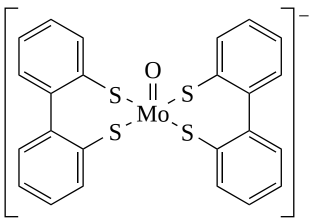
Two types of hydrido Mo^{IV} thiolato complexes have been described (i) 6-coordinated 14-electron species $[MoH(SR)_3(PMe_2Ph)_2]$ (R = mes, $C_6H_2^{iPr}{}_3$-2,4,6) and (ii) 5-coordinated, 12-electron complexes containing bulkier phosphines, $[MoH(SR)_3(PR'Ph_2)_2]$ (R = Mes, R′ = Me; R = $C_6H_2^{iPr}{}_3$, R′ = Et). The first group was prepared by reaction of $[Mo(NNH_2)Br_2(PMe_2Ph)_3]$ with RSH/NEt_3, and the structure of $[MoH(SC_6H_2^{i}Pr_3)_2(PMe_2Ph)_2]$ was trigonal bipyramidal, with apical phosphine and equatorial thiolate ligands, the H atom not being located. The second group was obtained from the reaction of $[MoH_4(PR'Ph_2)_4]$ or $[Mo(N_2)_2(PR'Ph_2)_4]$ with RSH, and was also trigonal bipyramidal, with an apical H atom trans to $PR'Ph_2$. These complexes afforded a variety of complexes by phosphine displacement, thiol elimination, hydride exchange with deuterium, hydrazine disproportionation, and/or ligand addition.

A distorted octahedral complex $[Mo^{IV}(dmsp)_2(S^tBu)_2]$ (dmsp = $Ph_2PCH_2CH_2S^-$) was obtained by reaction of $[Mo(S^tBu)_4]$ with dmsp. It formed heterobimetallic clusters with iron and copper species. Tridentate $PhP(C_6H_4SH)_2$ reacted with $[MoCl_4(PPh_3)_2]$ in methanol/NEt_3 to give diamagnetic $[Mo^{IV}\{PhP(C_6H_4S)_2\}]$ and when this reaction was carried out in acetonitrile, $[Mo\{PhP(C_6H_4S)_2\}(NCMe)]$ was produced. Reaction of $[MoCl_2(CO)_2(PPh_3)_2]$ with the same ligand in methanol/base afforded $[Mo(CO)\{PhP(C_6H_4S)_2\}_2]$.

The oxomolybdenum(V) thiolato species $[MoO(SR)_4]^-$ was obtained by several different routes: (1) reactions of thiols with precursors containing Mo^V, including $[MoOCl_3(thf)_2]$, (2) thiol exchange with $[MoO(SPh)_4]^-$, (3) reaction of $[MoO_2(acac)_2]$ or $[MoOCl_4]$ with thiolates, (4) reaction of $[MoCl_3(thf)_3]$ with thiols and 4-methylpyridine-*N*-oxide, or (5) reaction of $[MoCl_4(NCMe)_2]$ with thiolates in wet acetonitrile. These complexes carried a range of aryl substituents. Complexes have been prepared containing chelating dithiolato ligands, $[MoO(S\text{–}S)_2]^-$, where S–S = $S(CH_2)_nS$ with $n = 2$ or 3, α-2-toluenedithiolate (**19**), tri- and tetrapeptides, and 2,2′-dimercaptodiphenyl (**20**). These complexes are characterized by intense low-energy (500–650 nm) charge transfer bands mainly comprising multiple S → $Mo(d_{xy})$ transitions, the transition energies being strongly dependent on the orientation of the orbitals containing the S lone-pair electrons with respect to the magnetic orbital.



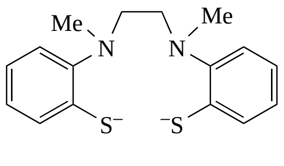
(**19**)



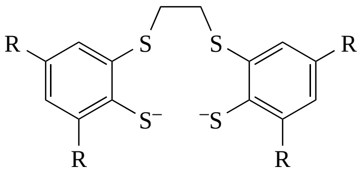
(**20**)

The syntheses of paramagnetic *cis*,*cis*-$[Mo^VOCl(L\text{–}N_2S_2)]$ ($H_2L\text{–}N_2S_2 \equiv$ (**21**)) and its thermal isomerization to the cis,trans isomer have been described, and a series of

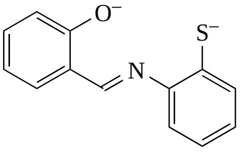
derivatives of *cis,cis*- and *cis,trans*-[MoOX(L–N_2S_2)] (X = Br, NCS, $OSiMe_3$, OPh, SPh), and [MoO(L–N_2S_2)]$^+$ have also been reported. Reactions of [$MoOCl_5$]$^{2-}$ with $dttdH_2$ (dttd^{2-}≡ (**22**), R = H) afforded the paramagnetic [MoOCl(dttd)], while reactions of [MoO(SR)$_4$]$^-$ with *N*-salicylidene(2-mercaptoaniline) (L–$NSOH_2$, (**23**)) gave [MoO(L–NSO)(SR)$_2$] (R = Ph, C_6H_4Me-4).



(**21**)



(**22**)

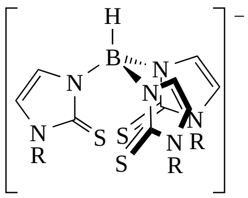


(**23**)

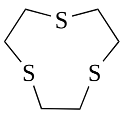
Nitrosyl complexes containing dttd^{2-} (**22**) are described in Section 5.8.

4.2 Thioether Complexes

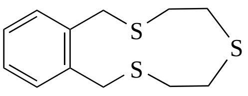
Tripodal S_3-donor ligands afforded a wide variety of complexes, including the tetra(methylthiomethyl)borate species [Mo(CO)$_2${κ^3-*S,S′,S″*-(MeSCH$_2$)$_3$BCH$_2$SMe}]$^-$, [Mo(CO)$_3$ {κ^3-*S,S′,S″*-(RSCH$_2$)$_3$ER′}] (R = alkyl, mainly Me, or aryl; ER = CMe, SiMe, and SnBu). Long Mo–S bonds (>2.6 Å) and ready ligand displacement indicated that these ligands were relatively weakly bound to the molybdenum tricarbonyl center. Thione ligands, based on the tris(pyrazolyl)borate motif, (**24**), were also used to form tricarbonyl anionic derivatives. A variety of linear and macrocyclic thioethers have also been coordinated by tricarbonyl molybdenum fragments, including [Mo(CO)$_2$(MeSCH$_2$CH$_2$SCH$_2$CH$_2$SMe)], [Mo(CO)$_3$(ttcn)], and [Mo(CO)$_3$(ttob)] (ttcn, (**25**); ttob, (**26**)).



(**24**)

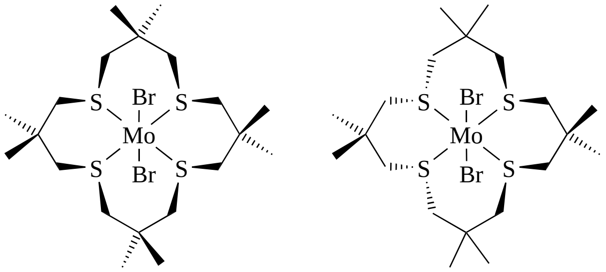


(**25**)



(**26**)

The Mo^{II} complex *trans*-[MoBr$_2${Me$_8$[16]aneS$_4$}] (**27**) was prepared by reaction of the macrocyclic tetrathioether with [{MoCO$_4$Br$_2$}$_2$] and this could be oxidized by Ag$^+$ to *trans*-[MoBr$_2${Me$_8$[16]aneS$_4$}]$^+$ in which the ligand adopted a syn–anti conformation. Reduction of *trans*-[MoBr$_2${Me$_8$[16]aneS$_4$}] by sodium amalgam under nitrogen in thf afforded the Mo^0 complexes, *trans*-[Mo(N$_2$)$_2${Me$_8$[16]aneS$_4$}], the macrocyclic thioether adopting a syn conformation.



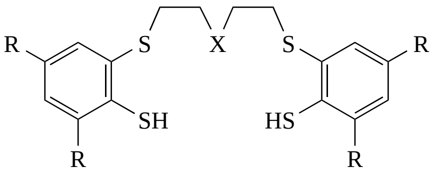
syn conformation　　*syn-anti* conformation

(**27**)

Reactions of [MoCl$_3$(thf)$_3$] with cyclic trithioethers *c*-S_3 afforded the Mo^{III} complexes, [MoCl$_3$(*c*-S_3)] and [MoCl$_3$(ttob)], and with neat tetrahydrothiophene (tht), *mer*-[MoCl$_3$(tht)$_3$] was formed. This latter complex was an active catalyst for the selective polymerization and cyclotrimerization of alkynes.

Reaction of *trans*-[Mo(N$_2$)$_2${Me$_8$[16]aneS$_4$}] with S_8 afforded *trans*-[Mo^{IV}(S)$_2${Me$_8$[16]aneS$_4$}] which, on treatment with RX, was converted to *trans*-[Mo(S)(SR){Me$_8$[16] aneS$_4$}]X. Protonation of [Mo(S)$_2${Me$_8$[16]aneS$_4$}] by HBF$_4$ gave [Mo$_2$(S)$_3${Me$_8$[16]aneS$_4$}$_2$]$^{2+}$ (containing a near-linear {S=Mo–S–Mo=S}$^{2+}$ group) and *trans*-[Mo(S)F{Me$_8$[16]ane S$_4$}]$^+$. All of these complexes contained the macrocyclic tetrathioether in the syn conformation.

The distorted octahedral oxomolybdenum(V) complexes [MoO(S–S–X–S–S)] were prepared by reaction of [MoCl$_4$ (NCMe)$_2$] with the free pentadentate ligand (HS–S–X–S–SH, (**28**)) or its Ni^{2+} complex in wet thf, or by oxidation in air of [Mo(CO)$_2$(S–S–X–S–S)]. Related dioxomolybdenum(VI) species [MoO$_2$(S–S–X–S–S)] were also reported.



(**28**) (X = S, R = H; X = O, R = H; X = S, R = Bu^t; X = NH, R = H)

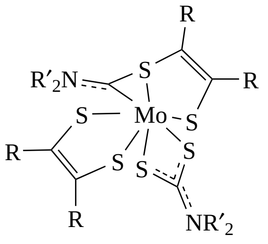
4.3 Dithiocarbamato and Related Dithioacid Complexes

Reaction of [MoI$_2$(CO)$_3$(NCMe)L] (L = EPh$_3$, E = P, As, Sb) with NaS$_2$CNR$_2$ (R = Me, Et, Bz) afforded

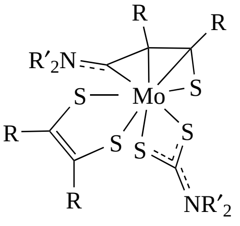
$[Mo^{II}I(CO)_3(S_2CNR_2)]$, and similar ethyl xanthate and pyridine- and pyrimidine-2-thiolates have been reported. Treatment of $[MoX_2(CO)_3(NCMe)L]$ with S-donor ligands, including $RS(CH_2)_2SR$($R = Ph$, C_6H_4X-4 where $X = Me$ or F)[7], ttcn (**25**), and related tridentate ligands, afforded di- and tricarbonyl derivatives, $[MoX_2(CO)_3\{RS(CH_2)_2SR\}]$, and $[MoI_2(CO)_2(MeSCH_2CH_2SCH_2CH_2SMe)]$.

Reaction of $[MoX_2(CO)_3(NCMe)_2]$ with two equivalents of dithioacid ligands affords complexes of the type $[Mo(CO)_n(S_2CX)_2]$, for example, $[Mo(CO)_3\{S_2P(OEt)_2\}_2]$, which reacted with tertiary phosphines forming $[Mo(CO)_2(PPh_3)\{S_2P(OEt)_2\}_2]$ and $[Mo(CO)(diphos)\{S_2P(OEt)_2\}_2]$. Similar species containing S_2CPCy_3 were also prepared.

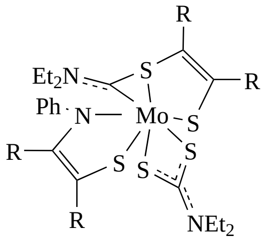
Reactions of $[Mo_2(\mu\text{-}S_2)_2(S_2CNR'_2)_4]^{2+}$, $[Mo(O)(S_2)(S_2CNR'_2)_2]$ ($R' = Me$ or Et) or $[Mo(S_2)(S_2CNEt_2)_2]$ with alkynes ($RC{\equiv}CR$) afforded a variety of mixed ligand ethenedithiolato dithiocarbamato complexes containing Mo^{IV}, including (**29**) and (**30**). The iminothiolene complexes (**31**) and (**32**) were obtained by reaction of alkynes with $[Mo(NPh)(S_2)(S_2CNEt_2)_2]$



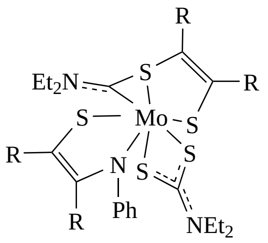
(**29**)



(**30**)



(**31**)



(**32**)

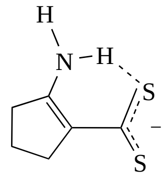
Reaction of $[MoCl(S_2CNR_2)_3]$ ($R = Me$, Et) with silver triflate afforded diamagnetic $[Mo_2(dtc)_6][OTf]_2$ which could act as the source of tris(dithiocarbamato)Mo^{IV} cations in the synthesis of $[MoL(dtc)_3]^{n+}$ ($n = 0$, $L = Cl$, I, N_3; $n = 1$, $L = O$, NCMe, PR_3). The molybdenum atom in paramagnetic seven-coordinate $[Mo(PMe_2Ph)(S_2CNEt_2)_3][OTf]$ has pentagonal-bipyramidal coordination with an apical phosphine ligand.

Reaction of $[NEt_4]_2[MoS_4]$ with tetraethylthiuramdisulfide afforded the paramagnetic molybdenum(V) complex $[Mo(S_2)(S_2CNEt_2)_3]$ ($S = 1/2$). This reacted with 3-chloroperoxybenzoic acid to give $[Mo(S_2O\text{–}S,S')(S_2CNEt_2)_3]$ which also had one unpaired electron. Both molecules have a pentagonal-bipyramidal structure, the former with an apical S_2^{2-} group. Ferrocenium oxidation of $[Mo(S_2)(S_2CNEt_2)_3]$ afforded either $[Mo(S_2CNEt_2)_4]^+$ or $[MoO(S_2CNEt_2)_3]^+$, depending on whether the solvent was dry or wet.

Reaction of $[Mo(S_2CNR_2)_4]$ with TCNQ and TCNE produced radical cation−anion salts $[Mo(S_2CNR_2)_4]Z$ (Z = TCNQ or TCNE). The TCNQ salt reacted with additional TCNQ giving $[Mo(S_2CNR_2)_4][TCNQ]_2$ which contained neutral and anionic forms of TCNQ. The crystal structures of $[Mo(S_2CNR_2)_4][TCNQ]$ ($R = Me$ or Et) showed that the cation in each has an eight-coordinate dodecahedral structure, but that the anion packings are distinctly different. These complexes have interesting optical, magnetic, and electrical properties.

Reaction of $[MoO_2(S_2CNR_2)_2]$ with silanes afforded siloxo, halide, pseudohalide, and tris(dithiocarbamato species, $[Mo^{VI}OX_2(S_2CNEt_2)_2]$ ($X = I$, NCS), $[MoO(OSiMe_3)(S_2CNEt_2)_2]^+$, and pentagonal-bipyramidal $[MoO(OSiMe_3)(CN)(S_2CNEt_2)_2]$.[3]

The 2-aminocyclopent-1-ene-1-dithiocarboxylato complex $[MoO_2(acpd)_2]$ (acpd, (**33**)) afforded access to a wide range of Mo^{VI}, Mo^V, Mo^{IV}, and Mo^{III} complexes, including $[Mo^VO(acpd)_3]$, $[Mo^VOX_2(acpd)_2]$ (X = halide), $[Mo^{VI}O(acpd)_3]^+$, $[Mo^{VI}O(cat)(acpd)_2]$, and $[Mo(N_2R)(acpd)_3]$. Reaction of $[Mo^VOX(acpd)_2]$ with Hacpd, RSH, RNHOH, and Ph_3PNR gave $[Mo^{IV}(acpd)_4]$, $[Mo^VO(SR)(acpd)_2]$ ($R = Ph$, $C_6H_4NH_2$-2, $CH_2CH_2NH_2$), $[Mo^{VI}(ONR)X_2(acpd)_2]$, and $[Mo^{VI}(NR)X_2(acpd)_2]$. The complexes $[Mo^{IV}(SC_6H_4NH_2\text{-}2)(acpd)_3]$ and $[Mo^{III}(PPh_3)(acpd)_3]$ were obtained from $[Mo^{VI}O(acpd)_3]^+$, while $[Mo(acpd)_2(S_2CNR_2)_2]$ and $[Mo(acpd)(S_2CNR_2)_3]$ were prepared from $[MoOCl_2(S_2CNR_2)_2]$ and $[MoO(S_2CNR_2)_3]^+$, respectively.



(**33**)

The complexes $[MoO(S_2)(S_2CNR_2)_2]$ are effective catalysts for the episulfurization of (*E*)-cycloalkenes by elemental sulfur. Oxidation of the same complex by 3-chloroperoxybenzoic acid, or reaction of $[Mo_2O_3(S_2CNEt_2)_4]$ or $[MoO(S_2CNEt_2)_2]$ with 'S_2O' sources, afforded the pentagonal-bipyramidal $[MoO(S_2O\text{-}S,S')(S_2CNEt_2)_2]$ which contains axial Mo=O and equatorial κ^2-S_2O^{2-}.

Reaction of $[MoS_4]^{2-}$ with tetraalkythiuramdisulfides afforded $[Mo(S_2)(S_2CNR_2)_3]$, while reaction with disulfides, RSSR, gave dinuclear $[Mo_2S_2(\mu\text{-}S)_2(S_2)_2]^{2-}$.

4.4 Dithiolene Complexes

4.4.1 Dicarbonyl Bis(Dithiolene) Complexes and their Reactions

All three members of the electron transfer chain $[Mo(CO)_2(S_2C_2Me_2)]^{n-}$ ($n = 0, 1, 2$) were isolated and characterized. The complexes have trigonal prismatic geometries, and structural, spectral, and electrochemical properties that are consistent with the redox orbital having predominantly sulfur-ligand based character (>80%); behavior consistent also with DFT calculations. Closely related benzene- and 2,4-di-*t*-butyl-benzene-dithiolene complexes, $[Mo(LL')(bdt)_2]$ (L = O, L = PPh_3, L = L′ = $PMeR_2$ (R = Me or Ph)) were obtained by thioether S-dealkylation of appropriate $dttd^{2-}$ (**22**) complexes of molybdenum carbonyls and oxo species. $[Mo(CO)(PPh_3)\{S_2C_6H_2(Bu^t)_2\}_2]$ and $[Mo(PMe_3)_2(bdt)_2]$ have trigonal prismatic structures in the solid state, similar to $[Mo(CO)_2(S_2C_2Me_2)_2]$, although, in solution, it is possible that $[Mo(CO)(PR_3)\{S_2C_6H_2(Bu^t)_2\}_2]$ could have an octahedral structure (*trans* CO/PR_3). Reaction of $[MoCl_4(NCMe)_2]$ with $Na_2S_2C_2H_2$ or Na_2bdt in the presence of $PMePh_2$ or isocyanides afforded trigonal prismatic $[MoL_2(S_2C_2H_2)_2]$ and $[MoL_2(bdt)_2]$ (L = $PMePh_2$ or CNR (R = Me or Bu^t)), also with structures analogous to $[Mo(CO)_2(S_2C_2Me_2)_2]$.

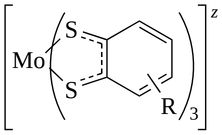
Reaction of $[Mo(CO)_2(S_2C_2R_2)_2]$ with OR'^- afforded $[Mo(OR')(S_2C_2R_2)_2]^-$ (R = Me, R′ = Pr^i, Ph, Ar, 2-Ad, C_6F_5; R = Ph, R′ = Ph, Ar), and with Et_4NOH $[MEt_4N]_2[Mo(O)(S_2C_2R_2)_2]$ (R = Me, Ph) was formed. Related complexes $[Mo(OSiBu^tPh_2)(SCH_2CH_2S)_2]^-$ and $[Mo(OSiBu^tPh_2)(bdt)_2]^-$ were formed in the reaction of $[Mo(O)(dithiolate)_2]^{2-}$ with $ClSiBu^tPh_2$. All of these complexes have square-pyramidal structures with axial alkoxide groups. Kinetic and isotope-labeling studies of the oxygen-atom transfer reactions of $[NEt_4][Mo(OR')(S_2C_2Ph_2)_2]$ with Se-, N-, and S-oxides were consistent with the initial formation of $[Mo(O)(OR')(S_2C_2Ph_2)_2]^-$ which decayed by internal redox processes to the final product, $[Mo(O)(S_2C_2Ph_2)_2]^-$. These complexes and the reactions are regarded as excellent models for dmso reductases and, in this context, the large reduction potentials required to reduce $[Mo(OR')(S_2C_2R_2)_2]^-$ may account for the absence of Mo^{III} enzyme states.

Reaction of $[Mo(CO)_2(S_2C_2R_2)_2]$ with SR'^- and SeR'^- were more complicated, producing two types of complexes depending on ligand and reaction conditions: trigonal prismatic $[Mo(ER')(CO)(S_2C_2R_2)_2]^-$ (R = Me, E = S or Se, R′ = Ph′R = Me or Ph, E = Se, R′ = $C_6H_2Pr^i_3$-2,4,6) and square-pyramidal $[Mo(ER')(S_2C_2R_2)_2]^-$ (R = Me, E = S, R′ = 2-Ad, $C_6H_2Pr^i_3$-2,4,6; E = Se, R′ = 2-Ad; R = Ph, E = S, R′ = $C_6H_2Pr^i_3$-2,4,6; R = Me, E = Se, R′ = 2-Ad).

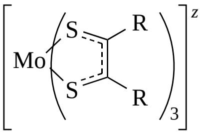
4.4.2 Dianionic Tris(Dithiolene) Complexes

The complexes (**34**–**39**) were prepared by a variety of methods, including reaction of the dithiolato ligand salt $(S–S)^{2-}$ or a precursor mixture involving $[MoS_4]^{2-}$ or $MoCl_5$, or by reaction of Mo^{VI} or Mo^{V} derivatives. All of these complexes are members of at least a three-membered electron transfer chain (equation 1):

$$[Mo(S–S)_3]^0 \rightleftharpoons [Mo(S–S)_3]^{-1} \rightleftharpoons [Mo(S–S)_3]^{-2} \quad (1)$$

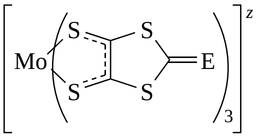


(**34**)

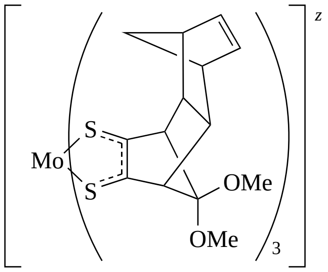


(**35**)

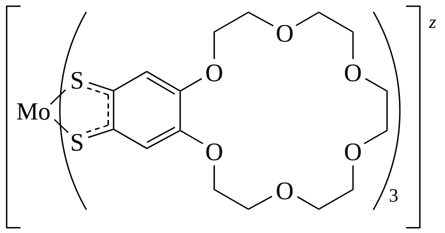
Many of the dianionic species ($z = 2$) have trigonal prismatic geometries which may partly be defined by the twist angle ϕ, shown in Figure 3, for example, (**35**), R = CO_2Me, $\phi = 10.6°$, R = CF_3, $\phi = 0°$ as Fc^+ salt, 16° as NEt_4^+ salt, R = Me, $\phi = 2.6°$; (**36**) E = S, $\phi = 11°$; (**39**), $\phi = 4.5°$ as $[PPh_4]^+$ salt. Reaction of $[MoO_2(acac)_2]$ with H_2qdt in concentrated sulfuric acid gave $[Mo(qdt)_2]^{2-}$. Protonation of the N atoms in this complex caused a marked change in its electrochemical behavior.



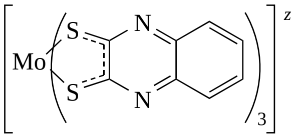
(**36**) E = O, S



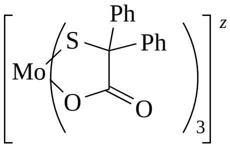
(**37**)



(**38**)



(**39**)



(**40**)

The complex (**40**) is diamagnetic, has a trigonal prismatic geometry and could be oxidized to a monoanion which was

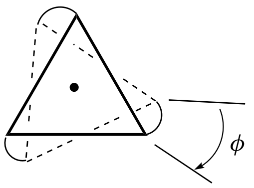


Figure 3 Idealized trigonal prism distortions as defined by angle

described as containing Mo^{V}. This species, however, did not exhibit dithiolenic behavior.

4.4.3 *Monoanionic Tris(Dithiolene) Complexes*

Monoanionic tris(dithiolene) complexes exhibited distorted trigonal prismatic geometries, for example, $[Mo(S_2C_2Me_2)_3]^-$ ($\phi = 1.6°$, as NEt_4^+ salt) and $[Mo(bdt)_3]^-$ ($\phi = 33.5°$ as NBu_4^+ salt), and are paramagnetic (one unpaired electron) exhibiting characteristic EPR spectra ($g \approx 2.002$). These results indicated that the complexes were not appropriately described as containing Mo^{V}. Iodine or ferrocenium cation oxidation of dianionic tris(dithiolene) complexes afforded salts of $[Mo\{S_2C_2(CF_3)_2\}_3]^-$ (**35**) $z = -1$, ϕ ca. 0° as Fc^+ salt; $[Mo(qdt)_3]^-$ (**39**) $z = -1$; $\phi = 14.6°$ as PPh_4^+ salt, and $[Mo(dmit)_3]^-$ (**36**) Z = E). Multifunctional EPR spectra studies of the iminothiolene complex $[Mo(abt)_3]^-$ and computational studies of other related species provided information on the delocalized nature of the ground state of these unusual complexes.

4.4.4 *Neutral Tris(Dithiolene) Complexes*

Tris(dithiolene) complexes carrying no formal charge were produced by reacting dithiolato ligands or their precursors with MoO_4^{2-}, $[MoO_2(acac)_2]$, $MoCl_5$, or $[MoCl_4(thf)_2]$, or via oxidation of Mo^{V} or Mo^{IV} counterparts. Among the complexes generated were $[Mo(bdt)_3]$, $[Mo(S_2C_2H_2)_3]$, $[Mo\{S_2C_2(SR')_2\}_3]$, $[Mo(S_2C_2S_2CE)_3]$ [E = O, S, (**37**) and (**38**) (dmit)]. These complexes had trigonal prismatic geometries, again characterized by a twist angle, ϕ (Figure 3), approaching 0° as observed in $[Mo\{S_2C_2(CF_3)_2\}_3]$ and $[Mo(S_2C_2Me_2)_3]$ ($\phi = 5.4°$). Nuclear magnetic resonance (NMR) and other spectroscopic studies confirmed substantial electron delocalization in the ground states of these complexes, it being suggested that the metal has a formal +4 oxidation state. The complexes, of course, existed within at least a three-membered electron transfer series as shown above. Detailed structural, spectroscopic, and DFT studies of isolated members of the three-membered electron transfer chain $[Mo(S_2C_2Me_2)_3]^z$ (z = 0, −1, −2) established that the redox orbital in all members of the series was predominantly ligand based (ca. 80%).

4.4.5 *Oxo Bis(Dithiolene) Complexes*

Square-pyramidal $[MoO(S{-}S)_2]^{2-}$ (S–S is a wide range of 1,2-dithiolato ligands), formally containing Mo^{IV}, could be prepared by a variety of routes: by reaction of the dithiolate ligand with Mo^{IV} starting materials such as $[MoO_2(CN)_4]^{2-}$, $[MoO(SC_6H_4Cl\text{-}4)_4]^{2-}$, or $[MoOCl(CNMe)_4]^+$, by reaction of the dithiolate ligand with Mo^{VI} or Mo^{V} precursors in the presence of reducing agents, by induced internal redox reactions involving $[MoO_2S_2]^{2-}$ with the dithiete $[S_2C_2(CCF_3)_2]$, by reaction of $[MoO(S_4)_2]^{2-}$ with alkynes, reduction of oxomolybdenum(V) or dioxomolybdenum(VI) dithiolene complexes, by reaction of $[Mo(CO)_2(S_2C_2R_2)_2]$ with $[Et_4N]OH$, or by treatment of nitrido-dithiolene species with dioxygen. These complexes were reversibly oxidized to Mo^{V} counterparts and some belong to a three-membered electron transfer chain (equation 2):

$$[MoO(S{-}S)_2]^0 \rightleftharpoons [MoO(S{-}S)_2]^{-1} \rightleftharpoons [MoO(S{-}S)_2]^{-2} \qquad (2)$$

Many of these complexes also participated in oxygen-atom transfer reactions, giving dioxomolybdenum(VI) species and reduced substrates, and associated kinetic studies have been reviewed.[15]

Iodine oxidation of $[MoO(S_2C_2R_2)_2]^{2-}$ afforded $[MoO(S_2C_2R_2)_2]^-$ (R = H, Me, Ph; H/CN), the central member of the electron transfer chain $[MoO(S_2C_2R_2)_2]^z$ shown in equation (2). Similarly, ferrocenium ion oxidation of $[MoO\{SC(H)C(R)S\}_2]^{2-}$ [R = Ph, pyridinyl, quinoxalin-2-yl, 2(dimethylaminomethyleneamino)-3-methyl-4-oxopteridin-6-yl] and $[MoO(qdt)_2]^{2-}$ afforded monoanions. $[MoO(qdt)_2]^-$ was thermochromic due to thermally driven intramolecular charge transfer processes. However, chemical or electrochemical oxidation of $[MoO(mnt)_2]^{2-}$ to the corresponding monoanion resulted in its disproportionation to $[Mo(mnt)_3]^{2-}$ (formally containing Mo^{IV}) and MoO_3. When generation of $[MoO(mnt)_2]^-$ was carried out in the presence of Cl^-, $[MoOCl(mnt)_2]^{2-}$ was formed. Oxidation of $[MoO(dmit)_2]^{2-}$ likewise afforded $[MoO(dmit)_2]^-$, fully or partially oxidized salts of this monoanion exhibiting interesting electrical properties.

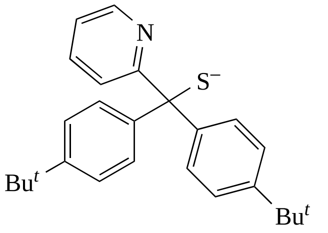
Reaction of $[MoO(S{-}S)_2]^-$ (S–S = $S_2C_2Me_2$, bdt) with SR'^- gave $[MoO(SR')_2(S{-}S)_2]^-$ (R = 2-Ad, $C_6H_2Pr^i_3$-2,4,6), which exhibited rhombic EPR spectra and underwent reversible electrochemical reduction.

Modeling of the pterin-dithiolate center in Mo enzymes has provided the spur for much work of oxodithiolene complexes in which the metal is formally in oxidation state VI. This included the synthesis of $[MoO_2(mnt)_2]^{2-}$, $[MoO_2\{S_2C_2(CO_2Me)_2\}_2]^{2-}$, $[MoO_2(bdt)_2]^{2-}$, $[MoO_2(S_2C_6H_3R)_2]^{2-}$ [R = H (≡bdt), R = 4-Me (≡tdt), R = 3-$SiPh_3$]. These complexes have distorted octahedral structures with cis-dioxo groups, and resonance Raman spectral studies showed that the sulfur ligands exerted a trans

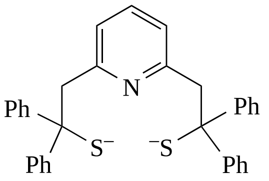
influence on the oxo ligands, and not *vice versa*, as might have been expected. Mo K- and $L_{2,3}$-edge X-ray absorption spectroscopy (XAS) data for these and related complexes have been reported. Some of these complexes reacted with silyl chlorides giving mono(oxo) silyloxo species, for example, $[MoO(OSiBu^tPh_2)(bdt)_2]^-$, and $[Mo(OPh)(S_2C_2Me_2)_2]^-$ reacted with Me_3NO giving $[MoO(OPh)(S_2C_2Me_2)_2]^-$. These species also have octahedral structures in which the oxo and alkoxo groups are mutually cis. Reaction of $[MoO_2(OSiPh_3)_2]$ with Li_2bdt afforded $[MoO_2(OSiPh_3)(bdt)]^-$ which reacted further with $(SC_6H_2Pr^i_3\text{-}2,4,6)^-$ giving $[MoO_2(bdt)(SC_6H_2Pr^i_3\text{-}2,4,6)]^-$, a structural model for sulfite oxidase. These anions have square-pyramidal (pseudotetrahedral) structures.

4.5 Complexes with N/S-Donor Atom Sets

Cis-dioxomolybdenum(VI) complexes of sterically bulky (thiolato)pyridine (**41**) and bi(thiolato)pyridine (**42**) ligands were designed to prevent comproportionation and maintain mononuclearity during oxygen-atom transfer reactions. The complex with (**41**) had a distorted octahedral structure and achieved its designed objective, whereas that with (**42**) did not, having trigonal bipyramidal structure with axial thiolate donors.

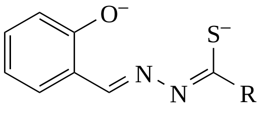


(**41**)

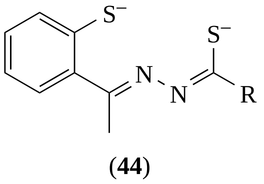


(**42**)

The Schiff bases (**23**), (**43**), and (**44**) formed Mo^{VI} complexes of the type *cis,mer*-$[MoO_2(ligand)]$ (which was associated in the solid state) and *cis,mer*-$[MoO_2(ligand)L]$ (L = neutral donor). The structures, electrochemical and chemical properties of these complexes, and their oxygen-atom transfer capabilities were extensive studies. These species were generally more active catalysts than their N–O–O-donor atom Schiff base counterparts, but oxygen-atom abstraction reactions with tertiary phosphines led to dinuclear Mo^V species rather than monomeric Mo^{IV} complexes.



(**43**)



(**44**)

4.6 Complexes of Chalcogenide, Persulfide, and Polychalcogenide Ions

Thio Mo^V centers are implicated in the turnover of industrial catalysts and enzymes, but mononuclear thiomolybdenyl complexes are rare. Examples include $[MoSTp^*X_2]$, where X = OPh, OC_6H_4X-2 (X = SEt, Pr); X_2 = catecholate, tdt, bdt. These species have octahedral structures with short Mo=S bonds ($d_{Mo\text{–}S}$ = 2.13 Å).

Reaction of $[Mo(NRAr)_3]$ with S_8, ethylene sulfide, Se, and Te/PEt_3 afforded $[MoE(NRAr)_3]$ (E = Ss, Se, Te). These species were paramagnetic (μ = 1.6–1.9 BM) and have distorted tetrahedral structures ($d_{Mo\text{–}E}$ = 2.17 (S), 2.31 (Se), 2.54 (Te) Å), respectively. A pentagonal-bipyramidal persulfide complex, $[MoO(S_2)_2(bipy)]$ has also been described ($d_{S\text{–}S}$ = 2.04–2.06 Å).

Reaction of $[Mo(CO)_3Tp^z]^-$ (Tp^z = Tp, Tp*) with S_8 afforded $[MoSTp^z(S_4)]$ which has a distorted octahedral geometry. Treatment of $[Mo(=O)_2Tp^*X]$ with B_2S_3 and H_2S mixtures afforded $[MoTp^*X(S_4)]$ (X = halide, NCS). These complexes have very short Mo–S distances ($d_{Mo\text{–}S}$ = 2.19 Å), and the alternation of the S–S distances within and the planarity of the MoS_4 ring system implied strong Mo–S d_π–p_π bonding.

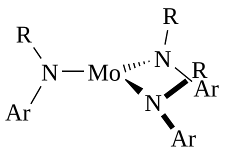
Nonoxo, mixed-cage ligand complexes, $[Mo(AsSe_5)_2]^{2-}$, $[Mo(CO)_2(As_3Se_5)_2]^{2-}$ have been described, the first containing long intramolecular Se···Se interactions indicative of partial internal redox behavior.

5 COMPLEXES WITH N-DONOR ATOMS

Although complexes containing C-donor atoms (except occasionally carbonyls and isonitriles) are not the subject of this section, a major aspect of the chemistry of molybdenum with particular N-donor atom ligands involves carbide, {Mo≡C:}, alkylidyne, {Mo≡CR}, alkylidene {Mo=CRR′} and alkyl, {Mo–R}, species. These species, and in particular, the alkylidyne and alkylidenes, are extremely important as catalysts for olefin metathesis, ‘living’ ring-opening metathesis polymerization, ring-closing metathesis reactions, and other processes of industrial significance. Many aspects of the chemistry of these have been extensively reviewed[16–18] and comprehensive reports published, so they are not described in detail here.[6,19]

5.1 Carbido Complexes

The carbido anion $[MoC(NRAr)_3]^-$ (R = $C(CD_3)_2CH_3$; Ar = $C_6H_3Me_2$-2,5) was obtained from three-coordinate $[Mo(NRAr)_3]$ (**45**) via $[Mo(CO)(NRAr)_3]$ and the latter’s decarbonylation and reduction using sodium amalgam, followed by deprotonation of $[Mo(CH)(NRAr)_3]$ using KBz. The carbide anion is a strong reductant and nucleophile, forming alkylidyne derivatives readily.



(**45**)

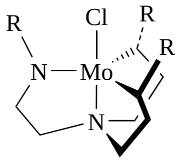
5.2 Nitrido Complexes

The structures and spectroscopic properties of, and aspects of bonding in molybdenum nitrido complexes have been reviewed.[6,18,20,21] Generally, the {Mo≡N} group only occurs in relatively simple mononuclear compounds or complexes, but $[MoN_4]^{6-}$ occurred in melt products, stabilized by Ba^{2+} or Sr^{2+}. Nitrido complexes may have tetrahedral, square-pyramidal, or octahedral geometries, and the nitrido ligand normally occupies apical or axial positions, exerting a strong trans influence. The nitrido ligands themselves may interact with neighboring metal centers, counterions, or lattice molecules.

Nitrido–Mo^V complexes are restricted to porphyrin and phthalocyanine derivatives and are discussed in Section 5.7.

Reaction of the Mo^0 bis(dinitrogen) complex containing tetradentate 3,3,7,7,11,11,15,15-octamethyl-1,5,9,13-tetrathiacyclhexadecane, Me_8[16]aneS_4 with Me_3SiN_3 afforded the molybdenum(VI) complex *trans*-$[MoN(N_3)\{Me_8$[16]ane$S_4\}]$. Protonation or reaction of this with acetone or benzaldehyde afforded *trans*-$[Mo(NH^+\cdots{}^-OTf)(OTf)\{Me_8$[16]ane$S_4\}]$ and *trans*-$[Mo\{NCRR'(OH^+\cdots{}^-OTf)(OTf)\}\{Me_8$[16]ane$S_4\}]$ ($R = R' = Me$; $R = H$, $R' = Ph$), respectively, these complexes having $\angle Mo{=}N{-}C > 174°$. Treatment of *trans*-$[Mo(N_2)_2(depe)_2]$ with Me_3SiN_3 also gave *trans*-$[MoN(N_3)(depe)_2]$ and the mixed-valence species $[\{Mo^{IV}N(N_3)(depe)_2\}_2\{\mu\text{-}Mo^VN(N_3)_2\}]$.

Reaction of $[Mo(NRAr)_3]$ with many simple nitrogen-containing molecules, for example, N_2O, arylazides, and following reduction, N_2, resulted in formation of the molybdenum(VI) nitride $[MoN(NRAr)_3]$. These species are diamagnetic and have tetrahedral geometries, as shown by $[MoN(NBu^tPh)_3]$. Cleavage of N_2 by $[Mo(NRAr)_3]$ was catalyzed by N/Hg, and unusual intermediates, such as $[Mo(N_2)(NRAr)_3]^-$ (stabilized by coordination of $[Na(thf)_x]^+$) and $[\{Mo(NPr^iAr)_3\}_2(\mu\text{-}N)]$, have been characterized. Treatment of $[MoCl\{N(CH_2CH_2NR)_3\}]$ (**46**), ($R = SiMe_3$, Ar) with Me_3SiN_3 also afforded nitrido complexes, $[MoN\{N(CH_2CH_2NR)_3\}]$.



(**46**)

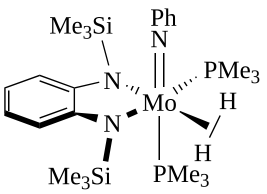
Treatment of $[\{MoNCl_3\}_4]$ with $LiOBu^t$ afforded $[MoN(OBu^t)_3]$ which readily underwent ligand exchange reactions giving $[MoN(OR)_3]$ (R = Et, Pr^i, CH_2Bu^t). These species are monomeric in solution but form linear polymers in the solid state. Anionic species such as $[MoN(OPh)_4]^-$ were obtained by treatment of $[MoNCl_4]^-$ with NaOPh. Relatively few thiolato nitrides are known, $[MoN(SR)_3]$ being prepared by reaction of $[MoN(OBu^t)_3]$ with RSH ($R = Pr^i$, Bu^t).

5.3 Imido Complexes

Although there are some parallels between imido and oxo-Mo^{IV} chemistries, the differences are more pronounced. Thus, there are many tetrahedral bis(imido) complexes of Mo^{IV} and apparently only one oxo counterpart. Reduction of $[Mo(NAr)_2Cl_2(dme)]$ by Mg in the presence of PMe_3 afforded $[Mo(NAr)_2(PMe_3)_2]$, which has a distorted tetrahedral geometry with linear Mo=N–C bonds. This complex, and its *t*-butyl analog $[Mo(NBu^t)_2(PMe_3)_2]$, underwent phosphine exchange reactions, and reaction with the diphosphene $Ar'P{=}PAr'$ ($Ar' = C_6H_2(CF_3)_3$-2,4,6) afforded the unusual species $[Mo(NR)_2(PMe_3)(\eta^2\text{-}Ar'P{=}PAr')]$, which has a pseudotetrahedral structure.

Trans-$[Mo^{IV}N(N_3)(depe)_2]$ and $[\{Mo^{IV}N(N_3)(depe)_2\}_2\{\mu\text{-}Mo^VN(N_3)_2\}]$ acted as precursors for *trans*-$[Mo(NH)X(depe)_2]^+$ ($X = Cl$, N_3) and *trans*-$[Mo(NMe)(N_3)(depe)_2]^+$, and an electrochemical study established that related dppe complexes would be reduced in an overall four-electron process releasing RNH_2 and regenerating *trans*-$[Mo(N_2)_2(dppe)_2]$. Protonation of the nitrile α-carbon atom in $[Mo(N_2)(NCR)(dppe)_2]$ afforded alkyl- and benzylimido complexes, $[Mo(NCH_2R)X(dppe)_2]^+$.

Sodium amalgam reduction of *cis,mer*-$[Mo(NR)Cl_2L]$ ($L = 2PR'_3$ or dme) in the presence of PR'_3 gave $[Mo(NR)Cl_2(PR')_3]$, which has an octahedral geometry and an essentially linear Mo=N–C bond angle. Oxidation addition of RNCO ($R = Bu^t$, C_6H_4Me-*p*) to $[MoCl_2(PMePh_2)_4]$ afforded $[Mo(NR)Cl_2(CO)(PMePh_2)_2]$, although reaction of *p*-MeC_6H_4NCO with $[MoCl_2(PMe_3)_4]$ afforded an equilibrium mixture of $[Mo(NC_6H_4Me\text{-}p)Cl_2(CO)(PMe_3)_2]$ and $[Mo(NC_6H_4Me\text{-}p)Cl_2(PMe_3)_3]$. Reaction of *mer*-$[Mo(NPh)\{(Me_3SiN)_2C_6H_4\}(PMe_3)_3]$ with H_2 at −10 °C gave $[Mo(NPh)(\kappa^2\text{-}H_2)\{(Me_3SiN)_2C_6H_4\}(PMe_3)_3]$, (**47**) ($d_{H\text{–}H}$ = 1.17 Å), which transformed into *mer*-$[Mo(NPh)\{(Me_3SiN)(NH)C_6H_4\}(PMe_3)_3]$, with loss of $SiHMe_3$, at 30 °C.



(**47**)

The most common imido-Mo^{V} species are of the type *mer*-$[Mo(NR)Cl_3L_2]$ (L = neutral ligand, ∠Mo=N–C > 175°). A general synthetic route involved the comproportionation of $[Mo^{VI}(NR)_2Cl_2(dme)_2]$ with $[Mo^{IV}Cl_4(thf)_2]$, which gave *mer*-$[Mo(NR)Cl_3(dme)]$.

Phosphiniminato Mo^{V} complexes are relatively rare, but include *trans*-$[Mo(NPPh_3)Cl_4py]\cdot CH_2Cl_2$ (∠Mo=N–C 177°) and $[Mo(NPPh_3)Cl_5]^-$.

Research on imido complexes has been stimulated by the role of imido molybdenum(VI) species in ammonia and amine oxidation, and because of the isolobal relationship between $[Mo(NR)_2X_2]$ and the catalytically active Ti and Zr catalysts $[M(\eta^5\text{-}C_5H_5)_2X_2]$.[18] The NR^{2-} ligand may be regarded as a four-electron π-donor, being isoelectronic with the widely encountered oxo ligand. There are many parallels between the chemistry of molybdenum oxo and imido species, but imido species having four-coordination and the metal in a low oxidation state have no counterpart in oxomolybdenum chemistry. Imido ligands are classified as bent (∠Mo=N–R < 150°) with an sp^2-hybridized N atom, or essentially linear, with an sp-hybridized N atom. The only two substantiated cases of bent, nonchelating imido ligand complexes are $[Mo(NPh)_2(S_2CNEt_2)_2]$ and $[Mo(NAr)_2(pdpe)]$ [$pdpeH_2$ = pyridine-2,6-bis(2,2-diphenylethanol)], although there are some borderline cases. Mono(imido) complexes may be five-, six-, or seven-coordinate, with trigonal bipyramidal, octahedral, or pentagonal-bipyramidal geometries. Bis(imido) complexes may adopt, four-, five-, or seven-coordination, and tetrahedral, trigonal bipyramidal, square-pyramidal, or octahedral geometries are common. The two imido ligands adopt a cis arrangement, like all other π-donor ligand complexes of Mo^{VI}, in order to facilitate effective π-donation into empty metal orbitals. In addition, π-donor ligands prefer to be *cis* to the imido groups, the weakest π-donors binding to sites trans to the NR^{2-} ligand.[18,22]

Deprotonation of $[Mo^{VI}(NBu^t)_2(NHBu^t)_2]$ by LiMe in ether afforded $Li_4[Mo_2(NBu^t)_8]$ and reaction with AlX_3 (X = Me, Cl) afforded monomeric $[Mo(\mu\text{-}NBu^t)_4(AlX_2)_2]$. Reaction of $[Mo(NAr)_2Cl_2(thf)_2]$ with two equivalents of LiNHAr afforded the kinetically unstable $[Mo(NAr)_3Cl]^-$, which provided access to $[Mo(NAr)_3(PMe_3)]$ and $[Mo(NAr)_3Br]^-$.

Bis(imido) complexes, *cis*-$[Mo(NR)_2Cl_2L_2]$ (R = alkyl, aryl) were obtained from molybdate, amines, or anilines, Me_3SiCl and NEt_3 in solvents such as dme (L_2), pyridine, or thf (L). These were useful for the formation of other complexes by metathesis or ligand exchange, giving species such as $[Mo(NR)_2(OBu^t)_2]$, $[Mo(NAr)_2Cl(NEt_2)]$, and $[Mo(NAr)_2(NHAr)_2]$. Thiolato species $[Mo(NR)_2(SAr)_2]$ (R = Mes, Ar) have also been described. Monoanionic bidentate ligands such as deprotonated 8-hydroxyquinoline, $[OC_6H_4CH_2NMe_2\text{-}2]^-$ and a range of bidentate pyrrolide or arene species carrying NMe_2 groups (L–L) formed $[Mo(NR)_2Cl(L\text{–}L)]$ and $[Mo(NR)_2(L\text{–}L)_2]$.

Chelating imides have been generated by reaction of *o*-$(Me_3SiNH)_2C_6H_4$ with $[Mo(NPh)_2Cl_2(dme)]$. Complexes

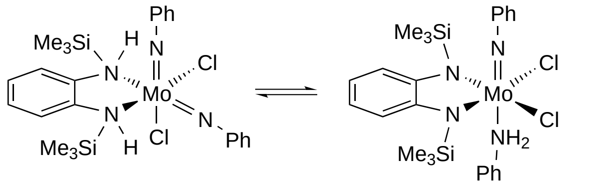


Figure 4 Imide/amine equilibria in $[Mo(NPh)_2\{(Me_3Si)(H)NC_6H_4\}Cl_2]$

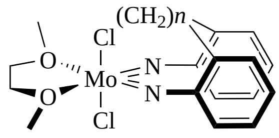
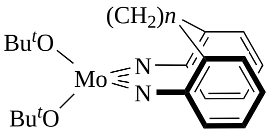
such as $[Mo(NPh)_2\{(Me_3Si)(H)NC_6H_4\}Cl_2]$ exist in an equilibrium such as that shown in Figure 4, and reaction with Lewis bases caused displacement of the aniline.

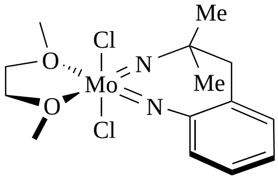
Because ansa metallocenes had been found to be effective polymerization catalysts, exploration of chelating bis(arylimido) complexes has been undertaken, typical examples being (**48**–**51**). In general, these have distorted octahedral structures with $d_{Mo\text{–}N}$ in the range 1.73–1.75 Å and ∠Mo=N–R in the range 155–162°. Complex (**51**), which is chiral, catalyzed the kinetic resolution of styrene oxide with an e.e of 30%.



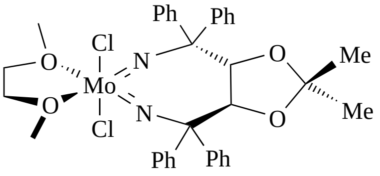
(**48**)



(**49**)



(**50**)

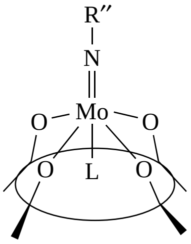


(**51**)

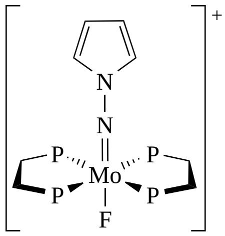
Reaction of $[MoCl_4(thf)_2]$ with *p*-tolylazide afforded $[Mo(Ntol)Cl_4(thf)]$ in which the thf is trans to the imido group, as expected.

The calix[4]arenes, $(HO)_4R'cal$ (Figure 1, R = H; R′ = H or Bu^t), reacted with Mo^{VI} imido species $[Mo(NAr)_2(OBu^t)_2]$, $[Mo(NBu^t)_2(NHBu^t)_2]$, $[Mo(NMes)_2Cl_2(dme)]$ giving calixarene complexes $[Mo(NR')(O_4R'cal)L]$ (R′ = H, R″ = Ar, L = NCMe; R′ = Bu^t, R″ = Ar, Bu^t, Mes, L = NCMe, $CNBu^t$, OH_2), (**52**).

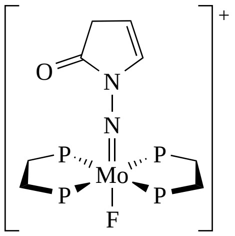
Reaction of substituted anilines with $[MoOCl_2(S_2CNEt_2)_2]$ afforded $[Mo(NAr)Cl_2(S_2CNEt_2)_2]$, the X-ray structural determination of the complexes with Ar = $C_6H_4NH_2$-2 confirming the expected pentagonal-bipyramidal geometry and an axial imido group (∠Mo=N–C 178°.). Similarly, seven-coordinate $[Mo(NR)(S_2)(S_2CNEt_2)_2]$ (R = alkyl, aryl) was obtained by reaction of $[MoO_2(S_2CNR'_2)_2]$ with RNCO



(**52**)



(**53**)



(**54**)

or $[Mo(NR)_2(S_2CNEt_2)_2]$ with H_2S or Lawesson's reagent. The Mo=N–C bond angles in these species varied from 165 to 179°.

Reaction of $[Mo(NSCl)Cl_4]$, $[Mo(N_3S_2)Cl_3]$, or $[\{MoNCl_3\}_4]$ with fluorine afforded $[Mo(=NCl)F_4]$ which converted to the octahedral $[Mo(NCl)F_4(solvent)]$ (solvent = NCMe or thf) in solution. The Mo=N–Cl bond angle in this and the related anion $[Mo(NCl)F_5]^-$ (as the $Na\{15\text{-}C\text{-}5\}^+$ salt), was in the range 176−177°.

Mixed imido-oxo complexes are relatively rare, but could be obtained by incomplete reaction of some amines and anilines with molybdate, Me_3SiCl, and NEt_3 in dme or pyridine, by reaction of $[MoO_2Cl_2(NCMe)_2]$ with one equivalent of RNCO followed by derivatization, or oxo/imido ligand metathesis of $[Mo(NMes)_2Cl_2(dme)]$ and $[MoO_2Cl_2(dme)]$. These complexes generally adopted distorted octahedral structures with cis imido and oxo ligands, with ∠Mo=N–C >154° (mostly >168°).

5.4 Hydrazido and Organohydrazido Complexes

There are parallels between the chemistry of imido and hydrazido complexes, mainly because of the common Mo=N– link. Nitrosyl hydrazido complexes are described in Section 5.8.

Hydrazido and organohydrazido ligands are important intermediates in the reduction or utilization of N_2 in biological and chemical systems, and their molybdenum complexes are potential catalysts for alkene polymerization and metathesis reactions.

Continued work on the protonation of dinitrogen complexes has afforded a range of complexes, including *syn,trans*-$[Mo(NNH_2)X(bdpe)(PPh_3)]^+$ [bdpe = $(Ph_2PCH_2CH_2)_2PPh$], and closely related derivatives. There has also been further development of electrochemical methods for the cleavage of hydrazido ligands to form ammonia. Reaction of *trans*-$[Mo(NNH_2)F(dppe)_2]^+$ with tetrahydro- and dihydrofurans afforded (**53**) and (**54**), work which led to the development of a system for the conversion of dinitrogen to pyrrole and *N*-aminopyrrole.

Alkylation of $[Na(thf)_n{}^+][Mo(N_2{}^-)(NRAr)_3]$ afforded $[Mo(NNR')(NRAr)_3]$. A range of *cis*-bis(diazenido) complexes containing bidentate S–S, N–S, S–O, N–O, and O–O ligands, or tetradentate N_2S_2 and N_4 macrocyclic ligands have been characterized. These are of the form $[Mo(NNAr)_2(L\text{–}L)_2]$, where L–L is a bidentate ligand or $[Mo(NNAr)_2](Q)$ (Q a tetradentate ligand), and they generally have distorted octahedral structures. Pentagonal-bipyramidal mono(diazenido) species $[Mo(NNAr)L_2]$ are also well-characterized.

Hydrazido(2−) complexes of Mo^V are uncommon, but include $[Mo(NNRR')X_3]$, $[Mo(NNRR')X_3L]$, and $[Mo(NNRR')X_3(L\text{–}L)]$ (R, R′ = Me, Ph, X = halide, L = PR_3, and L–L = dppe and other chelating diphosphines). Treatment of $[Mo(N_2)_2(dppe)(MePPh_2)_2]$ with HX/ZnX_2 afforded $[Mo(NNH_2)X_3(dppe)]$ (X = Cl, Br), the species with X = Br containing a linear hydrazido(2−) ligand, (∠Mo=N–N 173°). This complex reacted with further acid to release N_2, NH_3, and H_2NNH_2.

Molybdenum(VI) hydrazido(2−) complexes are frequently generated by the condensation of alkyl or aryl hydrazines with dioxomolybdenum precursors. Such reactions usually afforded mixed hydrazido or bis(hydrazido) species. $[Mo(NBu^t)_2Cl_2(dme)]$ reacted with $H_2NNPh_2{\cdot}HCl$ in refluxing dme to give *cis,trans*-$[Mo(NNPh_2)_2Cl_2(dme)]$ which, on treatment with Mg in the presence of PMe_3, afforded $[Mo(NNPh_2)_2Cl_2(PMe_3)_2]$. This latter species had an unexpected cis,cis,trans structure with linear hydrazido(2−) groups. Attempts to prepare it in a 'one-pot' procedure gave $[Mo(NNPh_2)(NHNPh_2)Cl_4]^-$, which contained both hydrazido(2−) and hydrazido(1−) ligands. The similar mixed ligand species *cis,trans*-$[Mo(NNRPh)(NHNRPh)X_2(acac)]$ was formed by reaction of $[MoO_2(acac)_2]$ with $H_2NNRPh{\cdot}HX$ (R = Me, Ph; X = halide).

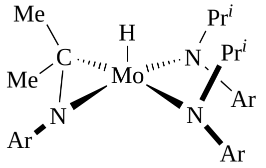
Monohydrazido complexes, formulated either as $[Mo(NNRR')Cl_4]$ or $[Mo(NNRR')Cl_3]$, were formed by reaction of $MoCl_5$ with H_2NNRR' (R = R′ = Ph; R = Me, R′ = Ph), but their precise structure remains uncertain.

Like their imido analogues, mixed hydrazido(2−) oxomolybdenum complexes have been prepared, including *cis,trans*-$[Mo(NNRPh)](O)X_2(bipy)$ (X = halide) and $[Mo(NNRPh)(O)(acac)_2]$.

5.5 Amido Complexes

The important compound $[Mo^{III}(NRAr)_3]$ (**45**) is conveniently made by reaction of $[MoCl_3(thf)_3]$ with $Li[NRAr](OEt_2)$ under argon. This species has a trigonal planar structure with $d_{Mo\text{–}N} = 1.96$ Å, the steric bulk of the R/Ar

groups being extremely important in preventing dinucleation and formation of Mo≡Mo bonds. These three-coordinate complexes are paramagnetic, $\mu = 3.4-3.9$ BM, consistent with an $S = 3/2$ ground state $\{a(\mathrm{n})^1 e(\mathrm{n})^2$ configuration$\}$. However, the complex formally represented as $[Mo(NPr^iAr)_3]$ contains a cyclometalated group and a hydride ligand, (**55**), but remains paramagnetic, $\mu = 2.1$ BM. This remarkable complex induced the cleavage of N_2 giving $[\{Mo(NPr^iAr)_3\}_2(\mu\text{-}N)]$ which could be reduced by sodium amalgam to a monoanion. This monoanionic species reacted further with N_2 to give $[Mo(N_2)(NPr^iAr)_3]^-$ and $[MoN(NPr^iAr)_3].[Mo(NPr^iAr)_3]$ also effected the reductive coupling of nitriles.



(**55**)

Reduction of (**46**) with magnesium in the presence of N_2 afforded $[(thf)_2Mg\{\text{–}N{=}N\text{–}Mo^{III}[N(CH_2CH_2NR)_3]\}_2]$ which, on treatment with Pd^{II} species, was converted to $[Mo^{III}(N_2)\{N(CH_2CH_2NR)_3\}]$. Reaction of this last compound with CO gave the corresponding carbonyl $[Mo^{III}(CO)\{N(CH_2CH_2NR)_3\}]$ which was converted by $SiClMe_3$ into $[Mo^{VI}\{{\equiv}C(OSiMe_3)\}\{N(CH_2CH_2NR)_3\}]$. Dinitrogen was displaced by isonitriles from $[Mo^{III}(N_2)\{N(CH_2CH_2NR)_3\}]$ giving $[Mo^{III}(CNR)\{N(CH_2CH_2NR)_3\}]$ which, on heating, afforded $[Mo^{IV}(CN)\{N(CH_2CH_2NR)_3\}]$ and which could be oxidized to $[Mo^{IV}(CNR)\{N(CH_2CH_2NR)_3\}]^+$.

Treatment of $[Mo(NMe_2)_4]$ with $LiNMe_2$ in thf afforded $[Li(thf)_2][Mo^{IV}(NMe_2)_6]$ in which octahedral $\{Mo(NMe_2)_6\}$ units are associated with two opposite face-capping $Li(thf)_2$ groups. Reaction of $[Mo(NMe_2)_4]$ with $PHPh_2$ or $LiPBu^t_2$ gave $[Mo(NMe_2)_2(PR_2)_2]$ which had a tetrahedral structure.

Direct protonation of *trans*-$[MoN(N_3)(dppe)_2]$ or *trans*-$[Mo(NH)(OMe)(dppe)]^+$ by triflic acid afforded *trans*-$[Mo(NH_2)(OH)(dppe)_2]^+$ which was octahedral, with $d_{Mo\text{–}N} = 2.05$ Å.

Paramagnetic $[Mo(NBu^tAr)_3X]$ (X = Cl, Br) was formed in reaction of $[Mo(NBu^tAr)_3]$ with X_2 or CH_2Cl_2. This tetrahedral species was an active catalyst for many alkyne metathesis reactions. The related triamidoamine complex (**46**) was obtained by reaction of $[MoCl_4(thf)_2]$ or $[MoCl_3(thf)_3]$ with $Li[N(CH_2CH_2NR)_3]$. This complex is paramagnetic ($\mu = 2.92$ BM) and has a trigonal bipyramidal structure. Reaction of (**46**) with $LiNMe_2$, ferrocenium triflate, and Me_3SiN_3 afforded $[Mo^{IV}(NMe_2)\{N(CH_2CH_2NR)_3\}]$, $[Mo^{IV}(OTf)\{N(CH_2CH_2NR)_3\}]$, and $[Mo^{VI}N\{N(CH_2CH_2NR)_3\}]$, respectively. Treatment of (**46**) with Me_3SiN_3 and with LiPHPh gave $[Mo^{VI}E\{N(CH_2CH_2NR)_3\}]$ (E = N or P), and reaction of $[Mo^{VI}N\{N(CH_2CH_2NR)_3\}]$ with ROTf afforded the imido species $[Mo^{VI}(NR)\{N(CH_2CH_2NR)_3\}][OTf]$ which could be reduced by lithium cyclooctatetraenide to give the Mo^V complex $[Mo^V(NR)\{N(CH_2CH_2NR)_3\}]$.

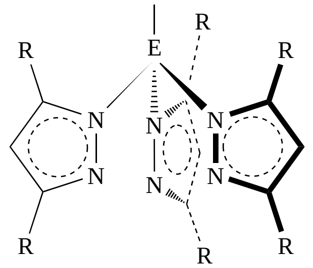
Oxidation of $[Mo(NRAr)_3]$ with pyridine N-oxide afforded the paramagnetic tetrahedral oxomolybdenum(V) compound $[MoO(NRAr)_3]$. Alkyl elimination from this afforded $[MoO(NAr)(NRAr)_2]$ while oxidation gave $[MoO(NRAr)_3]^+$.

Reaction of $[Mo(NMe_2)_4]$ with dry oxygen afforded blue $[Mo(NMe_2)_6]$ whose X-ray crystal structure confirmed its octahedral structure (overall T_h symmetry, $d_{Mo\text{–}N} = 2.03$ Å). Reaction of $[\{MoNCl_3\}_4]$ with $Me_3SiN{=}PR_3$ (R = Me, Ph) produced $[Mo(N{=}PR_3)_4]^{2+}$, while reaction of $[MoN(N{=}PPh_3)_3]$ with BF_3OEt_2 afforded $[Mo(N{=}PPh_3)_4][BF_4]_2$. Phosphiniminato complexes have been reviewed.[23]

5.6 Tris(pyrazolyl)borato and Related Triaza Ligand Complexes

5.6.1 *Tris(pyrazolyl)borato Complexes*

The chemistry of complexes containing a variety of tris(pyrazolyl)borato ligands (**56**) expanded substantially during the past decade, primarily in connection with oxomolybdenum(V), $\{MoO\}^{3+}$, and nitrosyl complexes containing the groups $\{Mo(NO)\}^{3+}$ and $\{Mo(NO)\}^{2+}$. These two sets of complexes were characterized by their ability to undergo reversible or quasi-reversible electron transfer processes which, in some cases, involved ligand redox behavior in addition to oxidation or reduction of the metal. Tris(pyrazolyl)borato ligands afforded a remarkable series of complexes where the interrelationship between electronic and magnetic behavior could be linked to the topology of the bridging ligands. The chemistry and physical behavior of this group of complexes has been extensively reviewed.[24–27]



(**56**)

Tp^-, E = H, R′ = R = H
Tp^{*-}, E = H, R′ = H, R = Me
Tpm^{*-}, E = H, R = Me

Oxidation of $[Mo(CO)_3Tp^*]^-$ by ferrocenium salts afforded the paramagnetic mononuclear Mo^I species $[Mo(CO)_3Tp^*]$ ($\mu = 2.13$ BM) which was octahedral (pseudo C_{3v} symmetry).

Related phosphine-substituted complexes [Mo(CO)$_2$(PR$_3$)Tp] have also been described.

The largest range of complexes containing molybdenum in the formal oxidation state I are the nitrosyls [Mo(NO)Tp*XL] (L = pyridines, pyrrolidine, and related species). These complexes are octahedral, with linear Mo–N–O bond arrangements, and are paramagnetic (1 unpaired electron). These complexes underwent one-electron oxidation and one-electron reduction, achieved chemically and electrochemically, spectroelectrochemical examination revealing that the former process was largely metal-based, whereas the latter had substantial ligand involvement.[24,27]

Paramagnetic di-, tri- and tetranuclear species containing the {Mo(NO)Tp*X} core linked by a range of oligopyridines have also been described, these complexes also exhibiting extensive redox behavior. For example, complexes containing the dipyridyl ligand 4,4′-NC$_5$H$_4$CH=CHC$_5$H$_4$N (dpe) existed within a five-membered electron transfer chain, (equation 3). Spectroelectrochemical studies of the reduced species showed that electron addition afforded metal-stabilized radical anion and dianionic ligands. Oxidation to the mono- and dicationic species was mainly a metal-based process and usually appeared in cyclic voltammograms as two coincident oxidation waves. An exception occurred with the pyrazine complex [{Mo(NO)Tp*Cl}$_2$pz], where all five species could be identified electrochemically and were characterized by EPR and IR spectrometry. Species containing $\{Mo(NO)\}^{2+}$ have one unpaired electron (17 valence electrons), and in the oligonuclear species, there was substantial evidence for long range (up to 30 Å) but weak coupling between the unpaired spins. The magnetic behavior of dinuclear complexes was examined extensively, leading to reliable predictions of antiferromagnetic and ferromagnetic coupling between the unpaired spins on each $\{Mo(NO)\}^{2+}$ center.[24,26,27]

$$[\{Mo(NO)Tp^*Cl\}_2(dpe)]^{2+} \rightleftharpoons [\{Mo(NO)Tp^*Cl\}_2(dpe)]^{+} \rightleftharpoons [\{Mo(NO)Tp^*Cl\}_2(dpe)]^{0} \rightleftharpoons [\{Mo(NO)Tp^*Cl\}_2(dpe)]^{1-} \rightleftharpoons [\{Mo(NO)Tp^*Cl\}_2(dpe)]^{2-} \quad (3)$$

Halogen oxidation of $[Mo(CO)_3Tp]^-$ afforded the Mo^{II} complex [Mo(CO)$_3$TpX] (X = Br, I), and oxidation of the Tp* analogue by PhCl$_2$ or I$_2$ afforded the unstable [Mo(CO)$_3$Tp*X] which converted to paramagnetic [Mo(CO)$_2$Tp*X] (μ = 2.8–3.0 BM) on standing. The hydride ligand in the unstable [Mo(CO)$_3$Tp*H] was located between a pair of CO ligands, giving an overall 3:4 coordination environment.

A very large series of nitrosyl complexes, [Mo(NO)Tp*XY] has been described where X and Y are halide, alkoxide, aryloxide, alkyl or arylamide, alkyl or aryl thiolate groups. These diamagnetic $\{Mo(NO)\}^{3+}$ species are regarded as containing 16 valence electrons, with a formal metal oxidation state of II, assuming NO$^+$ binding, and the metal center could be regarded as electron-deficient. As a consequence, there is substantial p_π–d_π bonding between the donor atoms of X and Y and the metal. The complexes adopt octahedral structures, and may be reversibly reduced to paramagnetic (17 valence electron) monoanionic species, the potentials for this electron transfer process being dependent on the donor atoms and their substituents, occurring over a range of at least 2000 mV, probably currently the largest range for a single family of compounds.[24] A substantial number of di- and trinuclear species containing the redox-active $\{Mo(NO)\}^{3+}$ core, in which the bridging ligands are di or tri-hydroxy benzene and naphthalene derivatives, or their amino analogues, were also prepared. These complexes could be reduced electrochemically in at least two reversible or quasi-reversible one-electron steps, and several mixed-valence (mono-reduced) species exhibiting Class 1, 2, and 3 behavior were identified using a combination of spectroelectrochemical, EPR, and IR spectral techniques. Ferrocene moieties have been attached to the {Mo(NO)Tp*X} core giving, for example, [FeC$_6$H$_4$CH=CHC$_6$H$_4$NHMo(NO)Tp*X]. These complexes were also redox active, the ferrocenyl group undergoing one-electron oxidation and the $\{Mo(NO)\}^{2+}$ group a one-electron reduction. These complexes were dipolar and solvatochromic, some of them exhibiting nonlinear optical behavior (frequency doubling) which could be switched on and off chemically and electrochemically.[6]

Treatment of [MoO$_2$Tp*X] with one equivalent of PR$_3$ in a donor solvent such as pyridine, NCMe, or DMF afforded mono-oxo Mo^{IV} complexes [MoOTp*X(solvent)], via a transient phosphine oxide adduct. One such adduct, [MoOTp^{Pr}(OPh)(OPEt$_3$)] was structurally characterized, and a number of more stable oxo-Mo^{IV} species, such as [MoOTp*X(py)] (X = OPh or SPh), have also been prepared. All have distorted octahedral geometries, with short Mo=O bonds. Dinuclear Mo^{IV} species [{MoOTp*Cl}$_2$(μ-N–N)] (N–N = dipyridines) are apparently diamagnetic, but could be oxidized electrochemically in two steps corresponding to Mo^{IV}Mo^V and Mo^{V}Mo^V species. Reduction appeared to mainly involve the bridging dipyridine ligands.

As mentioned above, [Mo^{VI}O$_2$Tp^{x}X] (x various pyrazolyl ring substituents) was readily reduced to relatively stable Mo^V species, $[MoO_2Tp^xX]^-$. These species exhibited broad anisotropic EPR signals at g 1.92, but readily protonated affording the conjugate acids [MoOTp^x(OH)X] whose EPR signals are less anisotropic (g ca. 1.94). Treatment of [MoO$_2$Tp^{x}X] with SH$^-$ caused reduction to $[MoO_2Tp^xX]^-$ and then replacement of one oxo group by a sulfido group, giving $[MoOSTp^xX]^-$. The EPR spectra of these species were characterized by a larger g-value and reduced anisotropy compared to their dioxo-analogues.

An extensive range of complexes of the type [MoOTp*XY] (X, Y = halide and/or alkoxide, aryloxide, alkyl or arene thiolate, bidentate 1,2-arenediolates, arenedithiolates, ethane diolates, and dithiolates) has been prepared. These octahedral species underwent quasi-reversible one-electron reductions

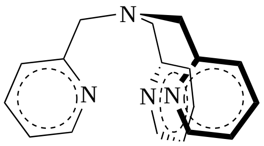
affording Mo^{IV} species, and, depending on the attached ligands, could also be oxidized to a monocation formally containing Mo^{VI}. These species have been studied by a range of spectroscopic and structural techniques partly because of their biological relevance. A large range of di- and trinuclear complexes containing the {MoOTp*Cl} fragment connected by bis- and tris-phenolato bridging ligands has also been prepared and characterized. These complexes exhibited a rich electrochemistry, like their $\{Mo(NO)\}^{2+/1+}$ analogues described above.[24] From spectroelectrochemical studies, it was established that oxidation of the dinuclear species could involve metal- or ligand-based processes, this system demonstrating 'non-innocent' behavior analogous to dithiolene and related complexes.[25] These complexes also displayed significant electronic and magnetic interactions between the metal centers which are controlled by the structure and properties of the bridging ligand. Detailed magnetic studies led to an understanding of the relationship between bridging ligand topology and magnetic coupling between the paramagnetic $\{MoO\}^{3+}$ ($S = 1/2$) centers, thereby facilitating the prediction of antiferromagnetic or ferromagnetic behavior.[26,27] The oxidized forms of some of the polynuclear complexes showed intense near-IR absorptions, behavior which lead to the construction of an embryonic electrochromic device.[28]

Thio-Mo^V species are implicated in the turnover of industrial catalysts and enzymes, but mononuclear thiomolybdenyl complexes are very rare. [$MoSTp^*Cl_2$], one of the first complexes of this type, was obtained by reaction of [$MoOTp^*Cl_2$] with B_2S_3, and related species [$MoSTp^*X_2$] (X = aryloxide, alkane thiolate, X_2 = catecholate, benzene dithiolate) have been described.

The Mo^{IV} complex [$MoOTp^z(S_2PR_2)$] reacted with B_2S_3 affording the thio analog, [$Mo^{IV}STp^z(S_2PR_2)$]. Both the oxo and thio complexes could be oxidized in a reversible one-electron step, affording monocationic Mo^V species. Oxidation of [$MoSTp^z(S_2PR_2)$] afforded the Mo^{VI} complex [$MoOSTp^z(S_2PR_2)$], which was also electrochemically active, reducing in a one-electron process to the corresponding Mo^V monoanion.

The Mo^{VI} and related Mo^V species [$MoNTp^*Cl_2$] and [$MoNTp^*Cl_2$]$^-$ were formed when [$MoNCl_5$]$^{2-}$ was treated with Tp^{*-}. However, only [$MoNTp^*(N_3)_2$] was formed when [$MoN(N_3)_4$]$^-$ reacted with Tp^{*-}.

Oxidative decarbonylation of [$Mo(CO)_3Tp^x$]$^-$ (Tp^x = Tp or Tp*, (**56**)) by dimethyldioxirane, [$Mo(CO)_3Tpm^*$]$^-$ or [$Mo(CO)_3$(tpa)] by HNO_3 afforded [MoO_3L]^z, $z = -1$, where L = Tp, Tp*, or Tpm; $z = 0$, L = tpa (**57**).



(**57**)

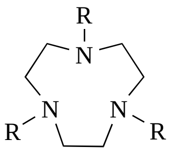
A very large number of dioxo-Mo^{VI} species have been prepared in the development of biomimicry of Mo^{VI}–Mo^{IV} interconversion. Reaction of [MoO_2X_2] (X = halide), [$MoO_2X_2L_2$] (L = $OPPh_3$, dmso), or [$MoO_2(NCS)_4$]$^{2-}$ with Tp^x–afforded *fac*-[MoO_2Tp^xX], from which closely related alkoxides or thiolates (X = OR, OAr, SR, SAr) were obtained by metathetical exchange. These complexes have distorted octahedral geometry and, unlike most dioxo-Mo^{VI} complexes, underwent reversible or pseudoreversible one-electron reductions, affording stable, epr-active Mo^V species. The redox potentials were influenced strongly by the nature of X, and correlated with Hammett functions. These Mo^{VI} complexes are extremely important models in the development of synthetic enzyme models encompassing many biologically relevant oxidation states, oxo centers, and reactions, and provided vital information on electronic structures. The oxygen-atom and coupled electron–proton transfer chemistries of this and related systems have been reviewed.[29]

[$MoOSTp^xX$] was formed by O-atom abstraction from [MoO_2Tp^xX] using PR_3. [$MoOTp^x(OPR_3)X$] was formed initially, and treatment of this with sulfur-donors ultimately afforded the oxo-thio complex. Sulfur donation from propylene sulfide to [$Mo^{IV}OTp^x(S_2PR_2)$] afforded [$MoOSTp^x(\kappa^1$-$S_2PPr_2)$] whose structure was confirmed crystallographically, the oxo-thio center being stabilized by an S···S interaction. Reduction or oxidation of these complexes afforded corresponding Mo^V complexes, [$MoOSTp^x(\kappa^1$-$S_2PPR_2)$]$^-$ and [$MoOTp^x(S_3PR_2)$]$^-$ with concomitant S–S bond formation. The related [$MoOSTp^{Pr}(OPh)$] was formed in a reaction of [$MoOTp^{Pr}(OPh)(OPEt_3)$] with propylene sulfide, preedge XAS studies indicating that this species was monomeric in solution. On isolation as a solid, it afforded the redox-active dinuclear species [$\{MoOTp^{Pr}(OPh)\}_2(\mu$-$S_2)$].

Reaction of primary amines with [$Mo^VOTp^*Cl_2$] in the presence of air and NEt_3 afforded the mixed oxo-imido species [Mo(NAr)OTp*Cl]. The hydrazido(2−) complexes [$Mo(NNR_2)Tp^xCl$] (Tp^x≡Tp, Tp*) have also been structurally characterized.

5.6.2 *Cyclic Triaza Ligand and Related Complexes*

Halogenation of [$Mo(CO)_3(R_3tacn)$] (**58**) (R = H, Me) afforded [$Mo(CO)_3(R_3tacn)X$]$^+$ (X = Br, I) analogous to [$Mo(CO)_3TpX$] and which may have 3:4 'piano stool' geometry.



(**58**)

The cationic species $[Mo(CO)_2(NO)(R_3tacn)]^+$, obtained by reaction of $[Mo(CO)_3(R_3tacn)]$ with HNO_3 or with $NOBF_4$, could be converted into $[Mo(NO)(R_3tacn)X_2]^+$ and $[Mo(NO)(R_3tacn)X(OR')]^+$, but these complexes did not exhibit the rich electrochemistry of their tris(pyrazolyl)borato analogues $[Mo(NO)Tp^*X_2]$ and $[Mo(NO)Tp^*X(OR)]$.

Oxidation of $[Mo(CO)_3(R_3tacn)]$ (R = Me, Pr^i) by $SOCl_2$, Br_2, or HI afforded paramagnetic $[Mo^{III}(R_3tacn)X_3]$, (μ = 3.9–4.7 BM), many of which species exhibited phosphorescence. Less sterically hindered triazacyclononanes gave dinuclear compounds. The related complexes $[MoTpm^*X_3]$ were obtained similarly, and underwent reversible oxidation to Mo^{IV} species.

Nitric acid oxidation of $[Mo(R_3tacn)X_3]$ afforded $[Mo^VO(Me_3tacn)X_2]^+$ which could be converted to $[MoO(Me_3tacn)(OMe)_2]$. These complexes, like their Tp* analogues, could be reduced to Mo^{IV} species, and dinuclear Mo^V and mixed-valence species were also isolated.

The structures of $[Mo^{VI}O_3(tacn)]\cdot 3H_2O$ (tacn = (**58**), R = H) and related species where R = Pr^i, have been confirmed crystallographically as octahedral with C_{3v} symmetry, and $[MoO_3(R_3tacn)]$ could function as a tridentate O-donor ligands to Co^{II} and Fe^{II}. Salts of $[MoO_2(Me_3tacn)X]^+$ ($Me_3tacn \equiv$ (**58**), R = Me) have also been characterized.

5.7 Porphyrin, Phthalocyanine, and Related Macrocyclic Complexes

Reduction of $[Mo^{IV}Cl_2(porph)]$ by Zn/Hg under CO afforded diamagnetic *cis*-$[Mo^{II}(CO)_2(porph)]$ which has trigonal prismatic geometry (porph = ttp) with the CO ligands staggered with respect to the Mo–N vectors. An additional ligand L (1-methylimidazoles, py, OMe^-, etc.) could bind trans to the CO ligands giving $[Mo(CO)_2(porph)L]^{n-}$, and the CO groups could be displaced by pyridine giving octahedral $[MoL_2(porph)]$. The metal–metal bonded $[\{Mo(pc)\}_2]$, obtained by reacting [Mo(O)(pc)] with molten PPh_3, reacted with molten $[NBu_4]CN$ giving paramagnetic *trans*-$[Mo(CN)_2(pc)]^{2-}$ (μ = 3.15 BM).

Reaction of bromine-activated [Mo(O)(pc)] or [MoN(pc)] with molten PPh_3 yielded the molybdenum(III) complex *trans*-$[MoBr_2(pc)]^-$, which was paramagnetic (μ = 3.84 BM) and had an octahedral geometry. This complex underwent pc-centered and metal-centered electrochemical oxidation.

Reaction of $[Mo^{IV}Cl_2(porph)]$ with Li_2S and Na_2Se afforded $[Mo^{IV}E(porph)]$ (E = S or Se), both of which reacted with PPh_3 giving $[Mo^{II}(porph)(PPh_3)_2]$.

Reaction of $[\{Mo(porph)\}_2]$ with Me_3SiN_3 affords the nitrido species $[Mo^VN(porph)]$ which had a square-pyramidal structure ($d_{Mo–N}$ = 1.63 Å). The nitrido group was reactive, treatment of [MoN(porph)] with H^+, S_8, and RI affording $[Mo(NH)(porph)]^+$, [Mo(NS)(porph)], and [Mo(NR)(porph)]I, respectively. Related phthalocyanine complexes, [MoN(pc)] were also described.

A wide range of five- and six-coordinate species $[Mo^VO(porph)]^+$ and *trans*-$[Mo^VO(porph)X]^{0,+1}$, where X = OH^-, alkoxide, halide, H_2O, dmso, and so on, were prepared. These complexes have characteristic EPR spectral properties and their electro-, photo-, and catalytic chemistry have been reviewed.[30] Similar phthalocyanine complexes, [Mo(O)(pc)X] (X = Cl, Br, OH) may be prepared by treatment of [MoO(pc)] with $FeCl_3$ or Br_2 or by oxidation of [MoO(pc)] in the presence of OH^-. Black–purple $[Mo(O)(pc)]I_3$ was obtained by reaction of 1,2-dicyanobenzene, MoO_3, and iodine at 210°, had a square-pyramidal structure, and was paramagnetic (μ = 1.72 BM).

Three types of Mo^{VI} porphyrin complexes are well-established: *cis*-$[MoO_2(porph)]$, *cis*-$[MoO(O_2)(porph)]$, and *trans*-$[Mo(O_2)_2(porph)]$ (porph(2−) = 5, 10, 15, 20-R_4-porphyrinato(2−); R = mes, Ph, tol, etc.).[30] These complexes could be oxidized and/or reduced in processes which involved both the metal and the porphyrinato ligands, leading to radical cation and radical anion complexes. $[Mo^{VI}O(O_2)(porph)]$, obtained by reaction of $[Mo^{IV}(O)(porph)]$ with O_2, was stable in the dark but lost O_2 on irradiation, with full or partial regeneration of [MoO(porph)].

5.8 Nitrosyl Complexes

Tris(pyrazolyl)borato and related cyclic triaza ligand complexes of the general class [Mo(NO)Tp′XY], in which the metal adopts a formal oxidation state of 0, I, or II, have been described above in Section 5.6.

Dinitrosyl complexes of the type $[Mo^0(NO)_2X_2]$ were obtained by reduction of $[MoO_4]^{2-}$ by hydroxylamine in the presence of added anionic ligands X, where X = dithiocarbamate, dithiocarboxylate, alkoxide, 2-$NH_2C_6H_4E^-$ (E = O or S), hydroxamic acids. Reaction of $[Mo(NO)_2(dttd)]$ ($dttd^{2-}$ = (**22**)) with hydrazine or $NaBH_4$ gave the κ^2-hydroxylamide, $[Mo(NO)(ONH_2)(dttd)]$.

[Mo(NO)Cl(dttd)] reacted with R_3O^+ giving the alkyl complex $[Mo(NO)(R)Cl(dttd)]^+$ (R = Me or Et). Treatment of [Mo(NO)Cl(dttd)] with LiSR afforded the thiolato complexes [Mo(NO)(SR)(dttd)] which could be reduced by $LiBu^n$ affording paramagnetic $[Mo^I(NO)(SR)(dttd)]^-$. Reaction of [Mo(NO)(SPh)(dttd)] with S_8 afforded a species containing a κ^2-S–SPh, a sulfur atom being readily extracted by PPh_3 to regenerate the starting phenylthiolato species. Treatment of [Mo(NO)(SAr)(dttd)] with PR_3 caused elimination of ArSSAr and reduction of the metal center, affording $[Mo^I(NO)(PR_3)(dttd)]$, and oxidation of this with halogen caused regeneration of Mo^{II} species, [Mo(NO)X(dttd)]. Treatment of $[Mo(NO)(PR_3)(dttd)]$ with R'_3O^+ effected alkylation of the sulfur macrocycle, giving $[Mo^I(NO)(PR_3)(R'dttd)]^+$. Similar behavior occurred when [Mo(NO)(SPh)(dttd)] was treated with HBF_4. Reaction of [Mo(NO)Cl(dttd)] with NH_2NR_2 gave the κ^2-hydrazido(1−) species $[Mo(NO)(NHNR_2)(dttd)]$, which has pseudo-octahedral structure with $d_{Mo–NH}$ = 2.10 Å, $d_{Mo–NR_2}$ =

2.17 Å (R = Me), and ∠N–Mo–N = 38°, with a linear Mo–N–O bond. Reaction of this species with HCl caused regeneration of the nitrosyl chloro precursor without cleavage of the hydrazido N–N bond. Other hydrazido complexes are described in Section 5.4.

6 COMPLEXES WITH P- AND As-DONOR ATOMS

6.1 Phosphido and Arsenido Complexes

The first terminal phosphido complexes containing Mo^{VI}, $[MoP(NRAr)_3]$, were prepared by reacting $[Mo(NRAr)_3]$ with P_4 in diethyl ether (R = Bu^{t,Pr^i}, 2-Ad; Ar). These complexes have pseudotetrahedral structures with $d_{Mo–P}$ = 2.11–2.20 Å. They reacted with Ar′N_3 (Ar′ = mesityl) and with dimethyldioxirane and S_8 or episulfides to give [Mo(P=NAr′)$(NRAr)_3$] and [Mo(–P=E)$(NRAr)_3$] (E = O or S), respectively. Related five-coordinate complexes $[MoE\{N(CH_2CH_2NR)_3\}]$ were obtained by reaction of $[MoCl\{N(CH_2CH_2NR)_3\}]$ (**46**) with LiEHPh (E = P or As). Trigonal bipyramidal $[MoAs\{N(CH_2CH_2NR)_3\}]$ has an axial terminal arsenido group, $d_{Mo–As}$ = 2.25 Å.

6.2 Tertiary Phosphine and Related Complexes

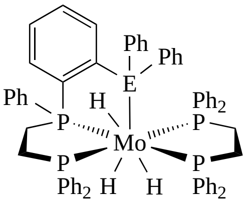
A convenient synthesis of the Mo^0 species $[Mo(PMe_3)_6]$ was developed, involving reaction of $MoCl_5$ dissolved in PMe_3 with Na/K. In solution, this species was in equilibrium with $[MoH(CH_2PMe_2)(PMe_3)_4]$. The chelating diphosphine complexes $[Mo(dmpe)_3]$ and $[Mo(tmbp)_3]$ (tmbp = 4, 4′-5,5′-tetramethyl-2,2′-diphosphine) have trigonal prismatic structures and significant Mo → P electron transfer was inferred from structural and computational studies. The thermally stable phosphinine complex, $[Mo(PC_5H_5)_6]$ was prepared by reduction of $MoCl_5$ with Mg in the presence of the ligand in THF. It has an almost ideal octahedral geometry, with $d_{Mo–P}$ = 2.38 Å.

Molybdenum(II) complexes containing CO, PR_3, and halides is very extensive, and research continued to consolidate this area, which has been comprehensively reviewed.[31,32] A significant number of complexes in this group are seven-coordinate, adopting distorted capped octahedral structures.

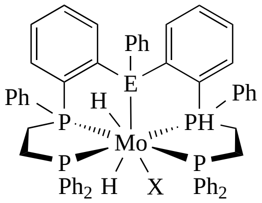
The molybdenum(III) complexes $[MoCl_4(PRR'_2)_2]^-$ (R = Et, R′ = Ph; R = Ph, R′ = Et; R = R′ = Et) were obtained by ligand exchange at $[MoCl_4(thf)_2]^-$ or by phosphine reduction and ligand exchange at $[MoCl_4(thf)_2]$. Treatment of $[MoX_3(thf)_3]$ with dppe afforded the paramagnetic *mer*-$[MoX_3(dppe)(thf)]$ (μ = 3.13–3.81 BM), the thf being readily displaced by acetonitrile of PMe_3. $[MoI_3(dppe)(PMe_3)]$ has a very rare fac structure, most other species, for example, $[MoI_3(PMe_3)_3]$ adopting a mer geometry.

Protonation of $[MoH_4(PR_3)_4]$ (PR_3 = PEt_3, PBu_3, PMe Ph_2) by anhydrous HX gave paramagnetic Mo^{IV} species $[MoHX_4(PR_3)_2]^-$, $[PHBu_3][MoXCl_3(PBu_3)_2]$ having pentagonal-bipyramidal structure with apical Cl and the hydride ligand located between the equatorial PBu_3 ligands.

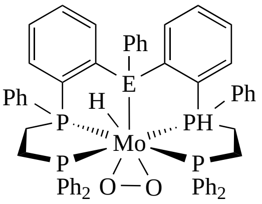
Reaction of $[MoH_4(dppe)_2]$ with EH_2Ph_2 (E = Si or Ge) afforded either the Mo^{IV} complexes (**59**) or ((**60**)) (X = H), depending on reaction conditions. Complex (**60**) (E = Si, X = H) reacted with O_2 or SiH_3Ph giving (**61**) (E = Si) and (**60**) (E = Si; X = SiH_2Ph). Complexes (**60**) and (**61**) (E = Si) catalyzed the formation of dmf from $NHMe_2$ and CO_2/H_2 in benzene at 110 °C.



(**59**)



(**60**)



(**61**)

Trans-bis(oxo) and bis(chalcogenido) Mo^{IV} complexes $[MoE_2(L_4)]$, where E = O, S, Se, L = PMe_3, or L–L = dppe or dppee, have distorted octahedral structures. Those where E = O (L = dppe, dppee) have tetragonally compressed structures with axial oxo groups, $d_{Mo–O}$ = 1.80–1.82 Å, ∠O–Mo–O = 180°. Reaction of $[MoO_2(dppe)_2]$ with non-coordinating acids afforded $[MoO(OH)^*(dppe)_2]^+$ whereas, with coordinating acids or acid/X^- mixtures, *trans*-$[MoOX(dppe)_2]^+$ was formed. *Trans*-$[MoE_2(PMe_3)_4]$ (E = S, Se, Te) was prepared by reaction of $[Mo(PMe_3)_6]$ with H_2S, H_2Se, Se, or Te/PMe_3.

7 METAL–METAL BONDS AND CLUSTERS

7.1 Dinuclear Complexes

Several reviews of dimolybdenum compounds having multiple bonds have delineated this area comprehensively.[33–36] In very general terms, the formal bond order for dimolybdenum compounds ranges from four to less than unity. The range of bond lengths is wide, from ca. 2.06 Å, representative formally of a quadruple bond, to ca. 3.27 Å, formally representing a single bond, although significant variations occur depending

on the nature of the terminal and bridging ligands. Quadruply bonded species are normally encountered in $Mo^{II}Mo^{II}$ complexes, triply bonded species in $Mo^{III}Mo^{III}$ compounds, and doubly bonded species in $Mo^{IV}Mo^{IV}$ complexes. Dinuclear complexes containing the $Mo^{V}Mo^{V}$ core usually have Mo–Mo single bonds. A great many multiply bonded dimolybdenum complexes carry the η^5-C_5H_5 or related ligands, which are not discussed here.

7.1.1 Complexes Containing $Mo^{I}Mo^{I}$

This is a relatively small group of complexes. Reaction of $[2,6\text{-}(Ph_2P)_2C_6H_3NMe]^-$, the anion of 2,6-bis(diphenylphosphino)-*N*-methylaniline, with $[Mo(CO)_6]$ gave the bridged species $[(OC)_4Mo\{\mu\text{-}PPh_2(C_6H_3NMe)PPh_2\}Mo(CO)_4]^-$. Oxidation of this by bromine afforded $[(OC)_3Mo(\mu\text{-Br})\{\mu\text{-}PPh_2(C_6H_3NMe)PPh_2\}Mo(CO)_3]$, which contains a Mo–Mo bond ($d_{Mo–Mo} = 2.99$ Å).

7.1.2 Complexes Containing $Mo^{II}Mo^{II}$

A very wide range of compounds containing the $Mo_2{}^{4+}$ core have been synthesized, including halides, mono- and bidentate tertiary phosphines, alkoxides, carboxylates, calixarenes, formamidinates, and related ligands. Most of these may be described as containing quadruply bonded dimolybdenum cores, having an eclipsed geometry, as represented by (a) in Figure 5. The normal range of metal–metal bond distances in this category of compounds is 2.06–2.17 Å. The dinuclear acetonitrile complex, $[Mo_2(NCMe)_8]^{4+}$ was a particularly useful precursor, and also could bind one or two additional acetonitrile ligands in the axial positions.

Potentially bidentate ligands, such as the formamidinates $[RNCR'NR]^-$, the monoanion derived from 2,6-bis(phenylamino)pyridine and 7-methyl-1,8-naphthyridin-2-one, and others, formed complexes with a 'paddle wheel' structural motif, Figure 5(d), and some of these complexes could be oxidized by ferrocenium cations to give mixed-valent species. Generally, such oxidation led to a slight lengthening of the metal–metal bond.

7.1.3 Complexes Containing $Mo^{III}Mo^{III}$

Dinuclear thiolato bridged complexes play a key role in the synthesis of cluster compounds and in biological

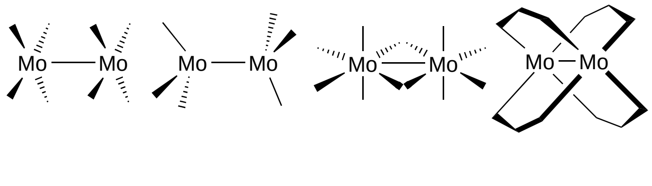


Figure 5 Structural types containing Mo–Mo quadruple bonds

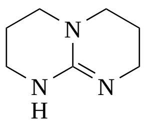
and catalytic applications.[37] A common structural motif in this group of dinuclear complexes is the edge-sharing bioctahedral geometry, represented by (b) in Figure 5, which can be derived directly from molecular constituents or by oxidative addition across a dinuclear Mo^{II} quadruple bond. This group of complexes has an ethane-like geometry. Typical species included $[Mo_2(\mu\text{-Cl})_2(\mu\text{-OAc})_2Cl_2(PEt_3)_2]$ ($d_{Mo–Mo} = 2.61$ Å), $[Mo_2(\mu\text{-O})(\mu\text{-OMe})(en)_4]^{3+}$ ($d_{Mo–Mo} = 2.44$ Å), and $[Mo_2(OCMe_2Ph)_6]$ ($d_{Mo–Mo} = 2.24$ Å).

Oxidation of $[Mo^{II}_2(hpp)_4]$ by Ag^+ afforded $[Mo_2(hpp)_4]^{2+}$ (hppH = (**62**)) ($d_{Mo–Mo} = 2.14$ Å as $BF_4{}^-$ salt), which formally contains the $Mo^{III}Mo^{III}$ core. Reaction of $[Mo_2(NCMe)_8]^{4+}$ with bis(diphenylphosphine)amine, dppa, in acetonitrile containing water generated $[Mo_2(\mu\text{-}\eta^2\text{-NCMe})(\mu\text{-O})(\mu\text{-dppa})_2(NCMe)_4]^{2+}$ ($d_{Mo–Mo} = 2.42$ Å, but in the absence of water, $[Mo_2(\mu\text{-}\eta^2\text{-NCMe})\{\mu\text{-NC(Me)PPh}_2\text{N PPh}_2\}(\mu\text{-dppa})(NCMe)_5]^{3+}$ ($d_{Mo–Mo} = 2.49$ Å) was formed. Reaction of $[Mo_2(OCH_2Bu^t)_6]$ with PMe_3 led to the formation of a mixed-valent compound containing Mo^{II} and Mo^{IV}, $[Mo_2(\mu\text{-}OCH_2Bu^t)(OCH_2Bu^t)_3(\mu\text{-O})(PMe_3)_4]$. This species, which contains a formal Mo=Mo bond ($d_{Mo–Mo} = 2.49$ Å), has one six-coordinate metal center, formally Mo^{II}, and one trigonal bipyramidal center, formally Mo^{IV}. The compound reacted with CO to give $[Mo_2(CO)(\mu\text{-}OCH_2Bu^t)(OCH_2Bu^t)_3(\mu\text{-O})(PMe_3)]$, in which the CO group is bonded to the Mo^{II} site.



(**62**)

7.1.4 Complexes Containing $Mo^{IV}Mo^{IV}$

The imido-formamidinato complex $[Mo_2(Ph_2NCHNPh_2)_2(\mu\text{-NPh})Cl_5]^-$ ($d_{Mo–Mo} = 2.53$ Å) could be prepared by cleavage of the formamidinate ligand in the reaction between $[MoCl_3(thf)_3]$ or $[MoCl_4(NCMe)_2]$ and diphenylformamidine and Cl^- in refluxing dichlorobenzene. Treatment of $Mo_2S_2Cl_6$ with tetrahydrothiophene (tht, SC_4H_8) afforded $[Mo_2(\mu\text{-}S_2)(\mu\text{-tht})Cl_6(tht)_2]$ ($d_{Mo–Mo} = 2.77$ Å), but reaction with Me_2S gave a paramagnetic mixed-valence $Mo^{V}Mo^{IV}$ complex $[Mo_2(\mu\text{-S})(\mu\text{-}S_2)Cl_5(SMe_2)]$ ($d_{Mo–Mo} = 2.74$ Å).

7.1.5 Complexes Containing $Mo^{V}Mo^{V}$

Reaction of $[MoOI_4(H_2O)]^-$ with Ph_3PO in acetonitrile afforded a mixture of $[MoOI_3(OPPh_3)_2]$ and the dinuclear $[Mo_2(O)_4I_2(OPPh_3)_3]$ ($d_{Mo–Mo} = 2.56$ Å). In the latter, each metal center is coordinated by two bridging and one terminal oxo ligand, with the iodo ligand and three phosphine oxides unsymmetrically coordinated, resulting in different coordination environments for each metal atom, *viz.*

$[MoO_3I_2]$ and $\{MoO_3(OPPh_3)_3\}$. Reaction of $[Mo_2(NMe_2)_6]$ with C_6F_5OH afforded the anion $[Mo_2O_2(\mu\text{-}O)_2(OC_6F_5)_4]^{2-}$ ($d_{Mo–Mo} = 2.56$ Å).

When $[Mo_2(OAc)_4]$ reacted with Na_2mnt (mnt = *cis*-1,2-dithiolato-1,2-dicyanoethene) in dry methanol, the species $[Mo_2(\mu\text{-}S)_2(O)(S)(mnt)_2]^{2-}$ ($d_{Mo–Mo} = 2.86$ Å) was formed. Reduction of $[(MoO_3)_2(\mu\text{-edta})]^{4-}$ by dithionite at pH = 6 afforded $[Mo_2(\mu\text{-}S)(\mu\text{-}O)O_2(\mu\text{-}N,N'\text{-}C_{10}H_{12}N_2O_8)]^{2-}$ ($d_{Mo–Mo} = 2.67$ Å), which contains the $\{Mo_2(\mu\text{-}S)(\mu\text{-}O)O_2\}$ core, and by refluxing $[\{Mo_2S_7Br_4\}_n]$ in $PBu_3{}^n$, $[Mo_2(\mu\text{-}S)_2O_2Br_4]^{2-}$ ($d_{Mo–Mo} = 2.86$ Å) could be formed.

Addition of benzene dithiol to $[Mo_2(S_2)_6]^{2-}$ under slightly different conditions afforded $[Mo_2S_2(bdt)_2]^{2-}$ ($d_{Mo–Mo}$ = 2.87 Å) and $[Mo_2S_4(S_2)_2]^{2-}$ ($d_{Mo–Mo} = 2.82$ Å).

7.2 Polyoxoanions

Polyoxometallate ions containing molybdenum form an enormous range of compounds which have been reviewed extensively[7,8] (*see also* ***Polyoxometalates***). They may be subdivided into (i) isopolyanions containing only Mo and (ii) heteropolyanions where other metal and/or nonmetal atoms may be present in the core structure.

7.2.1 Isopolyanions

The Mo^{VI} isopolyanions $[Mo_7O_{24}]^{5-}$, $[Mo_8O_{26}]^{4-}$, and their protonated analogs,[38] exist in aqueous NaCl/$NaClO_4$ media, and salts of $[Mo_{36}O_{110}(H_2O)_{16}]^{8-}$ have been isolated from such solutions. Salts of the octamolybdate ion occur in at least six different structural forms, containing $\{MoO_4\}$, $\{MoO_5\}$, and $\{MoO_6\}$ coordination units in various combinations. The structure of $[Mo_{36}O_{110}(H_2O)_{16}]^{8-}$ consisted of four pentagonal-bipyramidal Mo centers, and was loosely described as a centrosymmetric dimer of $\{Mo_{17}\}$ units linked by two *cis*-MoO_2 groups. The nitrosyl species $[Mo_{36}(NO)_4O_{108}(H_2O)_{16}]^{12-}$ is isostructural with $[Mo_{36}O_{110}(H_2O)_{16}]^{8-}$, with four $\{MoO_6\}$ units being substituted by $\{[Mo(NO)^{3+}]O_6\}$.

Mixed-valence species, often referred to as heteropoly blues or browns, were generated by reduction of stable polyoxomolybdates. These anions contain a significant number of Mo^V centers, typically 12 in $[(H_2)Mo_{12}O_{28}(OH)_{12}(Mo^{VI}O_3)_4]^{6-}$, 26 in $[H_{14}Mo_{37}O_{112}]^{14-}$, and 38 in $[H_{13}Mo_{43}O_{112}\{(OCH_2)_3CMe\}_7]^{10-}$, but may have six diamagnetic $\{Mo^V_2O_4\}^{2+}$ units assembled into an ε-Keggin conformation.

7.2.2 Heteropolyanions

The Keggin-structure anions α-$[XMo_{12}O_{40}]^{n-}$ are frequently investigated because of their potential and real catalytic applications.[8] A number of capped Keggin structures have been identified in which the α-Keggin core carries one or two VO units, as in $[PMo_5V_7O_{40}(VO)]^{7-}$, $[PMo^V_6Mo^{VI}_6O_{40}(V^{IV}O)_2]^{5-}$, and the extended chain structure $[\{(V^VO_4)Mo^{VI}_8V^{IV}_4O_{36}(V^{IV}O)_2\}_n]^{7n-}$. Species capped by As^{III} and *cis*-$MoO_2{}^{2+}$ groups, for example, $[H_4As^VMo^V_8Mo^{VI}_4OP_{40}As^{III}_2]^-$ and $[SiMo^V_4Mo^{VI}_8O_{40}(Mo^{VI}O_2)_2]^{4-}$ have also been characterized.

The diphosphate anions $[O_3PXPO_3]^{4-}$ (X = O or CH_2) have been incorporated into polymolybdate structures. The species $[(O_3PXCPO_3)Mo_6O_{18}(H_2O)]^{4-}$ has an unsymmetrical structure in which one PO_3 group is centered in a ring consisting of six-corner- and edge-shared $\{MoO_6\}$ octahedra. This complex may be an intermediate in the molybdate-catalyzed hydrolysis of $[P_2O_7]^{4-}$. In aqueous organic solvents, the diphosphate anion reacted with molybdate giving $\{(P_2)PMo_{18}\}$, $\{(P_2)Mo_{15}\}$, and $\{(P_2)Mo_{12}\}$-complex oxyanions. The first of these was shown to be $[P_2Mo_{18}O_{61}]^{4-}$, a structure based on the fusion of two $\{PMo_9O_{34}\}$ units, whereas the $(P_2)Mo_{15}$-species was shown to be a dimer of the lacunary ion, namely, $[(P_2O_7)_2Mo_{30}O_{90}]^{8-}$, at least in the solid state.

7.2.3 Mesoscopic Polyoxomolybdate Anions

Increasing numbers of extremely large polyoxomolybdate anions, with ring-shaped and hollow structures have been described. These contain mixed-valence polymolybdate anions that are constructed using common building blocks containing Mo_2, Mo_6, and Mo_8 units, some of which have no independent stable existence. This area of cluster molybdenum chemistry has been extensively reviewed.[39–42]

These extremely large structures are reproducibly generated by self-assembly processes involving careful reduction of aqueous molybdate solutions. The most common building block in these species is a cluster generated by an $\{MoO_4(NO)\}$ or $\{MoO_5\}$ pentagonal bipyramid surrounded by five edge-shared MoO_6 octahedra. Depending on the solution acidity, the degree of reduction, and the presence of appropriate linker groups, pentagonal $\{Mo\}_6$ clusters could be induced to form spherical (icosahedral) 'Keplerates' $[\{Mo^V_2O_4(OAc)\}_{30}\{(Mo)Mo_5O_{21}\}(H_2O)_{612}]^{42-}$ containing the $\{Mo_{72}(Mo^V_2)_{30}\}$ core, and $[Mo_{72}Fe_{30}O_{252}(OAc)_{12}\{Mo_2O_7(H_2O)\}\{H_2MoO_8(H_2O)\}(H_2O)_{91}]$ containing the $\{Mo_{72}(Fe^{III})_{30}\}$ core, or cyclic $[(Mo_{154}O_{420}(NO)_{14})(OH)_{28}(H_2O)_{70}]^{28-}$.

Surfactant-encapsulated $[\{Mo^V_2O_4(OAc)\}_{30}\{(Mo)Mo_5O_{21}\}(H_2O)_{612}]^{42-}$ and $\{Mo_{57}V_6\}$oxyanions have been obtained using dimethyldioctylammonium ions and have been fully characterized, and a Keggin molybdophosphate anion has been incorporated within $[Mo_{72}Fe_{30}O_{252}(OAc)_{12}\{Mo_2O_7(H_2O)\}\{H_2MoO_8(H_2O)\}(H_2O)_{91}]$. Furthermore, a two-dimensional layer structure has been generated using two $\{Mo_{72}(Fe^{III}_{30})\}$ units linked via an Fe–O–Fe bond. The species $[Mo_{72}Fe_{30}O_{252}(OAc)_{12}\{Mo_2O_7(H_2O)\}\{H_2MoO_8(H_2O)\}(H_2O)_{91}]$ contains 30 Fe^{III} $S = 5/2$ centers, and the magnetic

properties of this highly complex polyoxoanion have been satisfactorily explained using classical and quantum Heisenberg models.

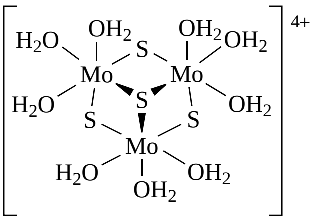
Even larger species have been generated by ageing solutions containing $[(MoO_3)_{176}(H_2O)_{80}H_{32}]$ species, which then acquired two $\{Mo_{36}\}$ 'hubcaps' assembling a giant $\{Mo_{248}\}$ cluster. Crystallization of an acidified solution containing sodium molybdate and sodium dithionite afforded an even more massive $\{Mo_{368}\}$ 'hedgehog' cluster anion, $[H_nMo_{368}O_{1032}(H_2O)_{240}(SO_4)_{48}]^{48-}$.[43]

7.3 Cluster Compounds Containing Chalcogenide Atoms

There are three main cluster types encountered in this group of important compounds: the incomplete cuboid $\{Mo_3(\mu_3\text{-E})(\mu\text{-E})_3\}^{4+}$, the sulfur-rich incomplete cuboid $\{Mo_3(\mu_3\text{-E})(\mu,\mu'\text{-E})_3\}^{4+}$, and the cuboid$\{Mo_4E_4\}^{5+}$.[9] These species are described as 'cuboidal' since this illustrates the best approximation in what are usually somewhat distorted structures. Several other cluster types, including $\{Mo_3E_7\}^{4+}$, $\{Mo_4S_6\}^{2+}$, and a range of heterometallic species $\{Mo_3M'E_4\}^{4+}$, $\{Mo_6M'_2E_8\}^{8+}$, and $\{Mo_6M'E_8\}^{4+}$ are also known.

7.3.1 Trinuclear Clusters, $[Mo_3E_4]^{4+}$

Improved methods of generating the green cluster $[Mo_3S_4(H_2O)_9]^{4+}$ (**63**) have been developed. New routes have been discovered involving reduction of $[NH_4]_2[Mo_2(S_2)_2Cl_8]$ by Pb or In in concentrated HCl, reaction of $[NH_4]_2[MoS_4]$ with $NaBH_4$, or abstraction of sulfur from S_2 bridges in $[Mo_3(S)(S_2)_3Cl_6]^{2-}$ by PPh_3, followed by cation-exchange chromatography – the yields from this last process being almost quantitative. The cluster $[Mo_3S_4(H_2O)_9]^{4+}$ could be a source of the mixed oxo-sulfido species $[Mo_3O_nS_{3-n}(H_2O)_9]^{4+}$ ($n = 1-3$), since it reacted with an excess of $NaBH_4$ to give mainly $[Mo_3OS_3(H_2O)_9]^{4+}$ together with a smaller amount of the other species. In all of these clusters, the capping position is occupied by a sulfur atom.



(**63**)

Brown $[Mo_3Se_4(H_2O)_9]^{4+}$ was obtained by aquation of $[Mo_3Se_7Br_6]^{2-}$ and subsequent Se abstraction from the resulting $[Mo_3Se_7(H_2O)_6]^{4+}$ by PPh_3. It could also be produced by reduction of $[Mo_2O_2Se_2(cys)_2]^{2-}$ (cys = cysteinate) by $NaBH_4$ in HCl solutions, the products from cation-exchange chromatography of this reaction mixture also affording $[Mo_3O_2Se_2(H_2O)_9]^{4+}$, $[Mo_3OSe_3(H_2O)_9]^{4+}$, and $[Mo_4Se_4(H_2O)_{12}]^{5+}$. The cluster $[Mo_3O_2Se_2(H_2O)_9]^{4+}$ was also obtained by reduction of $[Mo_2O_2Se_2(cys)_2]^{2-}$ with $[MoCl_6]^{3-}$ in HCl solution, while $[Mo_3O_3Se(H_2O)_9]^{4+}$ was formed by electrochemical reduction of $[Mo_2O_2(cys)_2]^{2-}$ in the presence of grey Se powder, or by reduction of $[Mo_3O_2Se_2(H_2O)_9]^{4+}$ with a very large excess of $NaBH_4$.

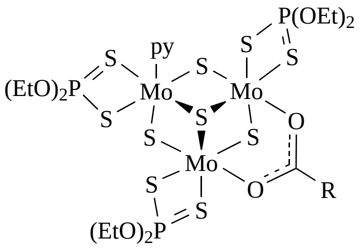
The mixed metal clusters $[Mo_2WS_4(H_2O)_9]^{4+}$ and $[MoW_2S_4(H_2O)_9]^{4+}$ were obtained by reaction of an equimolar mixture of $[WS_4]^{2-}$ and $[Mo_2O_2S_2(cys)_2]^{2-}$ with $NaBH_4$, followed by chromatographic separation of the resulting mixtures. However, an alternative method of synthesis made use of selective oxidative degradation of mixed metal tetranuclear clusters $[Mo_xW_{4-x}S_4(H_2O)_{12}]^{5+}$, where invariably only one W atom was lost, this procedure avoiding tedious chromatographic separations.

Water-exchange ligand substitution studies with $[Mo_3S_4(H_2O)_9]^{4+}$ using ^{17}O nmr studies showed that there are two types of kinetically distinct water ligands. Those trans to the capping S (c-H_2O) exchanged about 10^5 times more slowly than those trans to the bridging S and cis to the capping S atoms (d-H_2O). Replacement of μ_3-O by μ_3-S and then by μ_3-Se in $[Mo_3O_4(H_2O)_9]^{4+}$ resulted in a retardation in substitution of the d-H_2O by factors of 6 and 11, respectively. However, replacement of μ-O by μ-Se and μ-Se resulted in labilization with a factor of 10 (S) and 20 (Se) for each μ-O replaced.

The labile formato complex $[Mo_3S_4(O_2CH)_8(H_2O)]^{4-}$ was obtained by elution of $[Mo_3S_4(H_2O)_9]^{4+}$ on a cation-exchange column with formate in aqueous formic acid. The acetylacetonato complexes $[Mo_3E_4(acac)_3(py_3)]^+$ (E = S, Se) were obtained by reacting $[Mo_3E_4(H_2O)_9]^{4+}$ with Hacac and pyridine; the py ligands being trans to the μ_3-S atom. In acidic solution, $[Mo_3S_4(H_2O)_9]^{4+}$ reacted with the monovacant lacunary anions $[SiW_{11}O_{39}]^{8-}$ and $[P_2W_{17}O_{61}]^{10}$ giving $[\{(SiW_{11}O_{39})Mo_3S_4(H_2O)_3(\mu\text{-OH})\}_2]^{10-}$ and $[\{(P_2W_{17}P_{61})Mo_3S_4(H_{21}O)_3(\mu\text{-OH})\}_2]^{14-}$. The central core of these clusters consisted of two $\{Mo_3S_4(H_2O)_3\}^{4+}$ units connected by two OH^- groups that were cis to the μ_3-S units. A series of clusters containing the nitrilotriacetate ion (nta^{3-}) were also prepared, including $[Mo_3S_4(Hnta)_3]^{2-}$, $[Mo_3S_4(Hnta)_2(nta)]^{3+}$, $[Mo_2WS_4(Hnta)_3]^{2+}$, and $[MoW_2S_4(Hnta)_3]^{2+}$. The coordination mode of the $Hnta^{2-}$ ligand was tridentate, with one CO_2H group remaining unbound to the cluster core. The complexes were redox active, undergoing three consecutive one-electron reductions representing formal oxidation state changes from M_3^{IV} to M_3^{III}. Coordination of the $\{Mo_3S_4\}^{4+}$ core by 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol (taci) and its methylated (tris-dimethylamino) analogue (tdci) was achieved by reaction of taci and tdci with $[Mo_3S_7Br_6]^{2-}$ and PPh_3 in ethanol. This afforded $[Mo_3S_4(taci)_3]^{4+}$ and $[Mo_3S_4(tdci)_3]^{4+}$.

In solution, isomers were observed, corresponding to the binding of taci and tcdi in N,N,N, N,N,O, and N,O,O coordination modes, but no evidence for O,O,O-bonding was detected. Reaction of polymeric $[\{Mo_3S_7Cl_4\}_n]$ with PPh_3 in refluxing pyridine afforded $[Mo_3S_4py_5Cl_5]$, which reacted with I_2 giving $[Mo_3S_4py_6Cl_3]I$.

A range of diethyldithiophosphato ($[S_2P(OEt)_2]^-$, dtp) complexes have been characterized, including $[Mo_3S_4(dtp)_3(O_2C_6H_4X\text{-}o)py]$ (X = OH, NO_2) (**64**), $[Mo_3S_4(dtp)_3(O_3SC_6H_4Me)py]$, and $[Mo_3Se_4(dtp)_3(OAc)py]$. In most of these complexes, the $\{Mo_3(\mu_3\text{-}S)(\mu\text{-}S)_3\}^{4+}$ core is preserved, each Mo atom carrying a bidentate dtp, the carboxylate or sulfonate group bridging two of the Mo atoms and the remaining Mo atom being coordinated by the py ligand. When more than one dtp ligand was substituted by a carboxylato ligand, the latter functioned as bridging groups, as in $[Mo_3(\mu_3\text{-}O)(\mu\text{-}S)_3(dtp)_2(\mu\text{-}O_2CR)_2(py)]$ (R = Me, Ph). Reaction of $[Mo_3ES_3(H_2O)_9]^{4+}$ (E = O or S) with Hdtp, followed by recrystallization from acetonitrile, afforded $[Mo_3ES_3(dtp)_4(NCMe)]$. Treatment of $MoCl_3{\cdot}3H_2O$, P_4S_{10}, and H_2S in ethanol under conditions less acidic than those used to prepare $[Mo_3S_4(dtp)_3(\mu\text{-}dtp)(H_2O)]$ afforded $[Mo_3OS_3(dtp)_3(\mu\text{-}dtp)(H_2O)]$ in which the cluster core was identified as $\{Mo(\mu_3\text{-}O)(\mu\text{-}S)\}^{4+}$, isomeric with the more commonly encountered $\{Mo_3(\mu_3\text{-}S)(\mu\text{-}O)(\mu\text{-}S)_2\}^{4+}$.



(**64**)

Reaction of $[Mo_3Se_7(S_2CNEt_2)_3]^+$ with PPh_3 afforded $[Mo_3Se_4(S_2CNEt_2)_4(PPh_3)]$, and treatment of $[Mo_3Te_7\{S_2P(OPr)_2\}_3]^+$ with PBu_3 in the presence of benzoates gave $[Mo_3Te_4\{S_2P(OPr)_2\}_3(\mu\text{-}O_2C_6H_4X)(PBu_3)]$ (X = X or o-NH_2) whose structure was similar to that of (**64**) shown above.

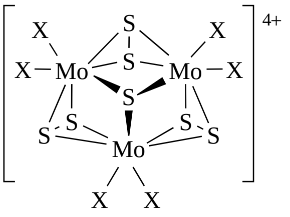
Reaction of $[Mo_3S_7X_6]^{2-}$ (X = Cl, Br) with PPh_3 or dppe in methanol afforded $[Mo_3S_4X_4(PPh_3)_3]$ and $[Mo_3Se_4X_4(dppe)_3]X$ in good yields, an improvement on reactions involving polymeric $[\{Mo_3Se_7X_4\}_n]$.

Treatment of $[\{Mo_3S_7Cl_4\}_n]$ with PEt_3 followed by reduction with Mg at −20 °C and addition of dppe, afforded the paramagnetic $[Mo_3S_4Cl_3(dppe)_2(PEt_3)]$ which contains the $\{Mo_3S_4\}^{3+}$ core. The Mo–Mo bonds in the reduced species (2.81 Å) are longer than those in analogous phosphine complexes of $\{Mo_3S_4\}^{4+}$.

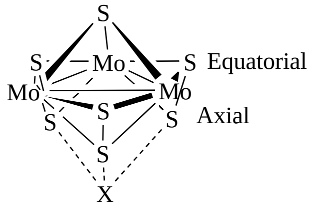
Addition of KCN in hot aqueous solution to $[\{Mo_3Se_7Br_4\}_n]$ gave $[Mo_3Se_4(CN)_9]^{5-}$ which is redox active, undergoing a one-electron reduction process affording a species with a formal $Mo^{III}Mo^{IV}_2$ core.

7.3.2 Trinuclear Complexes, $[Mo_3E_7]^{4+}$

The chalcogen-rich $[Mo_3S_7X_6]^{2-}$ (X = Cl, Br, I) (**65**) could be prepared either by melting the polymer $[\{Mo_3S_7X_4\}_n]$ with PPh_4X at 300 °C or grinding with NEt_4X in a ball mill. However, these anions could also be obtained by treatment of $[Mo_3S_7(S_2)_3]^{2-}$ with hot concentrated HX or by treatment with Cl_2 or Br_2 in acetonitrile. Reaction of $[Mo_3S_7(S_2)_3]^{2-}$ with Me_3CBr in DMF provided a high-yield route to $[Mo_3S_7Br_6]^{2-}$, which was an important precursor to the formation of other species containing the $\{Mo_3(\mu_3\text{-}S)(\mu,\mu'\text{-}S_2)_3\}^{4+}$ core. In some structures of $[Mo_3S_7X_6]^{2-}$, there was weak secondary coordination of an additional halide ion to the three axial atoms of the S_2 groups (**66**).



(**65**)



(**66**)

A range of complexes containing the $\{Mo_3S_7\}^{4+}$ core have been described, including $[Mo_3S_7(NCS)_6]^{2-}$, $[Mo_3S_7(S_2CNEt_2)_3]^+$, $[Mo_3S_7(dtp)_3]^+$, and $[Mo_3S_7(S_2PR_2)_3]^+$. Most of these clusters, in which the chelating ligands form a four-membered ring with each metal, were obtained from $[Mo_3S_7Br_6]^{2-}$, although the last was produced by reaction of $[Mo(CO)_6]$ with $R_2P(S)SSP(S)R_2$ in refluxing toluene. Cluster complexes containing chelating ligands which formed a six-membered ring with each metal included $[Mo_3S_7\{Ph_2P(E)NPPh_2(E)\}_3]^+$ (E = O or S), $[Mo_3S_7(tdt)_3]^{2-}$ (tdt = toluene-3,4-dithiolate), and $[Mo_3S_7(cat)_3]^{2-}$ (cat = benzene-1,2-diolate, catecholate).

The main characteristic of the Mo_3S core was found in the distinction between the equatorial and axial chalcogen atoms in the μ_2-S ligands (see (**66**) without additional X). Generally, the equatorial Mo–S bond distance was longer than the Mo–S axial distance. Consequently, the equatorial S atoms were more labile towards abstraction and substitution, as was demonstrated by the preparation of S^{32}/S^{34}-labelled isotopomers of $[Mo_3S_7(S_2)_3]^{2-}$. Vibrational spectra of a range of salts of $[Mo_3S_{13}]^{2-}$ established that they are correctly represented as $[Mo_3(\mu_3\text{-}S)(\mu\text{-}S)_3(\mu,\mu'\text{-}S_2)_3]^{2-}$.

The selenium clusters $[Mo_3Se_7X_6]^{2-}$ were obtained by reaction of $[\{Mo_3Se_7X_4\}_n]$ with X^- in the same way as their sulfur analogues. Complexes containing

chelating ligands analogous to their sulfur counterparts were also characterized, for example, $[Mo_3Se_7(S_2CNR_2)_3]^+$ and $[Mo_3Se_7(dtp)_3]^+$, while $[Mo_3Se_7(phen)_3]^{4+}$ was obtained by melting $[\{Mo_3Se_7X_4\}_n]$ with 1,10-phenanthroline.

Reaction of alkali metal polyselenides with MoO_3 under hydrothermal conditions afforded, inter alia, $[Mo_3Se_7(Se_2)_3]^{2-}$, whose structure is similar to its sulfur analog, $[Mo_3OSe_6(Se_2)_3]^{2-}$ and $[Mo_6Se_{27}]^{6-}$. The last species consists of an Se^{2-} ion sandwiched between two $[Mo_3Se_7(Se_2)_3]^{2-}$ units, a structure similar to that found in $[\{Mo_3Se_7(S_2CNEt_2)_3\}_2Se]$ ($Se^{2-}\cdots Se_{ax} = 2.81–3.04$ Å). Calculations showed that there is significant electron transfer from the Se^{2-} ion to the antibonding orbitals of the μ-Se_2 groups. $K_8[Mo_9Se_{40}]$, obtained by reaction of MoO_3, K_2Se_2, and water at 135 °C contains $[Mo_3Se_{13}]^{2-}$, an aggregate of three $\{Mo_3Se_7\}$ clusters linked by two Se^{2-}. One of the latter is the capping μ_3 atom of an Mo_3Se_7 cluster (Se···Se = 3.13 Å). Another Se^{2-} is sandwiched between two Mo_3Se_7 clusters as in $[Mo_6Se_{27}]^{6-}$ described above. The cluster can be described therefore as three $[Mo_3Se_{13}]^{2-}$ and one Se^{2-}, linked by short Se···Se contacts. A related anion, $[Mo_3Se_{18}]^{2-}$, obtained under the same conditions as $[Mo_9Se_{40}]^{8-}$ but using a different reagent ratio, contained the $\{Mo_3Se_7\}^{4+}$ core, coordinated by a $Se_3{}^{2-}$ and bridging $Se_4{}^{2-}$, thereby generating infinite chains, $[\{Mo_3Se_7(Se_3)(Se_4)_{4/2}\}_n]^{2n-}$. Reaction of Mo metal with K_2Se_4 in water at 140 °C afforded $K_{12}[Mo_{12}Se_{56}]$. In this species, the $\{Mo_3Se_7\}^{4+}$ cluster units are bound into tetrameric aggregates (clusters of clusters) via Se_3 bridges. The Mo atoms, which do not participate in the intercluster bridging, are coordinated by terminal $Se_2{}^{2-}$, each of them bound to the three axial Se atoms in the cluster. The cluster anion $[Mo_3Se_{42}]^{6-}$ contained $[\{Mo_3(\mu_3\text{-Se})(\mu\text{-}\kappa^2\kappa'^2\text{-}Se_2)_3(\kappa^2\text{-}Se_2)(\mu\text{-}\kappa^2\text{-}Se_5)(\kappa^1\text{-}Se_5)\}_2(\mu\text{-}\kappa^2\text{-}Se_4)]$.

The tellurium cluster anion $[Mo_3Te_7(CN)_6]^{2-}$ was prepared by heating Mo, Te, and I_2 in appropriate atomic ratios at 380 °C, followed by abstraction of the amorphous powder so formed with aqueous cyanide. In contrast to its sulfur and selenium analogues, this cyano cluster was inert to exchange of the Te atoms. The cluster core $\{Mo_3Te_7\}^{4+}$ has a strong affinity for I^-, via $Te_{ax}\cdots I$ contacts. In the reaction of $Mo_3Te_{10}I_{10}$ with $K_2S_2P(OR)_2$, $[Mo_3Te_7\{S_2P(OR)_2\}_3]^+$ (R = Et, Pr^i) was formed.

Clusters containing the $\{Mo_3O(S_2)_3\}^{4+}$ core are only known with dtp^-, *viz.* $[Mo_3O(S_2)_3(dtp)_3]^+$. Substitution of the axial S atom by O led to contraction of the Mo–Mo distances, from 2.72 to 2.63 Å. The $\{Mo_3O(Te_2)_3\}^{4+}$ core was found in $[Mo_3O(Te_2)_3(en)_3][In_2Te_6]$, which was formed by solvothermal reaction of Li_2Te, K_2Te, $MoCl_5$, $InCl_3$, and Te in ethylenediamine at 180 °C. Replacement of the apical Te by O resulted in contraction of the Mo–Mo distances.

Clusters containing the cores $\{Mo_3S(S_{eq}–Se_{ax})_3\}^{4+}$ and $\{Mo_3Se(S_{eq}–Se_{ax})_3\}^{4+}$ have been identified. Thus, chalcogen-exchange reactions between $[Mo_3S_7Cl_6]^{2-}$ and $P(Se)Ph_3$ or KNCSe resulted in selective substitution of the equatorial S atoms, giving, for example, $[Mo_3S(SSe)_3Cl_6]^{2-}$. With KNCSe, $[Mo_3S_7(SSe)_3(NCSe)_6]^{2-}$ was formed. These reactions were irreversible and the $\{Mo_3S(SSe)_3\}^{4+}$ core did not revert to $\{Mo_3S(S_2)_3\}^{4+}$ even when treated with an excess of $P(S)Ph_3$ or KNCS. Reaction of $[Mo_3S_7(S_2CNR_2)_3][S_2CNR_2]$ with KNCSe afforded $[Mo_3S(SSe)_3(S_2CNR_2)_3][SeCN]$ which contained essentially linear polymer chains $\{S–Se\cdots Se\cdots S–Se\cdots Se\cdots\}_n$ due to short (2.9–3.3 Å) cation–anion interactions. Aquation of $[Mo_3S(SSe)_3Br_6]^{2-}$ afforded $[Mo_3S(SSe)_3(H_2O)_6]^{4+}$ which reacted with PPh_3 to give $[Mo_3S_4(H_2O)_9]^{4+}$. Reaction of $[Mo_3Se_4(H_2O)_9]^{4+}$ with P_4S_{10} in ethanolic HCl afforded $[Mo_3Se(S_{eq}–Se_{ax})_3(dtp)_3]Cl$.

Reaction of $[NH_4]_2[Mo_3S_{13}]$ with an excess of PMe_3 in thf produced $[Mo_3(\mu_3\text{-}S)_2(\mu\text{-}S)_3(PMe_3)_6]$. This symmetrical species contains a trigonal bipyramidal core, in which an equilateral triangle of Mo atoms is capped by two S atoms and bridged by three other S atoms. All six PMe_3 groups were equivalent and showed only one sharp ^{31}P NMR signal in solution. This species was electroactive, underwent quasi-reversible one-electron reduction and oxidation. Reaction of $MoCl_3{\cdot}3H_2O$ with H_2S in ethanolic HCl afforded $[Mo_3(\mu_3\text{-}S)_2(\mu\text{-}S)_3Cl_6]^{3-}$ which reacted with $(dtp)^-$ giving $[Mo_3S_2(dtp)_3]$.

7.3.3 *Tetranuclear Cubic $\{Mo_4E_4\}^{5+}$ Clusters*

The structure of $[Mo_4S_4(H_2O)_{12}]^{5+}$ consisted of two interpenetrating Mo_4 and S_4 tetrahedra of different sizes, leading to a distorted pseudocubic geometry. The Mo–Mo distances are 2.80 Å, the cluster is paramagnetic, exhibiting Curie-like behavior with $\mu = 1.78$ BM between 300 and 20 K. The corresponding selenium cluster $[Mo_4Se_4(H_2O)_{12}]^{5+}$ was made in low yield by reaction of $[Mo_2O_2Se_2(cys)_2]^{2-}$ with $NaBH_4$ and is less stable than its sulfur analog in air, degrading to $[Mo_3Se_4(H_2O)_9]^{4+}$. Both pentacationic clusters are redox active, being reversibly reduced to $[Mo_4E_4(H_2O)_{12}]^{4+}$ and reversibly oxidized to $[Mo_4E_4(H_2O)_{12}]^{6+}$. The air-sensitive $[Mo_4S_4(H_2O)_{12}]^{4+}$ was prepared by reduction of $[Mo_4S_4(H_2O)_{12}]^{5+}$ electrochemically or using $NaBH_4$ or $[M(H_2O)_6]^{2+}$ (M = V or Cr). Oxidation of $[Mo_4S_4(H_2O)_{12}]^{5+}$ to $[Mo_4S_4(H_2O)_{12}]^{6+}$ was achieved by controlled stoichiometric addition of *cis*-$[VO_2(H_2O)_4]^+$, but it was not very stable, decaying spontaneously with formation of $[Mo_3S_4(H_2O)_9]^{4+}$. Controlled electrolytic oxidation of $[Mo_4S_4(H_2O)_{12}]^{5+}$ afforded only $[Mo_3S_4(H_2O)_9]^{4+}$ and $[Mo_2O_2S_2(H_2O)_6]^{2+}$. The oxo-cluster $[Mo_4OS_3(H_2O)_{12}]^{5+}$ was prepared by reduction of $[Mo_3OS_3(H_2O)_9]^{4+}$ by iron wire, its constitution being confirmed crystallographically.

Reaction of $[MM'_2E_4(H_2O)_9]^{4+}$ (M, M′ = Mo, W) with $K_4Mo_2Cl_8$ afforded the heterometallic cubes $[MoW_3S_4(H_2O)_{12}]^{5+}$, $[Mo_3WS_4(H_2O)_{12}]^{5+}$, $[Mo_2W_2S_4(H_2O)_{12}]^{5+}$, and $[MoW_3Se(H_2O)_{12}]^{5+}$. Air-oxidation or oxidation by $[Fe(H_2O)_6]^{3+}$ initially afforded $[Mo_nW_{4-n}E_4(H_2O)_{12}]^{6+}$ (n = 1, 2 or 3), but these subsequently exclusively lost one W atom giving trinuclear clusters of the type $[Mo_nW_{3-n}S_4(H_2O)_9]^{4+}$.

Electrochemical studies of the mixed metal cuboidal clusters revealed that, like $[Mo_4S_4(H_2O)_{12}]^{5+}$, they could be reversibly reduced and oxidized in one-electron steps. The corner-shared double cube $[Mo_7S_8(H_2O)_{18}]^{8+}$ is described in the Section 7.3.5.

Reaction of the reduced cluster $[Mo_4S_4(H_2O)_{12}]^{4+}$ with concentrated aqueous ammonia afforded $[Mo_4S_4(NH_3)_{12}]^{4+}$ which reverted to $[Mo_4S_4(H_2O)_{12}]^{5+}$ in air in acidic solutions.

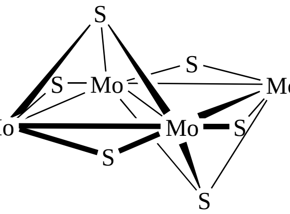
Reduction of $[Mo_2O_2S_2(edta)_2]^{2-}$ with aqueous $NaBH_4$, followed by acidification and air-oxidation, afforded $[Mo_4S_4(edta)_2]^{3-}$. From the crystal structure determinations of the Na^+ and Ca^{2+} salts, it was established that the hexadentate edta was tridentate with respect to two Mo centers and the Mo–Mo distances were in the range 2.76–2.88 Å. $[Mo_4Se_4(edta)_2]^{3-}$ (Mo–Mo, 2.81–2.92 Å) was obtained similarly from $[Mo_2O_2Se_2(cys)_2]^{2-}$. Reduction of $[Mo_4S_4(edta)_2]^{3-}$ by $NaBH_4$ afforded $[Mo_4S_4(edta)_2]^{4-}$ (60-electron cluster) in which the Mo–Mo distances fell in the range 2.77–2.79 Å. Oxidation afforded $[Mo_4S_4(edta)_2]^{2-}$ ($\{Mo_4S_4\}^{6+}$ core) in which the Mo–Mo distances were in the range 2.74–2.87 Å. It was observed that the mean values of the Mo–Mo bond lengths and the volumes of the Mo_4 tetrahedra decreased on progressing from the reduced $\{Mo_4S_4\}^{4+}$ through $\{Mo_4S_4\}^{5+}$ to the oxidized $\{Mo_4S_4\}^{6+}$ cluster core. The tetra- and dianionic species were diamagnetic while the 3– ion was paramagnetic (one unpaired electron). The related selenium clusters $[Mo_4Se_4(edta)_2]^{3-}$ exhibited similar redox behavior.

The diethyldithiophosphato (dtp) clusters $[Mo_4S_4(\mu\text{-dtp})_2(dtp)_4]$, $[Mo_4OS_3(\mu\text{-dtp})_2(dtp)_4]$, and $[Mo_4OS_3(\mu\text{-dtp})_3(dtp)_3]$ were obtained by reaction of $MoCl_3{\cdot}3H_2O$ with P_4S_{10} in ethanol, with or without HCl, or by reaction of $[Mo(CO)_6]$ with the disulfide $(dtp)_2$. The bridging dtp ligand in $[Mo_4S_4(\mu\text{-dtp})_2(dtp)_4]$ could be displaced by acetate or benzoate giving $[Mo_4S_4(\mu\text{-OCOR})_2(dtp)_4]$. All these clusters contain the cluster core $\{Mo_4S_4\}^{6+}$. However, reaction of $[Mo_3S_4(\mu\text{-dtp})(dtp)_4(H_2O)]$ with $[Mo(CO)_6]$ in acetic acid/acetic anhydride, or of $[Mo_3S_7(dtp)_3]Cl$, PPh_3, $[Mo(CO)_6]$ and dtp^-, afforded the $\{Mo_4S_4\}^{5+}$ cluster species $[Mo_4S_4(\mu\text{-OAc})(dtp)_4]^-$. The dithiocarbamato species $[Mo_4S_4(\mu\text{-}S_2CNR_2)_2(S_2CNR_2)_4]$ were obtained from reactions of $[Mo(CO)_6]$ with appropriate thiuram disulfides $R_2NC(S)SSC(S)NR_2$ (R = alkyl). The crystal structure determination of the cluster with R = Et revealed that the Mo–Mo bonds bridged by the two S_2CNEt_2 ligands contracted to 2.74 Å, whereas the other four intermetallic distances were in the range 2.85–2.87 Å. The ^1H NMR spectrum of this cluster in solution revealed two nonequivalent S_2CNEt_2 ligands indicating that the species was stereochemically rigid in solution. The cluster was also paramagnetic (μ = 2.96 BM). Related xanthato complexes $[Mo_4S_4(\mu\text{-}S_2COR)_2(S_2COR)_4]$ have also been described. This group of tetranuclear clusters containing chelating sulfur ligands bound to a $\{Mo_4S_4\}^{6+}$ core were electroactive, undergoing two quasi-reversible one-electron reduction processes, corresponding to the formation of $\{Mo_4S_4\}^{5+}$ and $\{Mo_4S_4\}^{4+}$, and two quasi-reversible one-electron oxidations, corresponding to the formation of $\{Mo_4S_4\}^{7+}$ and $\{Mo_4S_4\}^{8+}$. The potentials for these processes varied by as much as 670 mV depending on the ligand bridging the cube, with the relative ease of reduction being in the order $(S_2COR)^- > [S_2P(OR)_2]^- > (S_2CNR_2)^-$.

High-temperature treatment of polymeric $[\{Mo_3E_7Br_4\}_n]$ with KCN gave the cyano complexes $[Mo_4E_4(CN)_{12}]^{6-}$ (E = S, Se) and $[Mo_4Te_4(CN)_{12}]^{7-}$. The last was oxidized by bromine water to give a hexa-anionic cluster ($\{Mo_4Te_4\}^{6+}$ core). The clusters $[Mo_4E_4(CN)_{12}]^{6-}$ were redox active, undergoing two reversible or quasi-reversible electron transfers corresponding to the generation of seven- and eight-species containing $\{Mo_4E_4\}^{5+}$ and $\{Mo_4E_4\}^{4+}$ cores.

7.3.4 *Raft-like Clusters $[Mo_4(\mu_3\text{-}S)_2)(\mu\text{-}S)_4]^{2+}$*

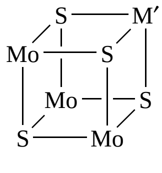
Reaction of $[Mo_3S_7(S_2)_3]^{2-}$ with PMe_3 in *n*-butylamine gave a raft-like Mo_4 cluster $[Mo_4(\mu_3\text{-}S)_2(\mu\text{-}S)_4(SH)_2(PMe_3)_6]$. The idealized cluster core, $\{Mo_4S_6\}^{2+}$ core (**67**) has five Mo–Mo bonds, including one between the 'hinge' metal atoms (2.83–2.85 Å). Treatment of this cluster with $SnCl_2$ in THF caused displacement of the SH groups and formation of $[Mo_4(\mu_3\text{-}S)_2(\mu\text{-}S)_4Cl_2(PMe_3)_6]$.



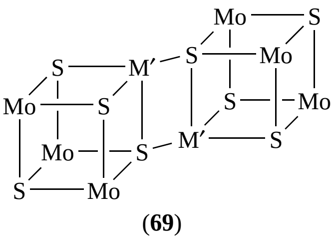
(**67**)

7.3.5 *Heterometallic Derivatives of $[Mo_3E_4(H_2O)_9]^{4+}$*

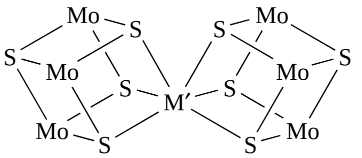
The incomplete cubes $[Mo_3E_4(H_2O)_9]^{4+}$ (E = S, Se) reacted with metal ions to generate cuboidal species. These are generally of three types, shown in (**68**–**70**).[9] The cluster (**68**) utilizes a heterometal atom with variable coordination preferences (usually octahedral or tetrahedral), constituting a cuboidal species. However, when M′ prefers tetrahedral geometry, the edge-linked double cube (**69**) can be formed. The incomplete cube can also function as a pair of tridentate 'ligands', generating a corner-shared cube, (**70**).



(**68**)



(**69**)



(**70**)

The conversion of (**68**) to (**69**) occurred when the anions accompanying the reaction were normally noncoordinating, such as ClO_4^- or p-$MeC_6H_4SO_3^-$, and regeneration of (**68**) would occur when ligands such as CO, PR_3, Cl^-, or NCS^- were added and attached to M′. An excess of $[Mo_3S_4(H_2O)_9]^{4+}$ and a reducing agent such as BH_4^- or H_3PO_2 was necessary to convert (**68**) into (**70**), a reaction which could be reversed using oxidants such as $[Fe(H_2O)_6]^{3+}$. In general, short Mo–M bonds (ca. 2.7 Å) are observed in (**68**) and (**69**), but relatively long nonbonding separations (>3.5 Å) are detected in (**68**) and (**70**), when M′ is a metal from groups 12–15. All of the corner-shared double cubes (**70**) carry an 8+ charge, and a formal charge distribution, $\{Mo_3S_4\}^{4+}\{M'\}^0\{Mo_3S_4\}^{4+}$ has been deemed useful. However, $[Mo_7S_8(H_2O)_{18}]^{8+}$, described in Section 'Corner-sharing Cubic Clusters $\{Mo_6M'E_8\}^{8+'}$, is an exception in that an alternative distribution of charge seems to apply. In the single cubes (**68**), where M′ = Co, Ni, Pd, or Cu, there are relatively short Mo–M′ distances, the formalism $\{Mo_3S_4\}^{4+}\{M'\}^0$ seeming reasonable particularly in view of the synthesis of these clusters from metallic M′. Single cubes of type (**68**), where M′ is Hg, Ga, Ge, and Sb, have been formulated as $\{Mo_4S_4\}^{4+}Hg^0$, $\{Mo_4S_4\}^{4+}Ga^I$, $\{Mo_4S_4\}^{4+}Ge^{II}$, and $\{Mo_4S_4\}^{4+}Sb^{III}$, respectively.

These air-sensitive heterometallic species were isolated using cation-exchange chromatography, especially when the aqua clusters were required. The species were handled in acidic solutions in order to avoid acid dissociation involving the H_2O ligands, and many of the complexes were isolated as p-$MeC_6H_4SO_3^-$ salts.

Single Cube $\{Mo_3M'E_4\}^{4+}$ and Double Cube $\{Mo_6M'_2E_8\}^{8+}$ Species. Reaction of $[Mo_3S_4(H_2O)_9]^{4+}$ with $[Cr(H_2O)_6]^{2+}$ afforded $[Mo_3CrS_4(H_2O)_{12}]^{4+}$ [**68**, M′ = $Cr(H_2O)_3$], which was air-sensitive, degrading into $[Mo_3S_4(H_2O)_9]^{4+}$ and $[Cr(H_2O)_6]^{3+}$. This cluster has been described as $[Mo_3^{III}Cr^{III}S_4(H_2O)_{12}]^{4+}$. Reaction of $[Mo_3S_4(H_2O)_9]^{4+}$ with $[Re(CO)_5Br]$ afforded $[Mo_3\{Re(CO)_3\}S_4(H_2O)_9]^{5+}$.

Treatment of $[Mo_3S_4(H_2O)_9]^{4+}$ with iron wire in acid afforded $[Mo_3FeS_4(H_2O)_{10}]^{4+}$ [**68**, M′ = $Fe(H_2O)$] in which the Fe atom was tetrahedrally coordinated. This species did not react with CO or water-soluble tertiary phosphines, but addition of Cl^- gave $[Mo_3(FeCl)S_4(H_2O)_{10}]^{3+}$. Solid samples of $[Mo_3FeS_4(H_2O)_{10}]^{4+}$ were paramagnetic ($\mu = 2.83$ BM at 22 °C) and magnetic susceptibility data over a temperature range of 2–270 K could be fitted to a model having a $Fe^{II}Mo^{IV}Mo_2^{III}$ core. However Mössbauer spectra at 4.2 K were thought to be more consistent with the presence of Fe^{III} ($S = 3/2$), effectively spin-coupled at the lowest temperatures. With concentrated NH_3, $[Mo_3\{Fe(H_2O)\}S_4(NH_3)_9]^{4+}$ was formed, a crystal structure of the p-$MeC_6H_4SO_3^-$ salt showing Mo–Mo, 2.68–2.69 Å and Mo–Fe, 2.77–2.83 Å.

Metallic cobalt reacted with $[Mo_3S_4(H_2O)_9]^{4+}$ to give air-sensitive solutions from which the edged-linked double cube $[\{Mo_3CoS_4(H_2O)_9\}_2]^{8+}$ [**69**, M′ = Co] was isolated, (Co–Co, 2.50 Å). Reaction of this species with CO afforded air-stable $[Mo_3\{Co(CO)\}S_4(H_2O)_9]^{4+}$. Reaction of $[Mo_3S_4(H_2O)_9]^{4+}$ with $RhCl_3$ in aqueous HCl gave $[Mo_3(RhCl_3)S_4(H_2O)_9]^{4+}$ [**68**, M′ = $RhCl_3$] which, on standing in dilute HCl for a few days, was converted into $[Mo_3RhS_4(H_2O)_{12}]^{4+}$ [**68**, M′ = $Rh(H_2O)_3$].

Reaction of metallic nickel with $[Mo_3S_4(H_2O)_9]^{4+}$ or $[Mo_4S_7Cl_6]^{2-}$, or reduction of Ni^{2+} by BH_4^- in the presence of $[Mo_3S_4(H_2O)_9]^{4+}$, afforded $[Mo_3NiS_4(H_2O)_{10}]^{4+}$. The mixed metal clusters $[Mo_2WNiS_4(H_2O)_{10}]^{4+}$ and $[MoW_2NiS_4(H_2O)_{10}]^{4+}$ have also been prepared, and in all of these species the nickel atom had a tetrahedral geometry. Both $[Mo_3NiS_4(H_2O)_{10}]^{4+}$ and $[Mo_2WNiS_4(H_2O)_{10}]^{4+}$ formed single cubes [**68**, M′ = $Ni(H_2O)$] as their crystalline p-$MeC_6H_4SO_3^-$ salts, the di-tungsten cluster adopting a double cubic arrangement, $[\{MoW_2NiS_4(H_2O)_9\}_2]^{8+}$ [**69**, M′ = Ni] with Ni–Ni, 2.55 Å. Solutions of $[Mo_3NiS_4(H_2O)_{10}]^{4+}$ were stable in air for short periods, but on heating degraded to Ni^{2+} and $[Mo_3S_4(H_2O)_9]^{4+}$. In HCl, $[Mo_3(NiCl)S_4(H_2O)_9]^{3+}$ was formed, and treatment of this with nitrilotriacetate, nta^{3-}, caused substitution at the Mo centers rather than Ni, giving $[Mo_3(NiCl)S_4(Hnta)(nta)_2]^{5-}$. Reaction of $[Mo_3(NiCl)S_4(H_2O)_9]^{3+}$ with dppe in methanol afforded $[Mo_3(NiCl)S_4Cl_3(dppe)_3]$, and the Cl coordinated by the Ni center could not be replaced by CO, PMe_3, or PMe_2Ph. However, the nickel atom in $[Mo_3NiE_4(H_2O)_{10}]^{4+}$ (E = S, Se) readily coordinated CO, ethene, and tertiary phosphines, affording $[Mo_3(NiL)S_4(H_2O)_9]^{4+}$, the CO being eliminated by passing N_2 through aqueous solutions, leading to regeneration of $[Mo_3NiE_4(H_2O)_{10}]^{4+}$.

$[Mo_3NiS_4(H_2O)_{10}]^{4+}$, as its p-$MeC_6H_4SO_3^-$ salt, exhibited antiferromagnetism ($\mu = 0.11$ BM at 2.0 K and 1.26 BM at 260.7 K) and was described formally as containing $Ni^{II}Mo^{IV}Mo^{III}_2$. However, this contrasted with the substitution behavior at the nickel center, which appeared to function more like Ni^0, showing that it is difficult to precisely assign formal oxidation states in these clusters.

Reaction of $[Mo_3S_4Cl_4(PEt_3)_4(MeOH)]$ with $[Ni(cod)_2]$ (cod = cycloocta-1,5-diene) afforded the pentanuclear $[Mo_3(NiPEt_3)_2S_4Cl_4(PEt_3)_3]$, whose X-ray structure revealed that the cluster had a square-pyramidal core with an Mo_2Ni_2 base and the third Mo at the apex. The metal–metal distances were relatively short (Mo–Mo, 2.65–2.67 Å; Mo–Ni, 2.5–2.67 Å; Ni–Ni, 2.71 Å), and the XPS spectrum was interpreted in terms of a $Mo_3Ni_2^0$ formalism.

$[Mo_3E_4(H_2O)_9]^{4+}$ (E = S, Se) reacted with Pd in dilute HCl solutions giving $[Mo_3(PdCl)E_4(H_2O)_9]^{3+}$ [**68**, M′ = PdCl] which, when Cl^- was abstracted in the

presence of p-MeC$_6$H$_4$SO$_3$H, afforded the double cube $[\{Mo_3PdS_4(H_2O)_9\}_2]^{8+}$ [**69**, M′ = Pd]. In these complexes, the Pd geometry was essentially tetrahedral, implying a formal oxidation state of 0 rather than II. This double cube reacted with halide ions, NCS$^-$, CO, and tertiary phosphines, with cleavage to give mono-cubic species $[Mo_3(PdL)S_4(H_2O)_9]^{n+}$. Treatment of $[Mo_3(PdCl)S_4(H_2O)_9]^{3+}$ with HP(O)(OH)$_2$ gave $[Mo_3\{Pd[P(OH)_3]\}S_4(H_2O)_9]^{4+}$, a unique example of coordinated P(OH)$_3$, and its As(OH)$_3$ analogue was also prepared. Treatment of $[Mo_3(PdCl)S_4(H_2O)_9]^{3+}$ with tacn (**58**) (R = H) afforded $[Mo_3(PdCl)S_4(tacn)_3]^{3+}$. The Pd site in this complex could bind π-acids such as CO, isonitrile, alkene, and alkynes.

Reaction of $[Mo_3S_4(H_2O)_9]^{4+}$ with $[PtCl_4]^{2-}$ in the presence of HP(O)(OH)$_2$ as reductant, afforded the edge-linked double cube $[\{Mo_3PtS_4(H_2O)_9\}_2]^{8+}$ [**69**, M′ = Pt], which was air-stable and much more inert to substitution than its Ni and Pd analogs. Treatment of $[Mo_3S_4(H_2O)_9]^{4+}$, as the Cl$^-$ salt, with [Pt(dba)$_2$] (dba = 1,5-diphenyl-1,4-pentadiene-3-one) afforded a brown precipitate which, on treatment with dppe, provided [Mo$_3$(PtCl)S$_4$Cl$_3$(dppe)$_3$]. This species contained Mo atoms coordinated by Cl, chelating dppe and S, and the {PtS$_3$Cl} group had tetrahedral geometry (Mo–Mo, 2.81–2.82 Å; Pt–Mo, 2.74–2.76 Å). $[Mo_3\{Pt(\kappa^1\text{-dppe})\}S_4Cl_3(dppe)]^+$ could also be obtained from this reaction, and both species were electroactive, the former undergoing reversible oxidation, and the second irreversible oxidation. The Cl ligand in [Mo$_3$(PtCl)S$_4$Cl$_3$(dppe)$_3$] could not be displaced by CO or tertiary phosphines.

Metallic copper reacted with $[Mo_3S_4(H_2O)_9]^{4+}$ giving air-sensitive paramagnetic $[Mo_3CuS_4(H_2O)_{10}]^{4+}$, [**68**, M′ = Cu(H$_2$O)] which, on recrystallization from aqueous p-MeC$_6$H$_4$SO$_3$H, afforded the edge-linked double cube $[Mo_3CuS_4(H_2O)_9]^{8+}$ [**69**, M′ = Cu]. This species was EPR-silent and exhibited $\mu = 0.48$ BM. The single cube $[Mo_3CuS_4(H_2O)_{10}]^{4+}$ was also formed on addition of CuCl to $[Mo_3S_4(H_2O)_9]^{4+}$ or by reduction of Cu^{2+} by BH$_4{}^-$ in the presence of the incomplete trinuclear cluster. The single cube (**68**), M = Cu was unstable in solution, breaking up into Cu^{2+} and reforming $[Mo_3S_4(H_2O)_9]^{4+}$, but was stabilized in aqueous dilute HCl, when $[Mo_3(CuCl)S_4(H_2O)_9]^{3+}$ was formed. Reaction of $[Mo_3(FeCl)S_4(H_2O)_9]^{3+}$ with a large excess of aqueous Cu^{2+} afforded a mixture of $[Mo_3(CuCl)S_4(H_2O)_9]^{3+}$, $[Mo_3(CuCl)S_4(H_2O)_9]^{4+}$ (containing a $\{Mo_3CuS_4\}^{5+}$ core) and $[Mo_3S_4(H_2O)_9]^{4+}$. Addition of nitrilotriacetate to $[Mo_3(CuCl)S_4(H_2O)_9]^{4+}$ gave $[Mo_3(CuCl)S_4(Hnta)_3]^{2-}$, whose structure was determined as K$^+$ and NH$_4$ salts; Mo–Mo, 2.75 Å; Mo–Cu, 2.85 Å, the core being formulated as $Mo_3{}^{IV}Cu^I$ which is formally isoelectronic with Mo$_3$Ni^0. The trinuclear clusters $[Mo_3E_4X_3(dmpe)_3]^+$ reacted with Cu^I halides or with $[Cu(NCMe)_4]^+$ giving $[Mo_3(CuX)E_4X_3(dmpe)_3]^+$ (as PF$_6{}^-$ salts: X = Cl, E = S; Mo–Mo, 2.78 Å, Mo–Cu, 2.82 Å; X = Cl, E = Se; Mo–Mo, 2.84 Å, Mo–Cu, 2.84 Å). Dithiophosphate complexes of the $\{Mo_3CuS_4\}^{5+}$ cluster core were also prepared, that is, [Mo$_3$(CuI)(μ-OCOR)(dtp)$_3$L] (R = Me or CF$_3$, L = DMF, DMSO, MeCN) and [Mo$_3$(CuI)(μ_3-OS$_3$)(μ-OAc)(dtp)$_3$L] (L = py, dmf). The dithiocarbamate [Mo$_3$(CuI)(S$_4$)(μ-S$_2$CNEt$_2$)(S$_2$CNEt$_2$)$_3$(py)], was also isolated. Diamagnetic dithiophosphinates, [Mo$_3$(CuI)S$_4$(μ-S$_2$PR$_2$)(S$_2$PR$_2$)$_3$(py)] (R = Et, Pr^n) were obtained by reacting [Mo$_3$S$_4$(μ-S$_2$PR$_2$)(S$_2$PR$_2$)$_3$] with CuI and pyridine (R = Pr^n: Mo–Mo, 2.76–2.78 Å, Mo–Cu, 2.84–2.87 Å).

Corner-sharing Cubic Clusters $\{Mo_6M'E_8\}^{8+}$. The single cube $[Mo_3CdS_4(H_2O)_{12}]^{4+}$ [**68**, M′ = Cd(H$_2$O)$_3$] was obtained by addition of Cd to $[Mo_3S_4(H_2O)_9]^{4+}$, and corner-sharing double cubes $[Mo_6CdS_8(Hnta)_6]^{4-}$ and [Mo$_6$CdS$_8$(dtp)$_8$(NCMe)$_2$] [**70**, M′ = Cd] were formed by addition of Cd metal powder to $[Mo_3S_4(Hnta)_3]^{2-}$ and [Mo$_3$S$_4$(dtp)$_4$(NCMe)$_2$], respectively. When mercury was added to $[Mo_3S_4(H_2O)_9]^{4+}$, only the corner-sharing double cube $[Mo_6HgS_4(H_2O)_{18}]^{8+}$ was formed, the crystal structure of selected clusters indicating Mo–Mo bonding but no Mo–Hg bonding. The structural data were consistent with Hg^0 coordinated by two $\{Mo_3S_4\}^{4+}$ 'ligands', that is, [**70**, M′ = Hg]. The related Se cluster $[Mo_6HgS_4(H_2O)_{18}]^{8+}$ was also prepared. Addition of the group 13 elements Ga, In, or Tl, either directly as metal powders or generated in situ by BH$_4{}^-$ reduction of appropriate aqueous salts to $[Mo_3S_4(H_2O)_9]^{4+}$ afforded the single cubes $[Mo_3M'S_4(H_2O)_{12}]^{5+}$ and double, corner-sharing cubes $[Mo_6M'S_8(H_2O)_{18}]^{8+}$, M′ = Ga, In, or Tl. The oxygen-containing cube $[Mo_6InO_2S_6(H_2O)_{18}]^{8+}$ was also isolated. The group 14 metal clusters $[Mo_3M'E_4(H_2O)_{12}]^{8+}$ and $[Mo_6M'E_8(H_2O)_{18}]^{8+}$ (E = S, Se, M′ = Ge, Sn, Pb) were also prepared by addition of the appropriate metal to $[Mo_3S_4(H_2O)_9]^{4+}$. The germanium clusters could also be generated from GeO or GeO$_2$. Again, there was no evidence for Mo–M′ bonding in these clusters. The corner-sharing cube $[Mo_6SnE_8(H_2O)_{18}]^{8+}$ [**70**, M′ = Sn^{II}] could be oxidized to give $[Mo_3SnE_4(H_2O)_{12}]^{6+}$ (**68**), [M′ = Sn^{II}(H$_2$O)$_3$] and then $[Mo_3E_4(H_2O)_9]^{4+}$ and Sn^{IV}, whereas the single cube $[Mo_3SnS_4(H_2O)_{12}]^{6+}$ could be made by direct addition of Sn^{II} to $[Mo_3S_4(H_2O)_9]^{4+}$. Treatment of $[Mo_3SnE_4(H_2O)_{12}]^{6+}$ (E = S or Se) with aqueous Cl$^-$ afforded $[Mo_3(SnCl_3)E_4(H_2O)_9]^{3+}$, but addition of NCS$^-$ to this resulted in substitution of the H$_2$O molecules at Mo only, the product being $[Mo_3(SnCl_3)E_4(NCS)_9]^{6-}$. Reaction of [Mo$_3S_4$(S$_2PEt_2$)$_4$] with Sn powder and [Et$_2$P(S)SSP(S)Et$_2$] in toluene afforded air-stable [Mo$_3$SnS$_4$(μ-S$_2$PEt$_2$)$_3$(S$_2$PEt$_2$)$_3$], which was also produced by direct addition of [Sn(S$_2$PEt$_2$)$_2$] to [Mo$_3$S$_4$(S$_2$PEt$_2$)$_4$]. The related species containing the $\{Mo_3(\mu_3\text{-O})(\mu\text{-S}_3)\}^{4+}$ core, *viz.* [Mo$_3$(SnCl$_3$)OS$_3$(dtp)$_3$(py)$_3$] was prepared by reaction of [Mo$_3$OS$_3$(dtp)$_4$(H$_2$O)] with [SnCl$_3$]$^-$ and pyridine. No single cube derivatives of $[Mo_3PbE_4(H_2O)_{12}]^{6+}$ have been prepared, and the corner-sharing double cubes $[Mo_6PbS_8(H_2O)_{18}]^{8+}$ [**70**, M′ = Pb] are air-sensitive. However, reaction of [PbI$_3$]$^-$ with $[Mo_3S_4(H_2O)_9]^{4+}$ and dtp$^-$ in the presence of pyridine afforded [Mo$_3$(PbI$_3$)S$_4$(dtp)$_3$(py)$_3$]. Similar chemistry of

the group 15 element-containing (As, Sb, Bi) clusters has been reported, both single and corner-sharing double cubes having been characterized. The redox chemistry of $[Mo_6AsS_8(H_2O)_{18}]^{8+}$ was consistent with the formalism $\{Mo_3S_4\}^{4+}As^0\{Mo_3S_4\}^{4+}$. The same was suggested for $[Mo_6SbS_8(H_2O)_{18}]^{8+}$ although the ^{121}Sb Mössbauer spectrum of this compound was regarded as more consistent with Sb^{III}; a situation also thought to be relevant to $[Mo_3SbS_4(H_2O)_{12}]^{4+}$. Addition of SbX_3 to $[Mo_3S_4(dtp)_4(H_2O)]$ in various organic solvents gave $[Mo_3(SbX_3)(dtp)_4L]$ (L = EtOH, py). No single cube derivative of Bi has been reported although $[Mo_3(BiI_3)S_4(\mu\text{-OAc})(dtp)_3(py)]$ has been described.

$[Mo_7S_8(H_2O)_{18}]^{8+}$ is also a double cube (**70**), M′ = Mo in which a single Mo atom is bonded to two $[Mo_3S_4(H_2O)_9]^{4+}$ units, the octacation having a $\{Mo_3S_4(Mo)S_4Mo_3\}$ core. Distances from the unique Mo atom to the other Mo atoms, 3.03–3.06 Å, are longer than the other Mo–Mo bond lengths within each subcluster (2.77 Å). Related clusters $[Mo_7Se_8(H_2O)_{18}]^{8+}$, $[MoW_6S_8(H_2O)_{18}]^{8+}$, and $[MoW_6Se_8(H_2O)_{18}]^{8+}$ have also been prepared. As was mentioned above, the formulation of this species as containing Mo^0 seems inappropriate but no alternative description has been established.

7.3.6 *Octahedral Clusters, Mo_6E_8*

Reduction of $[Mo_3E_4Cl_4(PEt_3)_n]$ (E = S, Se; $n = 3$, 4) afforded the molecular clusters $[Mo_6E_8(PEt_3)_6]$ in which E bridges the triangular faces of the octahedral Mo_6 core, the metal–metal distances being 2.66–2.67 Å (S) and 2.70–2.71 Å (E = Se). Related pyridine, pyrrolidine, and piperidine complexes have been described. $[Mo_6E_8(PEt_3)_6]$ is electroactive, undergoing a single one-electron oxidation and two one-electron reduction steps. Sodium amalgam reduction of the clusters afforded $[Mo_6E_8(PEt_3)]^-$, the octahedral structure becoming slightly distorted, and the Mo–Mo distances slightly longer than in the neutral precursor. Reaction of $[Mo_6S_8(PEt_3)_6]$ with NO^+ afforded paramagnetic $[Mo_6S_8(NO)(PEt_3)_5]$, which has a distorted octahedral metal core, the Mo–Mo bonds involving the Mo atom bound to NO (Mo–N–O 175°) being much longer than the others (2.63 Å). A second product obtained from this reaction, $[Mo_{12}S_{16}(PEt_3)_{10}]$ consists of two octahedral $\{Mo_6S_8\}$ cores connected to each other by two Mo–μ_4–S bonds, which is similar to the bridging mode found in solid-state Chevrel phases. This dodecanuclear cluster, and its selenium analog $[Mo_{12}Se_{16}(PEt_3)_{10}]$, could also be made by abstraction of PEt_3 by S_8 (giving $SPEt_3$) from $[Mo_6E_8(PEt_3)_6]$.

Reaction of the Chevrel phase $[Mo_6Se_8]$ with KCN at 650 °C gave the water-soluble paramagnetic $[Mo_6Se_8(CN)_6]^{7-}$ which could be oxidized in air to the hexa-anionic species. This reaction also afforded insoluble paramagnetic $[Mo_6Se_8(CN)_5]^{6-}$, whose structure shows that the Mo atoms in the basal plane of each $\{Mo_6Se_8\}$ cluster are bound to four terminal CN^- ligands, with the clusters being linked by CN groups into linear chains, represented as $\{Mo_6Se_8(\mu\text{-CN})\}^{6-}$. This species exhibits normal Curie–Weiss behavior over the temperature range 1.8–400 K, with $\mu = 1.99$ BM.

Other octahedral clusters were encountered in $[Mo_6\{Se_2Cl_6\}Cl_3]^{3-}$ and $[Mo_6(TeCl_7)Cl_6]^{3-}$.

7.3.7 *$Mo_6E_8{}^{6+}$ Clusters with Raft-like Structures*

Reaction of $[Mo_3E_4Cl_4L_5]$ (E = S, Se; L = PEt_3 and/or THF) with Mg in THF and −20 °C gave $[Mo_6E_8Cl_6(PEt_3)_6]$, (**71**). This species contains seven Mo–Mo single bonds and the structure was described as formed by two reduced $\{Mo_3E_4\}^{3+}$ triangular clusters held together via a Mo–Mo bond (E = S, 3.00 Å; E = Se, 3.06 Å). A similar structure was encountered in $[Mo_6S_{10}(SH)_2(PEt_3)_6]$, prepared by reaction of $[NH_4]_2[Mo_3S_{13}]$ with PEt_3 in THF. In this cluster a Mo–Mo bond again links the two $\{Mo_3S_4\}$ triangles (2.95 Å).

1 INTRODUCTION

The group 6 elements molybdenum (*Z* 42) and tungsten (*Z* 74) are the only second and third row transition metals (*see Transition Metals*) essential to all forms of life on Earth (*see also* ***Tungsten Proteins*** and ***Nutritional Aspects of Metals & Trace Elements***). Molybdenum is found at the active sites (*see Active Site*) of nitrogenase (*see* ***Nitrogenase: Metal Cluster Models*** and ***Nitrogenase Catalysis & Assembly***) and all of the more than 50 known Mo-MPT enzymes (*see Enzyme*).[1–7] The Mo-MPT enzymes feature active sites composed of a single (mononuclear) Mo atom coordinated by one or two MPT-based ligands (*see Ligand*) (MPT = 'molybdopterin' or *M*etal-binding *P*terin ene-1,2-di*T*hiolate); tungsten is also associated with MPT-based ligands in all its known biological manifestations (*see* ***Tungsten Proteins***). The Mo-MPT enzymes are important in the metabolism (*see Metabolism*) of small molecules and anions containing nitrogen, sulfur, carbon, selenium, arsenic, and chlorine, and in the global biogeochemical cycles of these elements. The attributes of selected enzymes are summarized in Table 1; details can be found in Sections 4–6.

There have been tremendous developments in this area since the publication of EIC-I.[1] Advances include: (1) the classification of the enzymes into three families based on sequence and structural comparisons, (2) confirmation of the presence of mononuclear Mo active sites, (3) establishment of the binding mode, redox state, and structural attributes of MPT-based ligands, (4) determination of the composition and structures of the active sites and the emergence of clear targets for model studies, (5) delineation of electron-transfer pathways and reaction mechanisms, and (6) the identification of the genes and proteins involved in MPT biosynthesis and Mo transport, homeostasis (*see Homeostasis*), and regulation.[2–7] Advances in Mo bioinorganic chemistry, particularly the development of OAT/CEPT models and dithiolene (*see Dithiolenes*) synthetic analogues, have accompanied developments on the biological front.[7] Progress in both spheres, viz. enzymatic and synthetic, has depended largely on the continual refinement and application of structural and spectroscopic methods, particularly X-ray crystallography (*see X-ray Crystallography*),[8–11] X-ray absorption spectroscopy (*see X-ray Absorption Spectroscopy*) (especially Extended X-ray Absorption Fine Structure (EXAFS) analysis, *see Extended X-ray Absorption Fine Structure*),[12,13] paramagnetic resonance techniques (Electron Paramagnetic Resonance (EPR), *see Electron Paramagnetic Resonance*; Electron Nuclear Double Resonance (ENDOR), *see Electron Nuclear Double Resonance Spectroscopy*; and Electron Spin Echo Envelope Modulation (ESEEM), *see Electron Spin Echo Envelope Modulation Spectroscopy*),[13–16] resonance Raman spectroscopy (*see Resonance Raman Spectroscopy*),[7,13] Magnetic Circular Dichroism spectroscopy (MCD) (*see Magnetic Circular Dichroism*),[7,13] and advanced electrochemical methods.[17,18]

This account focuses on the Mo bioinorganic chemistry (*see Bioinorganic Chemistry*) of the Mo-MPT enzymes and selected synthetic analogues. It is divided into two main parts. Part 1 (Sections 2–6) provides an overview of the enzyme systems, their distribution, roles, and essential chemistry, as well as a discussion of consensus structures and likely mechanisms. The genes and proteins involved in Mo trafficking and Mo-cofactor biosynthesis are also briefly described. Part 2 (Sections 7–11) summarizes important developments in the production of synthetic analogues, with a focus on new dithiolene, scorpionate (including trispyrazolylborate (*see Tris(pyrazolyl)borates*)) and other complexes sharing the structural, spectroscopic, or chemical attributes of the enzymes.

Current knowledge permits a more definitive description of the enzymes than was possible in EIC-I;[1] however, the fundamental chemistry described therein provides valuable context and valid background for the present account. Since 1994, many reviews of the Mo-MPT enzymes and/or their Mo chemistry have appeared; the major reviews of Hille,[2,3] Pilato and Stiefel,[4] and more recently, Tunney, McMaster, and Garner,[5] deserve special mention (focused reviews are cited in the text). Molybdenum-MPT enzymes and metallodithiolenes were the subjects of recent thematic issues of *Metal Ions in*

Table 1 Properties of selected Mo-MPT enzymes

Enzyme	Source	Subunits, mass (kDa)[a]	Composition[b]	Conversion catalyzed	PDB code[c]
DMSO Reductase Family					
DMSO reductase	*R. sphaeroides*	α, 85	$MoO(OSer)(MGD)_2$	$Me_2SO \rightarrow Me_2S$	1EU1
DMSO reductase	*E. coli* (dmsABC)	$\alpha\beta\gamma$, 140	$MoO(OSer)(MGD)_2$ $[Fe_4S_4]$	$Me_2SO \rightarrow Me_2S$	
Trimethylamine *N*-oxide reductase	*S. massilia*	α, 94	$MoO(OSer)(MGD)_2$	$Me_3NO \rightarrow Me_3N$	1TMO
Nitrate reductase (dissimilatory)	*E. coli* (NarGHI)	$\alpha\beta\gamma_2$, 200	$MoO(SCys)(MGD)_2$ $3[Fe_4S_4]$, $[Fe_3S_4]$, 2 heme	$NO_3^- \rightarrow NO_2^-$	1Q16
Formate dehydrogenase	*E. coli* (FdhF)	α, 79	$MoO(SeCys)(MGD)_2$ $[Fe_4S_4]$	$HCO_2^- \rightarrow HCO_3^-$	1AA6
Polysulfide reductase	*W. succinogenes*	$\alpha\beta\gamma$, 90	$MoX(SCys)(MGD)_2$	$S_n^{2-} \rightarrow S_{n-1}^{2-} + SH^-$	
Arsenite oxidase	*A. faecalis*	$\alpha\beta$, 85	$MoO(OH)(MGD)_2$ $[Fe_3S_4]$ or $[Fe_2S_2]$	$AsO_3^{3-} \rightarrow AsO_4^{3-}$	1G8K
Sulfite Oxidase Family					
Sulfite oxidase	Chicken liver	α_2, 106	$MoO_2(SCys)(MPT)$ b_5-heme	$SO_3^{2-} \rightarrow SO_4^{2-}$	1SOX
Sulfite oxidase	*A. thaliana*	α_2, 88	$MoO_2(SCys)(MPT)$	$SO_3^{2-} \rightarrow SO_4^{2-}$	1OGP
Sulfite dehydrogenase	*Starkeya novella*	$\alpha\beta$, 50	$MoO_2(SCys)(MPT)$ heme *c*	$SO_3^{2-} \rightarrow SO_4^{2-}$	
Nitrate reductase (assimilatory)	Plants	α_2, 228	$MoO_2(SCys)(MPT)$ cyt b, 2FAD	$NO_3^- \rightarrow NO_2^-$	
Xanthine Oxidase Family					
Xanthine oxidoreductase	Cow's milk	α_2, 290	MoOS(OH)(MPT) $2[Fe_2S_2]$, FAD	xanthine → uric acid (see Equation 9)	1FIQ $1FO_4$
Xanthine dehydrogenase	*R. capsulatus*	$(\alpha\beta)_2$, 275	MoOS(OH)(MPT) $2[Fe_2S_2]$, FAD	xanthine → uric acid (see Equation 9)	
Aldehyde oxidoreductase	*D. gigas*	α_2, 200	MoOS(OH)(MCD) $2[Fe_2S_2]$	RCHO → RCOOH	1HLR
CO dehydrogenase	*O. carboxidovorans*	$(\alpha\beta\gamma)_2$, 277	(MCD)MoO(OH)(SCu) $2[Fe_2S_2]$, FAD	$CO \rightarrow CO_2$	1N5W

[a]Total mass. [b]Per subunit. [c]Structural data can be obtained from the Brookhaven Protein Data Bank (PDB) at http://www.rcsb.org/pdb. Other Mo-MPT enzyme PDB codes include: *Hydrogenophaga pseudoflava* CO dehydrogenase, 1FFV; *Desulfovibrio desulfuricans* aldehyde oxidoreductase, 1DGJ; *Rhodobacter capsulatus* DMSO reductase, 4DMR; *R. sphaeroides* nitrate reductase (dissimilatory), 1OGY; *D. sulfuricans* nitrate reductase (dissimilatory), 2NAP.

Biological Systems[6] and *Progress in Inorganic Chemistry*,[7] respectively.

2 DISTRIBUTION, CLASSIFICATION, AND GENERAL CHEMISTRY OF Mo-MPT ENZYMES

2.1 General Distribution

The enzymes are widely distributed in microorganisms, plants, and animals.[1–6] Three Mo-MPT enzymes have been found in mammals: (1) xanthine dehydrogenase (*see Dehydrogenase*) has many, varied roles in purine catabolism, drug metabolism, and oxidative stress response, (2) aldehyde oxidase is important in drug metabolism and the synthesis of retinoic acid from retinal, and (3) sulfite oxidase plays a crucial role in the detoxification of sulfite produced in the degradation of cysteine and methionine. Genetic Mo-MPT deficiency in humans results in serious neurological disorders and infant death, while enzyme dysfunction manifests in a variety of afflictions.[19] Four MPT enzymes have been found in plants:[20] (1) nitrate reductase (*see Reductase*) catalyzes the conversion of nitrate to nitrite, a key step in the assimilation of nitrogen, (2) aldehyde oxidase catalyzes steps in the formation of phytohormones such as abscisic acid and indole-3-acetic acid, (3) xanthine dehydrogenase is involved in ureide synthesis, purine catabolism, senescence, and oxidative stress response, and (4) sulfite oxidase is responsible for the detoxification of sulfite, produced during sulfur assimilation or from air pollution. Molybdenum deficiency in plants affects many species, causing poor vigor and chlorosis (yellowing) of the leaves, whereas Mo-MPT deficiency causes loss of function and death. The majority of Mo-MPT enzymes (including all those in the DMSO reductase family) are found in microbes. They are responsible for metabolic functions and the adaptation of the organism to available nutrient levels and environmental conditions.[1–6]

2.2 Classification and General Chemistry

The Mo-MPT enzymes are classified into two broad functional types: oxotransferases and hydroxylases (Figure 1). Oxotransferases catalyze oxygen atom transfer (*see Atom Transfer* and *Oxo Transfer*) (OAT) to (for oxidases) or from (for reductases) the central atom of simple oxoanions (*see Oxoanion*), and *S*- and *N*-oxides, employing water as the source or destination of active oxygen (*O). The mediating role of molybdenum in oxygen transfer is obvious from equations (1) and (2), which combine to give the overall catalytic reaction in equation (3). The hydroxylases generally catalyze the insertion of an oxygen atom into C–H bonds of heterocyclic aromatic compounds and aldehydes, the oxygen atom again being derived from water (equation 4). The nature of the active oxygen atom varies by enzyme family (vide infra) as discussed in Sections 4–6. The enzyme reactions couple a two-electron net OAT process (equation 1) with sequential one-electron coupled electron-proton transfer (*see Proton Coupled Electron Transfer*) (CEPT) processes, centered on Mo/water and regenerating the active site (equation 2). Enzyme prosthetic groups (*see Prosthetic Group*) and physiological redox partners are responsible for electron transfer to or from the Mo center as required by equation (2).

$$X + Mo^{VI}[^{*}O] = X^{*}O + Mo^{IV} \quad (1)$$

$$Mo^{IV} + H_2{}^{*}O = Mo^{VI}[^{*}O] + 2H^+ + 2e^- \quad (2)$$

$$X + H_2{}^{*}O = X^{*}O + 2H^+ + 2e^- \quad (3)$$

$$X\text{–}H + H_2{}^{*}O = X^{*}OH + 2H^+ + 2e^- \quad (4)$$

The enzymes are subdivided into three families based on structural and sequence comparisons (Figure 1, Table 1).[2] Oxotransferases isolated from prokaryotes (*see Prokaryote*) belong to the DMSO reductase family. These enzymes include DMSO reductase, biotin *S*-oxide reductase, trimethylamine *N*-oxide reductase, dissimilatory nitrate reductase, formate dehydrogenase, selenate reductase, and arsenite oxidase; they feature distorted trigonal prismatic $[Mo^{VI}O(AA)L_2]^-$ (AA = serinate, cysteinate, selenocysteinate, and so on; L = MPT-based ligand (see Section 3)) oxidized active sites (**1**). Some members of the DMSO reductase family, such as formate dehydrogenase and polysulfide reductase, catalyze reactions other than net OAT (see Section 4). Only two oxotransferases, sulfite oxidase and assimilatory nitrate reductase, have been identified in eukaryotes (*see Eukaryote*); they are members of the sulfite oxidase family and contain square-pyramidal *cis*-$[Mo^{VI}O_2L(\text{cysteinate})]^-$ oxidized active sites (**2**) (see Section 5). The hydroxylases are all members of the xanthine oxidase family. These unique enzymes contain square-pyramidal $[Mo^{VI}OS(OH)L]^-$ oxidized active sites (**3**) featuring a catalytically essential terminal sulfido ligand (or bridged Mo–S–Cu) moiety. Again, several members of this family catalyze unusual reactions, including the conversion of CO to CO_2 by CO dehydrogenase, hydroxyl group transfer by pyrogallol transhydroxylase, and dehydroxylation by 4-hydroxybenzolyl-CoA reductase (see Section 6). The properties of selected enzymes are presented in Table 1.

3 MOLYBDENUM COFACTORS (Moco's) AND MPT LIGANDS

3.1 Moco's and the Structure and Function of MPT Ligands

The presence of a pterin-dithiolene (MPT-based) ligand at Mo is the unifying feature of the various molybdenum cofactors (Moco's) and enzymes.[1–7] The chemical nature of the pterin-dithiolene ligand was defined by degradative and spectroscopic studies performed by Rajagopalan, Johnson, and coworkers. They proposed the bicyclic structure (**4**) and

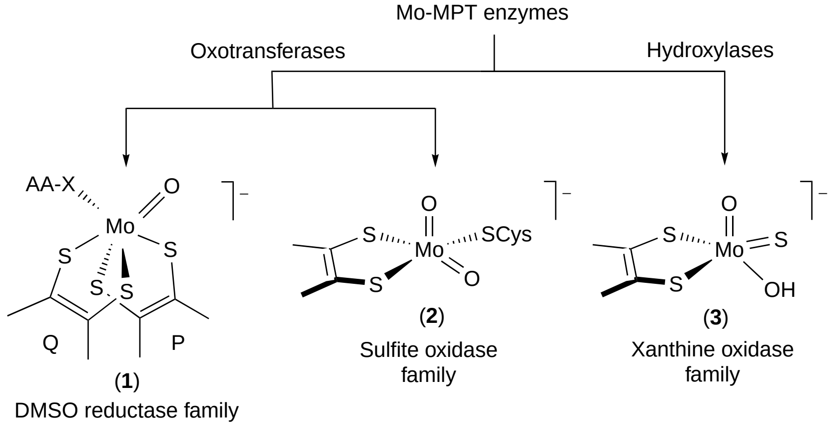

Figure 1 Classification of Mo-MPT enzymes. Structures (**1**)–(**3**) represent oxidized active-site structures (only the dithiolene moiety of each MPT-based ligand is shown)

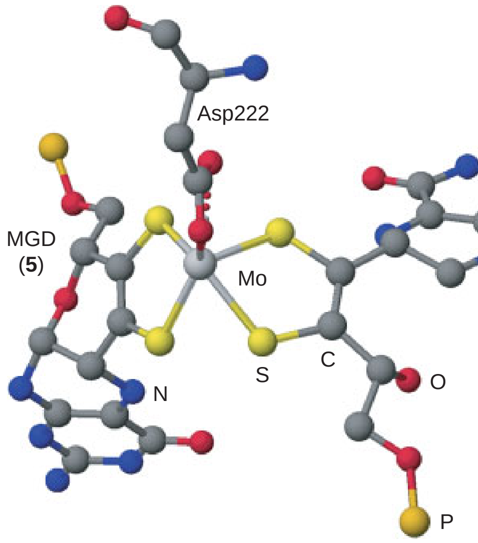

Figure 2 Active site of *E. coli* nitrate reductase, showing pterin forms (**4**) and (**5**). Only the pterin-dithiolene portions of the MGD ligands are shown

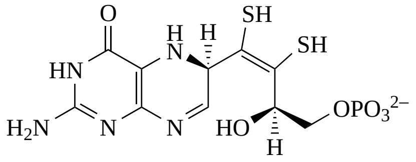
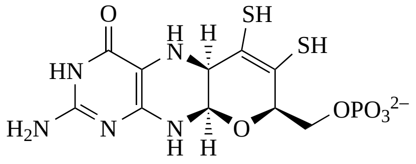


(**4**)



(**5**)

suggested that the dithiolene unit functions as a bidentate ligand (*see Bidentate Ligand*) to Mo. This form was recently identified in *Escherichia coli* nitrate reductase (see Figure 2)[21] and was invoked to explain the electrochemical behavior of *R. capsulatus* xanthine dehydrogenase.[18] Subsequent X-ray crystal structures (*see Crystal Structures*)[8–10] confirmed the general validity of these proposals but revealed an unexpected tricyclic 'pyranopterin' form of the ligand (**5**; see also Figures 2, 3, 5, and 7). 'Molybdopterin (MPT)' was the name originally coined for the pterin-dithiolene ligand, but the fact that it contains no Mo and binds equally well to W has prompted calls for improved nomenclature. *M*etal-binding *P*terin di*T*hiolate[4] or *M*etal-binding pyrano*P*terin ene-1,2-di*T*hiolate[5] have been proposed as alternative names allowing retention of the widely used MPT abbreviation (the former has the advantage of encompassing both ligand forms (**4**) and (**5**)). In prokaryotic enzymes, the phosphate group of MPT is usually linked to the phosphate group of a 5′-nucleotide of cytidine, guanosine, adenosine, or inosine; these are commonly referred to as 'dinucleotides,' and are abbreviated, for example, as MGD (*M*PT-*G*uanosine *D*inucleotide). Although conformationally flexible, MPT-based ligands adopt remarkably similar structures at enzyme active sites. In ubiquitous (**5**), the pyrazine and pyran rings of MPT are nonplanar, the three chiral (*see Chiral*) carbon atoms adopting the (*R*)-configuration. The pyran ring adopts a half-chair conformation and the mean planes defining the pterin and pyran moieties are related by an angle of ca. 40°. The polar groups of MPT (and any nucleotide appendage) are involved in an array of hydrogen bonds that anchor the ligand to the polypeptide chain. Crystallographic data are consistent with dihydropterin (**4**), or equivalent fully reduced tetrahydropterin (**5**) ligand redox levels.[8–10]

As well as its clearly established Moco-anchoring role, it is likely that the 'noninnocent' MPT ligand facilitates electron and proton transfer to and from the Mo center (possibly via structural changes modulating the covalency of the Mo–S bonds), the fine-tuning of redox potentials (*see Redox Potential*), and the buffering of oxidation state changes during turnover.[1–7]

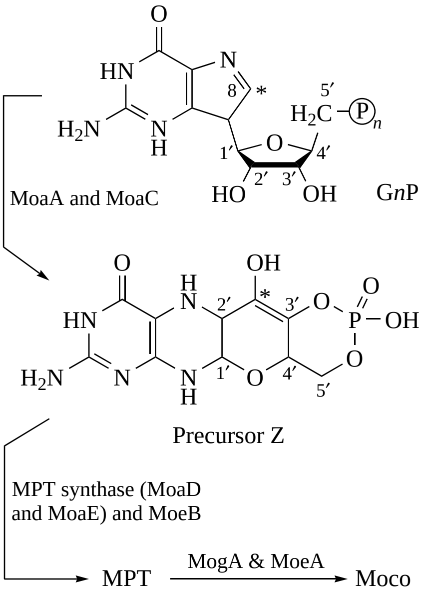
3.2 Biosynthesis of MPT and Moco

3.2.1 Molybdate Uptake and Storage

Molybdate is transported into bacteria (*see Bacteria*) and plants by low affinity pathways (on the back of Fe, phosphate, and sulfate uptake) and by specific proteins showing a high selectivity and affinity for $[MoO_4]^{2-}$ over closely related oxoanions. Molybdate transport proteins, designated ModABC, are part of an ATP-binding cassette transporter in the periplasm. Inside the cell, so-called molbindins (Mop-type proteins) store molybdenum and regulate its uptake and utilization. The genes and proteins involved in molybdate transport, homeostasis, and regulation have been reviewed by Pau and Lawson[22] (*see also* ***Metalloregulation***). Animals and humans require Mo as a trace element (*see Trace Element*) in their diets (*see* ***Nutritional Aspects of Metals & Trace Elements***).

3.2.2 Biosynthesis of MPT and Moco

The evolutionarily conserved Moco biosynthetic pathway consists of three steps (Scheme 1): (1) the conversion of a guanosine derivative (probably guanosine triphosphate) into sulfur-free Precursor Z via insertion of C-8 between the ribose C-2′ and C-3′ atoms, (2) sulfurization and transformation of Precursor Z into MPT, catalyzed by MPT-synthase, and (3) metal incorporation through chelation of the dithiolene moiety. Additional steps are involved in the attachment of a nucleotide to generate the dinucleotide forms found



Scheme 1

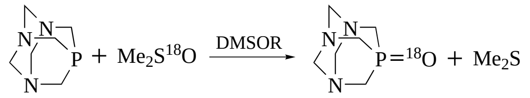
in bacteria. The biosynthetic pathway in *E. coli* has been extensively studied and many of the proteins involved have been structurally characterized. The multifunctional gephyrin protein is involved in Moco biosynthesis in mammalian and plant cells. The incorporation of the other (nonprotein) ligands at the Mo sites is not well understood; however, some of the enzymes responsible for the terminal sulfido ligand in hydroxylases have been identified. Moco deficiency in humans is a rare autosomal recessive condition marked by severe neurological abnormalities, ocular lens dislocation, and infant death.[19] The burial of Moco deep inside the holoenzymes implicates its incorporation prior to or during protein folding or aggregation, but the details of its incorporation remain unknown. Excellent reviews of Moco biosynthesis are available[9,23] (*see also* ***Metalloregulation***).

4 THE DIMETHYL SULFOXIDE (DMSO) REDUCTASE FAMILY

Enzymes in this family include DMSO reductase, biotin *S*-oxide reductase, dissimilatory nitrate reductase, trimethylamine *N*-oxide reductase, and formate dehydrogenase; they are found exclusively in bacteria and fungi and act as terminal respiratory reductases during anaerobic growth in the presence of their respective substrates.[1–4,24,25] DMSO reductases catalyze the reaction shown in equation (5); the water-soluble enzymes from the purple phototrophic bacteria *R. capsulatus* and *R. sphaeroides* are among the simplest Mo-MPT enzymes, being relatively small (ca. 85 kDa), single subunit (*see Subunit*) enzymes with the Mo center as the only prosthetic group. In contrast, the DMSO reductase from *E. coli* is a heterotrimeric membrane-bound enzyme that couples via the quinol pool to nitrate reductase, thus producing a transmembrane proton gradient for ATP synthesis. The production of dimethyl sulfide by bacteria in the world's oceans has a profound effect on marine life (influencing, e.g., the feeding behavior of sea birds) and global albedo (reflectance) and climate (through its role in cloud formation).[26]

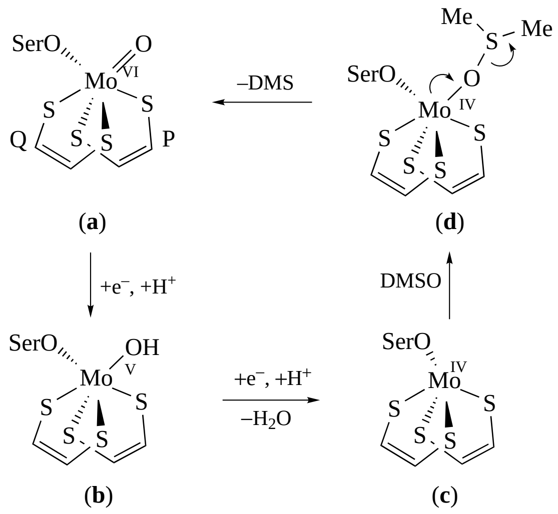
$$Me_2SO(DMSO) + 2H^+ + 2e^- \longrightarrow Me_2S(DMS) + H_2O \quad (5)$$

The enzymes from *Rhodobacter* sp. have been isolated and crystallized under a variety of conditions. A number of crystal structures have revealed the presence of two MGD ligands, designated P and Q, a serinate-147 ligand, and a variable number of water-based ligands; pterin Q displays a range of complexation and redox modes as a result of sample degradation and active-site heterogeneity/disorder.[8–10] EXAFS[27] and resonance Raman[28,29] results provide strong evidence for the presence of distorted trigonal prismatic (*see Trigonal Prism*) monooxo-Mo(VI) (**1**) and square-pyramidal desoxo-Mo(IV) (see species (**c**) in Scheme 2) sites in the oxidized and reduced enzymes, respectively. The active site of the trimethylamine *N*-oxide from *Shewanella massilia* exhibits a closely related structure.[9,10] Substrate specificities in these and related enzymes are determined by the nature of the protein surface, substrate access channel, and the active-site pocket; side-chain (Tyr114 in DMSO reductases, Trp90 in *R. sphaeroides* biotin sulfoxide reductase) interactions with the oxo group, or their absence (in TMSO reductase), are particularly important in fine-tuning redox potentials.



(6)

There is strong evidence for a direct OAT mechanism for DMSO reductases. Schultz *et al.*[30] have demonstrated that *R. sphaeroides* dimethyl sulfoxide reductase catalyzes the reaction in equation (6), an archetypal OAT reaction in synthetic chemistry (Sections 7–9). An intermediate along the OAT reaction coordinate has also been structurally characterized in the form of DMSO-bound *R. capsulatus* DMSO reductase (see species (**d**) in Scheme 2), the DMSO being generated in the reaction of DMS with the terminal oxo ligand.[9,10] Structural data from other techniques (EXAFS, Raman, EPR) have also contributed to the consensus mechanism in Scheme 2. Here, the oxidized oxo-Mo(VI) site (**a** = (**1**)) undergoes CEPT reactions, via Mo(V) (**b**) forms, converting the oxo group to labile water with formation of the desoxo-Mo(IV) active site (**c**). DMSO interacts with (**c**) giving (**d**) – this facilitates direct OAT to produce reduced



Scheme 2

substrate (DMS) and regenerate the oxo-Mo(VI) site (**a**) (cf. Scheme 3).

Two types of dissimilatory nitrate reductases, localized in either the cytoplasmic membrane or the periplasm, are widespread among bacteria.[1–5,25,31] The cytoplasmic membrane-bound nitrate reductase (Nar) catalyzes the first steps of denitrification ($NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$) and nitrate ammonification ($NO_3^- \rightarrow NO_2^- \rightarrow NH_3$). These reactions are the terminal electron-transfer reactions during anaerobic respiration, the enzymes being part of a redox loop generating a proton-motive force capable of driving ATP synthesis.[25,31] Periplasmic nitrate reductase (Nap) participates in cellular redox processes, aerobic denitrification, and nitrate scavenging.[25,31]

The heterotrimeric NarGHI from *E. coli* is composed of an Mo(MGD)$_2$ unit (NarG), an [Fe-S] cluster-containing electron-transfer unit (NarH), and a heme-containing membrane anchor (NarI). The Mo active site is remarkable in containing MGD in forms (**4**) and (**5**) and an unsymmetrically bound, bidentate Asp222 ligand (Figure 2).[21] The coupling of formate oxidation (by FdnGHI) and nitrate reduction (by NarGHI) by membrane-soluble menaquinol and/or ubiquinol drives proton translocation across the membrane.[21,25] The Asp222 ligand may function as an ambidentate ligand (*see Ambidentate Ligand*) during catalysis.

The periplasmic nitrate reductases are generally heterodimers, the larger unit (NapA, 90 kDa) binding catalytic Mo(MGD)$_2$ and [Fe_4S_4] centers and the small unit (NapB, 15 kDa) a pair of *c*-type heme groups. A membrane-anchored *c*-type cytochrome (NapC) uses the menaquinol pool to reduce the soluble NapAB complex. The X-ray structures of monomeric Nap from *D. desulfuricans* ATCC 27774 and heterodimeric NapAB from *R. sphaeroides* have been determined.[9,10] The trigonal prismatic oxidized Mo active sites are similar and contain two bidentate MGD ligands, an amino acid thiolate donor (Cys140 and Cys152, respectively), and a water-based ligand. EXAFS studies are consistent with the presence of monooxo (**1**) and desoxo Mo (cf., species (**c**) in Scheme 2) centers in the oxidized Mo(VI) and reduced Mo(IV) forms of the enzyme, respectively. In these enzymes, nitrate is proposed to bind through oxygen to an Mo^{IV}(Cys)(MGD)$_2$ center and undergo direct OAT via O–N bond cleavage, producing nitrite and an Mo^{VI}O(Cys)(MGD)$_2$ center. Regeneration of the active site occurs through proton and electron-transfer processes leading to dissociation of water from the coordination sphere (cf. Scheme 2).

The structure of another member of this family, the selenocysteine-containing formate dehydrogenase H from *E. coli*, has also been determined; it contains an [Mo^{VI}O(SeCys)(MGD)$_2$]$^-$ oxidized active site (*see* ***Selenium Proteins Containing Selenocysteine***).[8–10] Formate dehydrogenases catalyze the interconversion of formate and carbon dioxide and play an important role in global fixation of carbon dioxide.[32]

Enzymes catalyzing the oxidation of arsenite (AsO_3^{3-}) to arsenate (AsO_4^{3-}) have been identified or isolated from archaea, bacteria, and algae. The active site of arsenite oxidase from *Alcaligenes faecalis*[9,10] contains inequivalent P and Q pterins and two nonpeptide ligands, proposed to be oxo and hydroxo ligands on the basis of EXAFS studies.[33] *Chrysiogenes arsenatis* respires anaerobically using arsenate as the terminal electron acceptor and acetate as electron donor. Reduction of arsenate to arsenite is effected by a periplasmic heterodimeric enzyme, arsenate reductase. Enzymes metabolizing analogous selenium-containing species are also known.[2,3]

Reductive cleavage of sulfur–sulfur bonds in inorganic sulfur species is exploited in terminal electron transfer in some bacteria. The tetrathionate and thiosulfate reductases of the enteric bacterium *Salmonella enterica* LT2 and the polysulfide reductase of the rumen bacterium *Wolinella succinogenes* effect such reactions.[24]

5 THE SULFITE OXIDASE FAMILY

This family includes the sulfite oxidases and dehydrogenases of prokaryotes (*Thiobacilli* sp.), plants, birds, and animals, and the assimilatory nitrate reductases from bacteria, algae, fungi, and plants.[1–5,24] The sulfite oxidases of higher eukaryotes are 100–110 kDa homodimers (Table 1); they are located in the mitochrondrial intermembrane space and catalyze the oxidation of toxic sulfite to innocuous sulfate (equation 7). Human sulfite oxidase deficiency leads to major neurological abnormalities, mental retardation, dislocation of the ocular lenses, and early death.[19]

$$SO_3^{2-} + H_2O + 2\ \text{cyt}\ c^{III} \longrightarrow SO_4^{2-} + 2H^+ + 2\ \text{cyt}\ c^{II} \qquad (7)$$

The crystal structure of chicken liver sulfite oxidase revealed a five-coordinate, square-pyramidal (*see Square Pyramidal*) Mo center coordinated by a bidentate MPT ligand, a cysteine thiolate (from Cys185, conserved in all active enzymes from this family), and two O-donor ligands (Figure 3).[9,10] EXAFS[34] and resonance Raman[35] studies indicate the presence of two oxo ligands in the oxidized enzyme ($\nu(MoO_2)$ 903, 881 cm^{-1}); only one of these is exchanged into $H_2{}^{18}O$ buffer during redox cycling, the other being retained in Mo(V) and Mo(IV) forms. Paramagnetic resonance studies have defined the pH dependent nature of the active site and various anion (*see Anion*) bound forms of the enzyme.[24] The types of centers formed under various conditions are shown in Figure 4.

Comprehensive laser flash photolysis studies on chicken and human SO have probed the rates of *intermolecular* electron transfer (IET, *see Intermolecular*) between the Mo and heme centers. Data are consistent with a CEPT mechanism interconverting $Fe^{II}/[MoO_2]^{2+}$ and $Fe^{III}/[MoO(OH)]^{+}$ centers. To account for the wide range of IET rates (20–1400 s^{-1}), it has been proposed that protein conformational changes effectively gate IET by changing the Fe···Mo distance.[24,36]

The existence of sulfite oxidase in plants such as *Arabidopsis thaliana* (wall or thule cress), tobacco, pea, spinach, barley, carrot, and poplar trees has now been confirmed,[37] and the enzyme from *A. thaliana* has been structurally characterized.[38] The homodimeric, peroxisomal enzyme lacks the heme domain observed in animal sulfite oxidases, making it the simplest Mo-MPT enzyme yet isolated from eukarya. The animal and plant sulfite oxidases have an overall 47% sequence identity. The detoxification of sulfite, produced in the assimilation of sulfate into sulfur-containing amino acids and membrane components (sulfatides) and from environmental sources (acid rain), is also the principal role of the plant enzymes.

$$NO_3{}^- + NAD(P)H + H^+ \longrightarrow NO_2{}^- + H_2O + NAD(P)^+ \qquad (8)$$

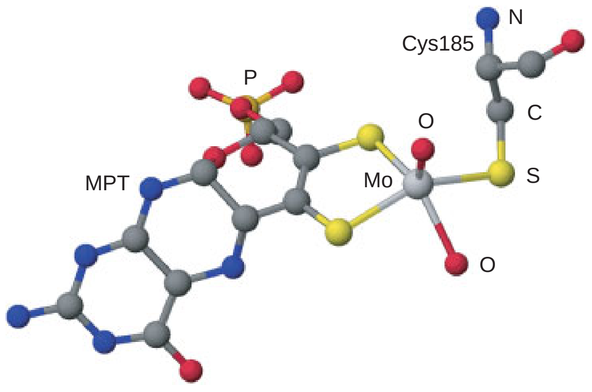


Figure 3 Active site of chicken liver sulfite oxidase. The apical group is a terminal oxo ligand, the second oxygen is an oxo ligand in the oxidized enzyme

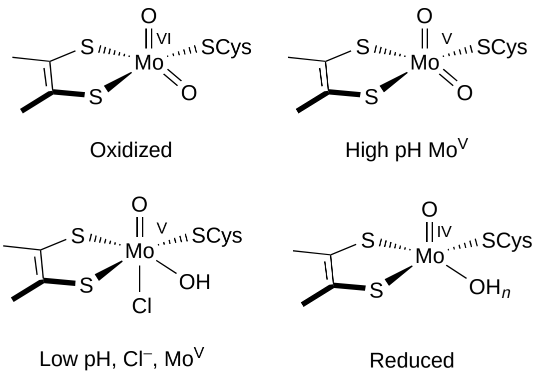

Figure 4 Important active-site states of sulfite oxidase

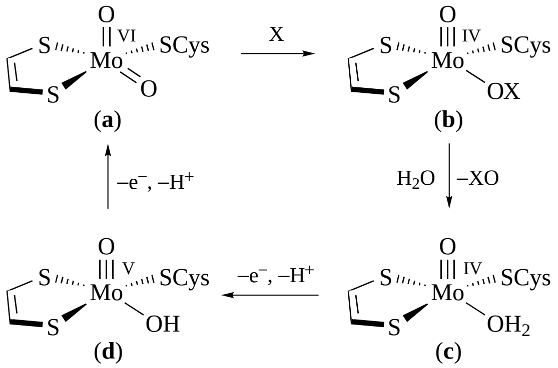
Assimilatory nitrate reductases catalyze the first step of nitrate assimilation by bacteria, fungi, algae, and plants (equation 8; Reductant: NADH in plants and most algae, NADPH in fungi); they are estimated to transform ca. 10^7 tons of inorganic nitrogen per year, as a prelude to nitrogen incorporation into proteins and nucleic acids.[1–5,25,31] Eukaryotic assimilatory nitrate reductases are cytosolic homodimers (ca. 220 kDa) containing one *b*-type cytochrome, one FAD, and one Mo-MPT center per subunit (Table 1). Two types of assimilatory nitrate reductases, ferredoxin/flavodoxin- and NADH-dependent (Nas) enzymes, are found in bacteria; these cytosolic enzymes contain Mo-MGD and Fe/S groups but not the heme groups found in eukaryotic enzymes. EPR and EXAFS studies of chicken liver sulfite oxidase and *Chlorella vulgaris* nitrate reductase indicate that both enzymes possess similar active sites.[25,31]

With respect to the molybdenum center, it appears that a spectator oxo ligand (*see Spectator Ligand (Ion)*) controls the electronic structure allowing the second oxo ligand to participate in OAT reactions with the substrate (*see Substrate*), X = $SO_3{}^{2-}$ for sulfite oxidase (Scheme 3, **a** → **b**); the substrate enters the enzyme via a substrate (solvent) access channel directed toward the exchangeable oxo group. Egress of the oxidized substrate, XO = $SO_4{}^{2-}$, permits the

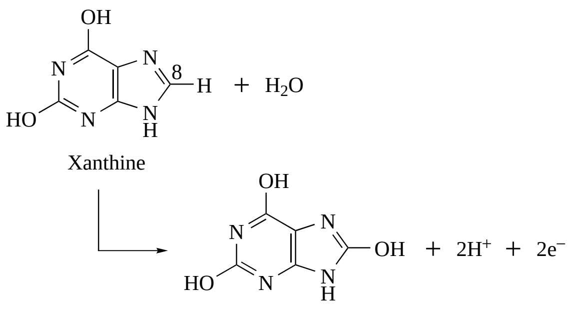


Scheme 3

generation of an *aqua*-Mo(IV) (*see Aqua*) species (**b** → **c**) that undergoes CEPT reactions leading to the regeneration of the active site (**c** → **d** → **a**).[1–4,24] Nitrate reductases would cycle in the opposite direction (cf. Scheme 2 for dimethyl sulfoxide reductase).[1–4,25] The OAT chemistry is represented as a concerted two-electron event, the CEPT chemistry as two consecutive (e^-, H^+) transfers. Other possible mechanisms involve oxoanion binding to Mo prior to OAT or attack of sulfite by activated water (or hydroxide) within the active-site pocket.[2–4,24]

6 THE XANTHINE OXIDASE FAMILY

These enzymes (hydroxylases) are distributed across all phyla and include xanthine oxidoreductase (*see Oxidoreductase*) (oxidase and dehydrogenase),[1–5,39–41] aldehyde oxidoreductase,[1–5,41,42] and a host of lesser known enzymes like 4-hydroxybenzolyl-CoA reductase,[2–4] pyrogallol transhydroxylase,[2–4] picolinate dehydrogenase,[39] CO dehydrogenase,[32] and various quinoline[43] and nicotinate oxidoreductases.[44] They generally catalyze net OAT reactions through the insertion of an oxygen atom into a C–H bond in aromatic heterocycles (e.g., purines, pyrimidines, pterins) and aldehydes, yielding hydroxylated products and carboxylic acids, respectively. Some enzymes catalyze the translocation of hydroxy groups on aromatic substrates and many are selenium-dependent.[45]



(9)

The xanthine oxidoreductases are large, complex molybdoflavoproteins with roles in the catabolism of purines, for example, oxidizing hypoxanthine to xanthine and xanthine to uric acid (equation 9).[39–41] Xanthine oxidase can also catalyze the reduction of nitrate to nitrite (or in the presence superoxide, peroxynitrite) and the reduction of nitrite to nitric oxide. Peroxynitrite, a powerful and destructive oxidant, has been implicated in diseases such as arthritis, atherosclerosis, multiple sclerosis, and Alzheimer's and Parkinson's diseases. The microbicidal role of milk and intestinal xanthine oxidase may also involve the generation of peroxynitrite in the gut. The high levels of the enzyme in the mammary glands of pregnant or lactating animals suggests a possible role for xanthine oxidoreductases in mammogenesis and lactogenesis.[41] A genetic deficiency of xanthine dehydrogenase leads to the rare but benign condition of xanthinuria (type 1) in humans, whereas enzyme overactivity is associated with hyperuricemia and gout. Allopurinol, a drug for these conditions, acts to suppress xanthine dehydrogenase activity. An excellent review of the potential pathophysiological roles of xanthine oxidase has been prepared by Harrison.[46]

Aldehyde oxidases oxidize azaheterocycles and aldehydes and are involved in the biosynthetic pathways producing retinoic acid and various phytohormones including abscisic acid and indole-3-acetic acid. Aldehyde oxidase and xanthine dehydrogenase both play vital roles in the metabolism of drugs and pollutants, for example, in the metabolism of famciclovir to the antiviral agent penciclovir. Aldehyde oxidoreductase is also important in the metabolism of alcohol (following its transformation to acetaldehyde) and the antimigraine agent almotriptan.[42,46]

The cytosolic, mammalian hydroxylases are homodimeric, with three distinct binding domains for [Fe_2S_2] (20 kDa, N-terminus), FAD (40 kDa), and Mo-MPT (85 kDa, C-terminus) centers.[39–42] Mammalian xanthine oxidoreductases exist in two interconvertible forms, a dehydrogenase (dominant in vivo) employing NAD^+ as electron acceptor and an oxidase employing dioxygen as electron acceptor; the dehydrogenase/oxidase transformation is induced by proteolytic cleavage or cysteine modification.[47] The generation of superoxide and hydrogen peroxide by xanthine oxidase is believed to be responsible for tissue damage due to postischaemic reperfusion injury. The avian and bacterial (*R. capsulatus*) enzymes are stable dehydrogenases. The xanthine dehydrogenase from *R. capsulatus* is unusual for a bacterial Mo-MPT enzyme in that it contains MPT (as in eukaryotic enzymes) rather than a nucleotide derivative.

The presence of a catalytically essential active-site sulfur atom was demonstrated by cyanide deactivation/sulfide reactivation studies performed around 1970. In the 1980s, EXAFS revealed the presence of terminal oxo (Mo=O = 1.73 Å) and terminal sulfido (Mo=S = ca. 2.15–2.18 Å) ligands, as well as two additional sulfur donor atoms. Enzymes from a number of sources have now been structurally characterized (Table 1). These include bovine milk xanthine dehydrogenase and its BOF-4272-inhibited form, the active and alloxanthine-inhibited xanthine dehydrogenase from *R. capsulatus*, the aldehyde oxidoreductases from *D. gigas* and *D. desulfuricans*, and the CO dehydrogenases from *Oligotropha carboxidovorans* and *H. pseudoflava*.[8–10] Crystallographic and spectroscopic data together indicate the presence of five-coordinate, square-pyramidal (or pseudotetrahedral (*see Tetrahedral*)) $[Mo^{VI}OS(OH_n)(MPT)]^{0/-}$ (n = 1, 2) oxidized active sites. Resonance Raman studies have allowed the assignment of bands at 899 and 474 cm^{-1} to ν(Mo=O) and ν(Mo=S), respectively; the oxo O atom is nonlabile.[48] Crystallographic evidence supports the presence of an apical terminal

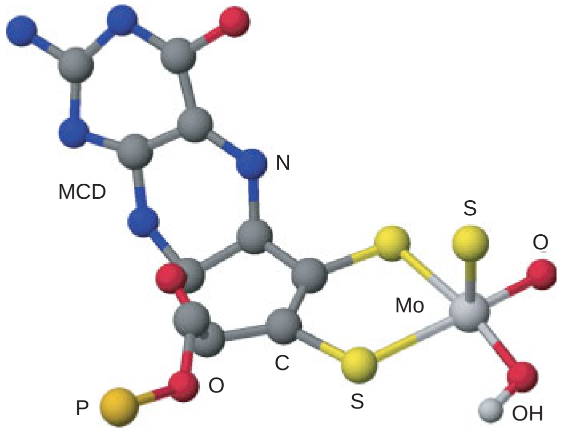


Figure 5 The active site of *D. gigas* aldehyde oxidoreductase. An apical sulfido group is indicated by crystallographic studies but its position remains ambiguous. Although labeled as a hydroxy group, the second oxygen donor may be an aqua ligand. Only the pterin-dithiolene portion of the MCD ligand is shown

sulfido ligand in the square-pyramidal description (Figure 5), but the oxo ligand may in fact be the apical ligand (Figure 6, cf. position of ligand S in CO dehydrogenase (Figure 7)). (Evidence of an equatorial sulfido group has been presented by Okamoto *et al*. Proc. Natl. Acad. Sci. U.S.A., 2004, 101, 7931). The Very Rapid EPR signal of xanthine oxidase ($t_{1/2} \sim 10$ ms) appears during turnover under substrate *limiting* conditions and is assigned to an $[Mo^{V}OS(urate)(MPT)]^{2-}$ species on the basis of ^{17}O and ^{33}S superhyperfine and ^{13}C-8 ENDOR coupling data (see Section 11.2).[1,40] The unpaired electron is highly delocalized, with ca. 35% sulfido ligand character. In the presence of *excess* substrate, the Rapid signal also appears; ^{1}H and ^{33}S superhyperfine coupling data suggest the presence of an $[Mo^{V}O(SH)]^{2+}$ center. The presence of bound urate in the Mo(IV) state has been inferred from EXAFS and resonance Raman studies; an $[Mo^{IV}O(SH)(urate)(MPT)]^{2-}$ center is postulated.[1,40] The detection of intermediates during a *single* catalytic turnover of xanthine oxidase shows that the oxygen atom transferred to substrate originates from the enzyme center and not directly from solvent water.[49] Proposed structures for the important states of active xanthine oxidase are shown in Figure 6. The mechanism shown in Scheme 4 is supported by many lines of evidence but is not the only one possible.[2,4,40] Outstanding mechanistic questions include the nature of the active oxygen, the role of the terminal oxo and thio ligands, and the choreography of proton and electron transfer.

The carbon monoxide dehydrogenase from aerobic, carboxidotropic bacteria catalyzes the oxidation of CO to CO_2, and thereby contributes to the maintenance of subtoxic concentrations of CO in the lower atmosphere. The enzymes are included in the xanthine oxidase family because of sequence similarities and their conversion to inactive 'desulfo' (and/or 'decupro') forms upon cyanolysis. However, and quite remarkably, the CO dehydrogenase from the bacterium *O. carboxidovorans* (formally *Pseudomonas carboxidovorans*) contains an $\{(MCD)Mo^{VI}(=O)(OH)(\mu\text{-}S)Cu^{I}(S\text{-}Cys388)\}$ active site featuring an unprecedented Mo–S–Cu unit (Figure 7).[10,50] The

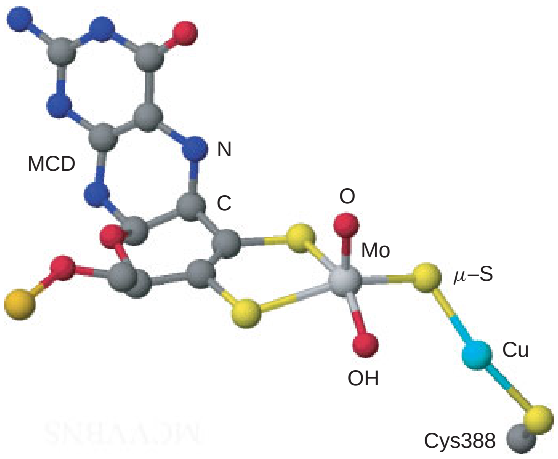

Figure 7 The active site of *O. carboxidovorans* CO dehydrogenase. Although labeled as a hydroxy group, the second oxygen donor may be an aqua ligand. Only the pterin-dithiolene portion of the MCD ligand is shown

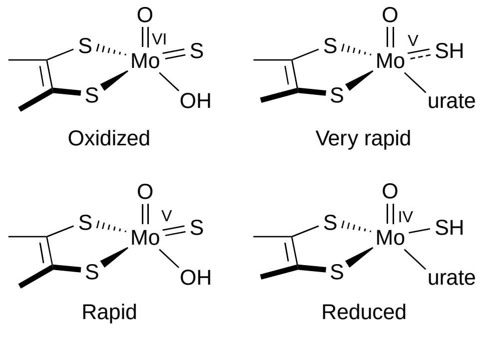

Figure 6 Important active-site states of xanthine oxidoreductase

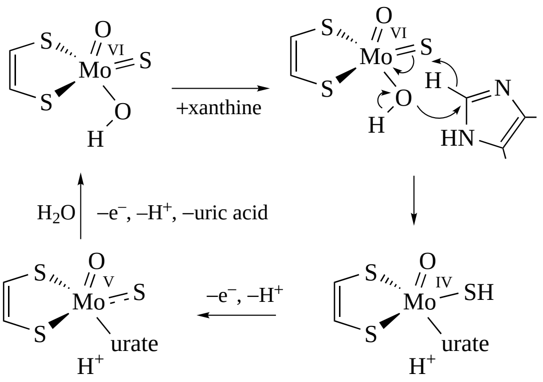


Scheme 4

five-coordinate, square-pyramidal Mo center closely resembles that of active xanthine oxidase, with an oxo ligand in the *apical* site and a longer (as expected) Mo–(μ-S) distance; the geometry at the Cu(I) center is close to linear. The presence of the binuclear heterometallic unit has been confirmed by complementary EXAFS studies.[51] A mechanism involving a thiocarbonate intermediate formed by cooperative binding of the polar CO molecule by the two metal centers has been proposed.

7 SYNTHETIC ANALOGUE CHEMISTRY

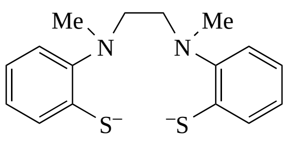
7.1 The Contribution of Synthetic Analogues

The synthetic analogue or model approach provides insights into bioinorganic systems through the synthesis and study of closely related 'model' compounds. It garners structural, electronic, spectroscopic, and chemical information crucial to a complete understanding of enzyme behavior.[4,52] This section begins with some general observations relating to biologically relevant ligands and OAT and CEPT reactions. Selected chemistry relating to specific enzyme families is then presented. An exhaustive review of mononuclear Mo chemistry can be found in *Comprehensive Coordination Chemistry II*[53] (*see also* ***Molybdenum: Inorganic & Coordination Chemistry***).

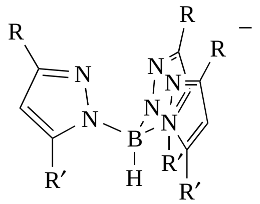
7.2 Ligands Important in Biomolybdenum Chemistry

7.2.1 Ligands Derived from Water: Oxo, Hydroxo, Aqua

High-valent molybdenum chemistry is dominated by oxo complexes.[53] The terminal oxo group is characterized by multiple bonding (one σ and up to two π components) to the metal, a short Mo=O distance (1.64–1.72 Å), and group-specific IR absorptions. The strong trans influence (*see Trans Influence*) of the oxo ligand is responsible for lengthening (by 0.15–0.3 Å) or disfavoring *trans* Mo–L interactions. Complexes containing *fac*-MoO_3, *cis*-$[MoO_2]^{2+}$, and $[MoO]^{4+}$ units are common in oxo-Mo(VI) chemistry. Dioxo complexes are very common and tetrahedral, trigonal bipyramidal, and (in the main) distorted octahedral (*see Octahedral*) geometries are observed. Seven-coordinate, pentagonal bipyramidal (*see Pentagonal Bipyramid*) peroxo complexes currently constitute the largest class of monooxo-Mo(VI) complexes. A wide variety of O-, N-, S-, and mixed-donor ligands serve as coligands in these oxo complexes. Mononuclear Mo(V) and Mo(IV) complexes generally contain a single oxo group and exhibit square-pyramidal or distorted octahedral structures. The highly reactive *cis*-dioxo-Mo(V) complexes, $[(L\text{-}N_2S_2)MoO_2]^-$ and $[Tp^*MoO_2X]^-$ (see (**6**) and (**7**) for ligand structures), are rare exceptions (but EPR signals from such centers have never been observed in enzymes). In the absence of steric protection, Mo(V) complexes exhibit a marked tendency for di- or polynucleation reactions. The chemical reactions of oxo-Mo(VI–IV) complexes have been extensively reviewed.[53,54]

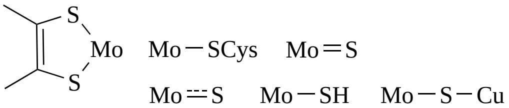


(**6**) L-N_2S_2



(**7**) Tp*: R = R′ = Me
Tp^{Pr}: R = ^{i}Pr, R′ = H

Mo-MPT enzymes mediate formal exchange of an oxygen atom between the substrate and water (equation 3), and at some stage water is bound to the Mo center. CEPT reactions are responsible for the interconversion of aqua, hydroxo, and oxo ligands upon the oxidation state change; hydroxo ligation is inferred from enzyme EPR spectra, but direct evidence for aqua ligation is lacking. Aqua(oxo) complexes, exemplified by *cis*-$Mo^{VI}O_2(OH_2)_2Cl_2$, $[Mo^VOX_4(OH_2)]^-$, and $[Mo^{IV}O(OH_2)(dppe)_2]^+$, generally possess trans aqua(oxo) arrangements. However, certain coligands can induce a cis geometry, as observed in six-coordinate $(L\text{-}N_2S_2)MoO(OH)$ and Tp*MoO(OH)X (X = monodentate anion).[53]



(**8**)

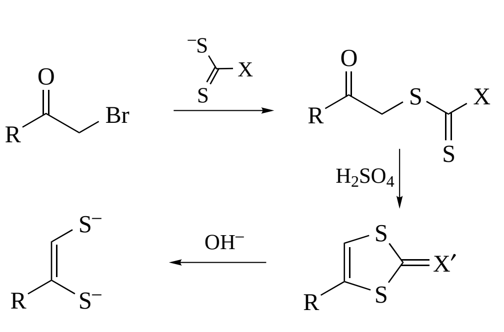
7.2.2 Sulfur Ligands

The Mo–S linkages shown in (**8**) are found at the active sites of Mo–MPT enzymes. Dithiolene, thiolate, and hydrosulfido complexes are known for all common Mo oxidation states, although the latter are extremely rare; terminal thio ligation is restricted to Mo(VI-IV) complexes.[53] Metallodithiolenes have been extensively studied and reviewed.[7,53] Biologically relevant dithiolene complexes feature two types of ligands: arene-1,2-dithiolates (where the 'ene' function is part of an aromatic ring) and authentic dithiolenes (see Sections 9 and 10). Two structural motifs are encountered in ternary oxo bis(dithiolene)-Mo complexes. Firstly, distorted octahedral geometries are observed for *cis*-dioxo-Mo(VI) complexes; here, the longest Mo–S distances (ca. 2.6 Å vs 2.4 Å) are trans to the terminal oxo ligands (d(Mo=O) = 1.70–1.73 Å). Secondly, square-pyramidal complexes with apical oxo

ligands are characteristic of both Mo(V) and Mo(IV) complexes.[53] The study of these and related complexes is relevant to the modeling of the DMSO reductase family of enzymes (see Sections 7.3 and 9.1). Mono(dithiolene) complexes relevant to the other two enzyme families are still quite rare and generally do not participate in clean OAT reactions.[53] Very recent progress in this area is described in Section 10.

The synthesis of Moco's (Mo-MPT complexes) presents significant challenges, however, progress is being made.[4,52,55] A general strategy for the synthesis of asymmetrically substituted dithiolenes, involving the generation of dimethylamino- or thione-protected 1,3-dithiolates and their subsequent deprotection by alkaline hydrolysis (Scheme 5), has been developed by Garner, Joule, and coworkers. In the presence of $[MoO_2(CN)_4]^{4-}$, square-pyramidal oxo-Mo(IV) complexes of the type $[MoO(dithiolene)_2]^{2-}$ are formed (R = phenyl, pyridyl, quinoxalinyl, or pterinyl derivatives). These are stepping stones to Mo(V) complexes and may serve as precursors to the Mo(VI) species.[55] The reactions of alkynes with polysulfido complexes (*EIC-1*)[1] or α-bromo ketones with $Cp_2Mo(SH)_2$,[56] have also been exploited in the synthesis of unsymmetrical dithiolenes, including some pterin derivatives. Some of these undergo oxidative decomposition producing molecules closely related to urothione, the excretory by-product of MPT degradation.

Investigations by Enemark, Kirk, and coworkers have provided insights into the electronic structure and function of dithiolene- and thiolato-Mo complexes and Mo-MPT enzymes.[7] For example, Tp*MoOL (L = arene dithiolate, e.g., benzene-1,2-dithiolate (bdt)) and related nitrosyl complexes feature a highly covalent, three-center, pseudo-σ bonding interaction between the redox-active Mo ϕ_{xy} and S (dithiolene) in-plane $\phi^{a'}$ orbitals; this interaction is optimized when the strong-field ligand is cis and perpendicular to the MoS_2 plane. A π interaction between the Mo ϕ_{xy} and S $\phi^{a'}$ out-of-plane orbitals is also possible depending on the electronic requirements of the metal; here, the degree of orbital interaction is determined by the fold angle of the Mo-dithiolene unit along the S···S vector. The redox potentials and rates of electron transfer to or from enzyme Mo-MPT centers may be controlled by variations in interactions of this type.[7,57] Related studies have defined the covalency and electronic structures of thiolate complexes, including known $[MoO(SR)_4]^-$[58,59] and $(L\text{-}N_2S_2)MoO(SR)$[60] complexes.



X = OPr → X′ = O; X = NMe$_2$ → X′ = NMe$_2^+$HSO$_4^-$

Scheme 5

Only a handful of pseudotetrahedral or octahedral oxosulfido-Mo(VI) and -Mo(V) complexes are known, and their chemistry is described in Section 11. Mononuclear sulfido-Mo(V) complexes are unstable due to their susceptibility to redox, polynucleation, and hydrolysis reactions. Trispyrazolylborate derivatives such as structurally characterized $Tp^*Mo^VSX_2$ (X = Cl, OPh derivative; X_2 = bdt, catecholate) are most commonly encountered. The Tp* complexes exhibit short Mo=S bonds (ca. 2.13 Å), intense S(1s) → π^* (Mo=S) XAS transitions characteristic of terminal thio ligands, and EPR g_{iso} (*see g-Factor*) values substantially lower than their oxo analogues.[53]

Speculation about the precise roles of active-site sulfur is tempered by an appreciation of the redox versatility and interplay of sulfur and molybdenum. This is evident from synthetic systems, where the catenation of sulfur (with attendant redox and/or ligand elaboration) and induced internal electron-transfer reactions are frequently observed. The redox interplay of Mo and S, reflected in 'undesirable synthetic outcomes,' may prove crucial to a full description of enzyme behavior.[61,62] (*see also* ***Sulfur: Inorganic Chemistry***)

7.3 Atom Transfer Chemistry

Molybdenum has a marked predilection for OAT reactions[53] and biomimetic systems have been reviewed.[54] OAT is a concerted two-electron process that results in the oxidation of the oxygen atom acceptor and the reduction of the donor. The most common reactions for Mo are shown in equations (10) and (11). Catalysis results from the coupling of these reactions, leading to net oxidation of X by X′O (equation 12, cf. equation 6). Transformations involving oxo-Mo(VI) and desoxo-Mo(IV) complexes are recent and important developments (see Section 9).

$$Mo^{VI}O_2L_n + X \longrightarrow Mo^{IV}OL_n + XO \quad (10)$$

$$Mo^{IV}OL_n + X'O \longrightarrow Mo^{VI}O_2L_n + X' \quad (11)$$

$$X + X'O \longrightarrow XO + X' \quad (12)$$

Comproportionation and concomitant formation of μ-oxo (*see μ-Oxo Bridge*)-Mo(V) species (equation 13) is a prevalent complication in Mo OAT chemistry; the formation of dinuclear (*see Dinuclear*) complexes can be reversible or irreversible, allowing access to both Mo(IV) and Mo(V) complexes or only Mo(V) species, respectively.[54]

$$Mo^{VI}O_2L_n + Mo^{IV}OL_n = Mo^V_2O_2(\mu\text{-}O)L_{2n} \quad (13)$$

For neutral complexes, comproportionation is usually encountered when L is not sufficiently bulky to prevent close

approach of the Mo atoms. Complexes containing dithio acid, cysteine ester (CysOEt), tridentate Schiff base (hpd), and 2,6-bis(2,2-diphenyl-2-thioethyl)pyridine(2−) (L-NS_2) ligands readily participate in comproportionation/dinucleation reactions.[54] Dinucleation must be prevented in the development of valid enzyme models and steric, electrostatic, and/or immobilizing strategies have been successful in this regard. Comproportionation to monomeric Mo(V) species is also observed but this can be controlled and exploited to produce models for the EPR-active Mo(V) states of enzymes.[54]

The ligands Tp* (and derivatives) (**7**), 2,2-diphenyl-2-mercaptoethanoate(2-) (L-SO), bis(4-*t*-butylphenyl)-2-pyridylmethanethiolate(1-) (L-NS), and various dithiolenes support clean OAT reactions between monomeric species (equations 10 and 11); the reactions have been extensively studied by kinetic methods (*see Kinetic Methods*).[54] The rate constants for these reactions span a ca. 10^6 range depending on the nature of the substrate and ligand (Table 2). In substrate oxidation reactions (equation 10), phosphines feature prominently as oxygen atom acceptors (X). Generally, these reactions are first order in both the phosphine and Mo complex; they are proposed to proceed by an associative mechanism involving nucleophilic attack of the phosphine lone pair on the π^* Mo=O orbital. Theoretical studies have shown these reactions are facilitated, both electronically and energetically, by the presence of a 'spectator oxo group,' and phosphine oxide intermediates have now been isolated and structurally characterized.[63] The mechanism of sulfite oxidation by dioxo-Mo(VI) complexes is less certain (see Section 10.2).

A much broader range of substrates is amenable to reduction by oxo-Mo(IV) complexes (equation 11). These include many biological substrates such as *S*- and *N*-oxides and nitrate, and species related to selenate and arsenate. These reactions are also first order in both the substrate and metal complex; they are proposed to proceed by associative mechanisms involving coordination of substrate to Mo and concomitant OAT.[54] A thermodynamic scale for OAT reactions has been described by Holm and Donahue.[64]

More recently, simple complexes such as $MoO_2X_2(DMSO)_2$ (X = Cl, Br), $(PPh_4)_2[MoO_2(NCS)_4]$, $MoO_2(NCS)_2(Bu^t_2bpy)$, and $MoO_2(acac)_2$ have been shown to catalyze OAT without apparent comproportionation.[54] These observations have challenged the accepted 'design criteria' for efficient OAT catalysis.

7.4 Coupled Electron-proton Transfer (CEPT) Reactions

Regeneration of enzyme active sites is proposed to take place via two one-electron CEPT reactions, accounting for the detection of EPR-active Mo(V) enzyme states. CEPT reactions are facilitated by the quite general interconversion of water-based (oxo, hydroxo, aqua) ligands induced by changes to the oxidation state of the metal. Related transformations interconverting thio and hydrosulfido coligands at oxo-Mo centers are envisaged in hydroxylases. The electron density at the metal center is communicated to the donor oxygen atom via the π-bonding framework; reduction of the center increases the basicity and level of protonation (*see Protonation*) of oxygen while oxidation decreases the basicity and level of protonation of oxygen. While detailed mechanistic information is often lacking, CEPT processes remain the most logical explanation for many synthetic outcomes and the generally irreversible reduction of high-valent oxo-Mo species.[53] The stoichiometries of the synthetic reactions represented by equations (14), (15), and (16) (E = electrophile (*see Electrophile*) (H^+, $SiMe_3$), vide infra) are well established and hint at CEPT or, more broadly, coupled electron-electrophile transfer (CEET) processes.[1] The literature should be consulted for a full overview of OAT and CEPT reactions.[4,53,54]

$$[Mo^{VI}O_2(L\text{-}SO)_2]^{2-} + RSH + H^+ \longrightarrow [Mo^{V}O(L\text{-}SO)_2]^- + H_2O + \frac{1}{2}RSSR \qquad (14)$$

$$Mo^{VI}O_2\{L\text{-}(NH)_2S_2\} + e^- \longrightarrow [Mo^{V}O\{L\text{-}N_2S_2\}]^- + H_2O \qquad (15)$$

$$Tp^*Mo^{VI}O_2(SPh) + e^- \longrightarrow [Tp^*Mo^{V}O_2(SPh)]^- \longrightarrow (+E^+) \longrightarrow Tp^*Mo^{V}O(OE)(SPh) \qquad (16)$$

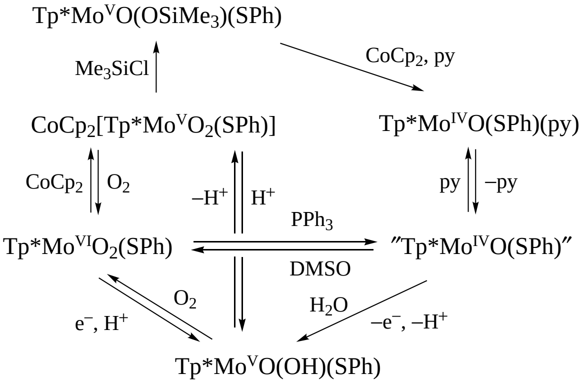
8 A COMBINED OAT/CEPT MODEL

The Mo-Tp* and Mo-Tp^{Pr} chemistry summarized in Scheme 6 represents a unique, holistic model of an important paradigm in Mo-MPT enzymes, the coupling of OAT and CEPT reactions during substrate turnover.[54,65]

The complexes *cis*-Tp*$Mo^{VI}O_2X$ (X = halide, monoanionic O-, N- or S-donor) react with PPh_3 to produce $OPPh_3$ and a variety of Mo-containing products, depending on the conditions (particularly the solvent) of the reaction (see Table 2 for rate constants); oxo-Mo(IV) complexes, Tp*MoOX(solv), are generated when coordinating solvents like dmf, MeCN, and pyridine are employed (cf. equation 1). Both types of complexes exhibit six-coordinate octahedral structures, as exemplified by the structure of Tp*MoO_2(SPh) in Figure 8. Complexes containing ambidentate dithiophosphate and -phosphinate complexes undergo similar reactions, the dithio ligands being monodentate and bidentate in the dioxo-Mo(VI) and oxo-Mo(IV) species, respectively.[54] An associative mechanism, in which the nucleophilic phosphine attacks a terminal oxo ligand, is supported by kinetics and computational studies.[54,66] The phosphine oxide intermediates in such reactions have now been isolated and structurally characterized.[63] The oxo-Mo(IV) complexes react with a variety of S- and N-oxides and nitrate to reform the dioxo-Mo(VI) species and catalyze the oxidation of phosphines by S- and N-oxides (equation 12, cf. equation 6).



Scheme 6

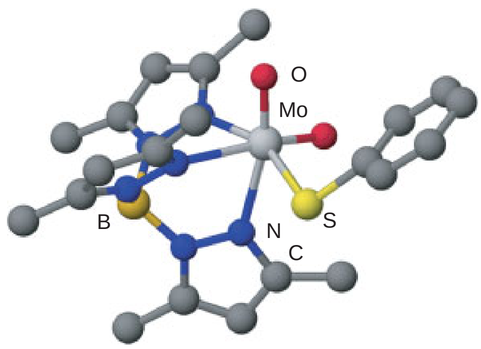


Figure 8 Structure of Tp*MoO_2(SPh)

One-electron redox processes (effected electrochemically or chemically) permit Mo(V) states to be accessed and facilitate the coupling of the two-electron OAT reactions to (regenerative) one-electron CEPT reactions. The dioxo-Mo(VI) complexes undergo electrochemically reversible one-electron reductions producing dioxo-Mo(V) species, for example, $[Tp^*MoO_2X]^-$, characterized by broad and anisotropic EPR spectra; these are readily protonated to give Tp*MoO(OH)X, which feature less-anisotropic doublet EPR signals (due to ^1H superhyperfine coupling) similar to those exhibited by enzymes. Chemical reduction permits the isolation of salts such as $CoCp_2$[Tp*MoO_2(SPh)], Tp*MoO(OH)(SPh) and derivatives of the type Tp*MoO($OSiMe_3$)X. The dioxo-Mo(V) complexes support a variety of one-electron processes but do not participate in two-electron OAT reactions.

The generation of oxo(hydroxo)-Mo(V) species, for example, Tp*MoO(OH)X, in the reactions of Tp*MoO_2X with half an equivalent of PPh_3 in wet solvents is interpreted in terms of combined OAT/CEPT reactions. Thus, water is an effective ligand for the binding site of putative Tp*MoOX, formed upon OAT from Mo to phosphine, and unreacted Tp*MoO_2X is an effective oxidant for Tp*MoOX(OH_2). Hence, comproportionation (equation 17) mimics oxidation of reduced enzymes by external oxidants.[54]

$$Tp^*Mo^{IV}OX(OH_2) + Tp^*Mo^{VI}O_2X \longrightarrow 2Tp^*Mo^{V}O(OH)X \tag{17}$$

Combined with the ready autoxidation (*see Autoxidation*) of the oxo(hydroxo) complex, it is possible to effect the catalytic aerial oxidation of substrates with this system. ^{18}O and ^{17}O-labeling studies have confirmed that the oxygen atom transferred to PPh_3 comes from Tp*MoO_2X, and that like the enzyme systems water, not dioxygen, is the source of active oxygen. Overall, the oxidation of PPh_3 by Tp*MoO_2X in wet aerobic solvents is represented by equation (18) (cf. equation 3).[65] An OAT/CEPT system interconverting monooxo and desoxo complexes, viz, $[Tp^*Mo^{VI}OX_2]^+$ to $[Tp^*Mo^{IV}(OPPh_3)X_2]^+$ (thence to $[Tp^*Mo(OH_2)X_2]^+$), is under development by Basu and coworkers.[67]

$$PPh_3 + H_2{}^*O + 2O_2 \longrightarrow {}^*OPPh_3 + 2HO_2 \tag{18}$$

9 MODELS FOR THE DMSO REDUCTASE FAMILY

9.1 Functional Models

The OAT reactions of bis(dithiolene) complexes are of interest from a biological perspective (nb. DMSO reductase

enzymes); here, comproportionation and dinucleation appear to be prevented by electrostatic factors.[54] Dioxobis(dithiolene) complexes react with oxygen atom acceptors (X) according to equation (10), and kinetics data are available for the reactions of $[MoO_2(bdt)_2]^{2-}$ with PPh_3[68] (Table 2) and $(NBu_4)_2[MoO_2(mnt)_2]$ (mnt = 1,2-dicyanoethenedithiolate) with HSO_3^- (Section 10.2), phosphites,[69] and phosphines[70] (Table 3). For phosphine reactions, OAT rates increase as the basicity of the substrate increases (inversely to the parameter χ; see Table 3). The rate ratio k_{Mo}/k_W of ca. 10^2-10^3 (Table 3) indicates that Mo complexes are more effective oxidants than their W analogues; the same is true of Mo-MPT enzymes and their W analogues (*see* ***Tungsten Proteins***).[55,71] Oxidation of benzoin by $[MoO_2L_2]^{2-}$ (L = bdt derivatives) proceeds according to equation (19); a deuterium isotope effect (*see Isotope Effect*), $k_H/k_D \sim 4.0$, is consistent with α-hydrogen atom abstraction by an oxo ligand in the rate-determining step.[68] Mo-MPT enzymes catalyze the conversion of $RCH(OH)CO_2^-$, a substrate similar to benzoin, to $RCOCO_2^-$.

$$[MoO_2L_2]^{2-} + PhCH(OH)COPh \longrightarrow [MoOL_2]^{2-} + PhCOCOPh + H_2O \qquad (19)$$

The reactions of $[MoOL_2]^{2-}$ with Me_3NO to give $[MoO_2L_2]^{2-}$ and Me_3N (cf. equation 11) are pseudo-first-order with k_{obs} values in the range $2.6(5) \times 10^{-3}$ to $5.7(4) \times 10^{-3}\,s^{-1}$ for L = bdt derivatives.[54] The reactions are proposed to occur via binding of Me_3NO to the trans vacant site (*see Vacant Site*) of $[MoOL_2]^{2-}$, followed by a *trans* → *cis* rearrangement and cleavage of the N–O bond. A dramatic rate enhancement (ca. 10^4-10^5) is observed for complexes stabilized by ligand NH···S(dithiolene) hydrogen bond interactions.[73]

9.2 Structural and Functional Models

The synthesis and study of monooxo-Mo(VI) and desoxo-Mo(IV) bis(dithiolene) complexes are recent developments in this area; associated chemistry is summarized in Scheme 7. The oxo-Mo(VI) complexes, $NEt_4[MoO(OR)L_2]$, are prepared by silylation of $(NEt_4)_2[MoO_2L_2]$ with $ClSi^tBuPh_2$ ($R = Si^tBuPh_2$) or by OAT to the Mo(IV) complexes $NEt_4[Mo(OR)L_2]$ ($R = {}^iPr$, 2-Ad, Ph etc.; L = bdt, $S_2C_2R'^{2-}_2$ (R′ = H, Me, Ph)).[74] Structurally characterized $NEt_4[MoO(OSi^tBuPh_2)(bdt)_2]$ (Figure 9) exhibits a severely distorted octahedral structure, with *cis* O-donors and d(Mo=O) 1.715(2) Å, d(Mo–O) 1.932(2) Å, and ∠(Mo–O–C) = 160.0(2)°; the Mo–S bond 'trans' to oxo is longer than the others present. Complexes containing authentic dithiolene ligands are unstable to hydrolysis but their W analogues have been isolated and structurally characterized.

The desoxo-Mo(IV) complexes, $NEt_4[Mo(OR)L_2]$, can be prepared by several methods. These include the silylation of $(NEt_4)_2[MoOL_2]$[74] or the reaction of the synthetically versatile complexes, $Mo(CO)_2L_2$, with aryloxide (RO^-), then NEt_4^+ salts.[75] Many of these compounds have been structurally

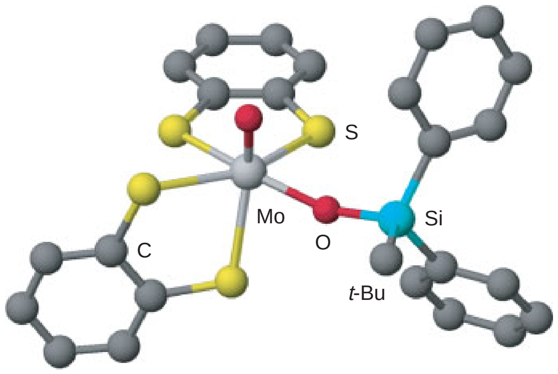

Figure 9 Partial structure of the anion of $NEt_4[MoO(OSi^tBuPh_2)(bdt)_2]$ (^{t}Bu methyl groups excluded)

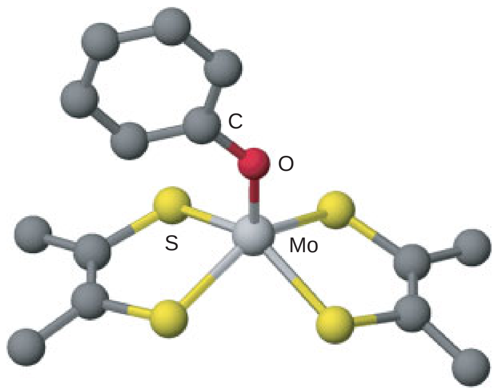

Figure 10 Structure of the anion of $NEt_4[Mo(OPh)(S_2C_2Me_2)_2]$

characterized and they all contain square-pyramidal anions with apical RO^- (d(Mo–O) ca. 1.84 Å, ∠(Mo–O–C) >166°), and basal S-donor ligands (see Figure 10);[74–76] they are prone to hydrolysis according to Scheme 7.[76] Various *S*-, *N*- and *Se*-oxides react with $NEt_4[Mo(OR)(S_2C_2Ph_2)_2]$ to produce $NEt_4[MoO(OR)(S_2C_2Ph_2)_2]$, which subsequently converts to $NEt_4[MoO(S_2C_2Ph_2)_2]$. Kinetics and isotope labeling studies are consistent with initial OAT through associative mechanisms (Table 4).[76] The desoxo-W(IV) analogues are oxidized at significantly increased rates compared to the Mo complexes (Table 4).[77] Similar comparative rates are observed for Mo-MPT enzymes and their W analogues.[55,71] Theoretical studies have shown that the OAT reactions of $[Mo(OR)L_2]^-$ complexes are favored over those of $[MoOL_2]^{2-}$ species by a lower-energy transition state and more stable products.[78,79] The Mo(VI) and Mo(IV) complexes above are excellent structural and functional models for the oxidized and reduced states of DMSO reductase. They also reproduce absorptions at similar wavelengths to those observed for the enzyme from *R. sphaeroides*. The desoxo-Mo(IV) complexes are reduced only at very negative potentials, a fact likely to account for the absence of Mo(III) enzyme states.

Table 4 Kinetics data for OAT from XO to $NEt_4[Mo(OPh)(S_2C_2Me_2)_2]$[76]

XO	k ($M^{-1}\,s^{-1}$)^a	$\Delta H^{\ddagger b}$	$\Delta S^{\ddagger c}$
Me_3NO	$2.0(1) \times 10^2$	8.1(6)	−21(2)

$DMSO^d$	1.3×10^{-6}	14.8(5)	−36(1)

^{a}Measured at 298 K. $^b\Delta H^\ddagger$ in kcal.mol^{-1}. $^c\Delta S^\ddagger$ in eu. ^{d}For analogous reactions of $[W(OPh)(S_2C_2Me_2)_2]^-$ (units as above): C_4H_8SO, k $9.0(3) \times 10^{-4}$, $\Delta H^\ddagger$11.6(4), $\Delta S^\ddagger$ −33(1); DMSO, k $3.9(4) \times 10^{-5}$, $\Delta H^\ddagger$14.4(2), $\Delta S^\ddagger$ −30(1).[77]

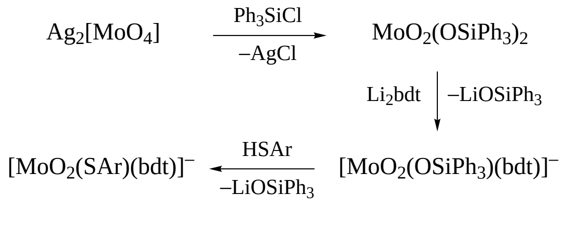
Thiolates and selenolates react with $Mo(CO)_2(S_2C_2Me_2)_2$, allowing the isolation of compounds of the type $NEt_4[Mo(ER)(S_2C_2Me_2)_2]$ (E = S, R = $C_6H_2{}^iPr_3$-2,4,6, 2-Ad; E = Se, R = 2-Ad).[75,76] Like the desoxo complexes above, these exhibit square-pyramidal structures, with apical RE^- groups and basal S-donor ligands. Interestingly, the Mo–E–C angles are considerably more bent (at ca. 102°) than the corresponding angles in RO^- complexes. These compounds are valuable structural and spectroscopic models for the active sites of dissimilatory nitrate reductases (E = S) and formate dehydrogenases (E = Se). Analogous W complexes are known.

10 MODELS FOR THE SULFITE OXIDASE FAMILY

10.1 Structural and Spectroscopic Models

Holm and coworkers have very recently described advanced structural models for the Mo(VI) and Mo(V) states of sulfite oxidase. Thus, the reaction sequence shown in Scheme 8 yields dioxo mono(dithiolene) complexes bearing either silyloxo or thiolate ligands. The thiolate complex, $[MoO_2(SC_6H_2{}^iPr_3\text{-}2,4,6)(bdt)]^-$, exhibits a square-pyramidal (pseudotetrahedral) structure closely related to that of oxidized sulfite oxidase (Figure 11).

The reaction represented by equation (20) is key to the generation of mono(dithiolene)-Mo(V) complexes that



Scheme 8

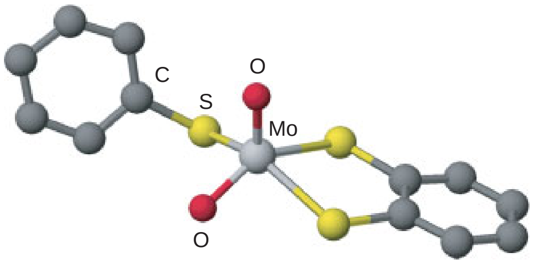


Figure 11 Partial structure of the anion of $NEt_4[MoO_2(SC_6H_2{}^iPr_3$-2,4,6)(bdt)]·MeCN (^{i}Pr groups not shown)

model the intermediate states of sulfite oxidase. Thereafter, chloride ligand exchange yields thiolate complexes such as $[MoO(SAd)_2(S_2C_2Me_2)]^-$, $[MoO(SR)_2(bdt)]^-$, and $[MoOCl(SC_6H_2{}^iPr_3$-2,4,6)(bdt)]$^-$. These exhibit square-pyramidal geometries with apical oxo groups and rhombic EPR spectra similar to the low-pH and high-pH forms of sulfite oxidase (Figure 4).[80]

$$NEt_4[MoOL_2] + 2PhSeCl \longrightarrow NEt_4[MoOCl_2L] + C_6H_4(SSePh)_2 \quad (L = \text{bdt, and likewise } S_2C_2Me_2) \qquad (20)$$

The energy and profile of the X-ray absorption edges of the above mono(dithiolene) complexes are sensitive to the oxidation state and ligands present. In particular, the Mo K-edge XAS and EXAFS spectra of $NEt_4[MoO_2(SC_6H_2{}^iPr_3$-2,4,6)(bdt)] are remarkably similar to the corresponding spectra of oxidized sulfite oxidase. Further developments in this area, including biomimetic chemistry, are eagerly anticipated.

The most recent oxo-Mo(V) models for sulfite oxidase include (L-N_2S)MoO(SPh)$_2$ and (L-N_2S)MoO(bdt), prepared by thiolate ligand exchange at $[MoO(SPh)_4]^-$, then (L-N_2S)MoO(SPh)$_2$, respectively (L-NS_2 = anion of (2-dimethylethanethiol)bis(3,5-dimethylpyrazolyl)methane). Both complexes exhibit distorted octahedral structures and *facial* L-N_2S ligands and have been characterized by electronic and EPR spectroscopy.[81]

10.2 Functional Models

Functional models for sulfite oxidase are extremely uncommon. A well-studied example is the reaction of $(NBu_4)_2[MoO_2(mnt)_2]$ with $NaHSO_3$ in acetonitrile/water mixtures, which proceeds smoothly according to equation (21). However, the mechanism of this 'simple' reaction remains controversial.[54]

$$[Mo^{VI}O_2(mnt)_2]^{2-} + HSO_3^- \longrightarrow [Mo^{IV}O(mnt)_2]^{2-} + HSO_4^- \qquad (21)$$

The reaction exhibits substrate saturation kinetics, consistent with a pre-equilibrium between $[MoO_2(mnt)_2]^{2-}$ and HSO_3^-, rather than the substrate first-order dependence typical of direct OAT reactions (Section 7.3). Originally, Sarkar and coworkers proposed that HSO_3^- binds to Mo via its anionic oxygen, prior to nucleophilic attack by sulfur at an oxo group of putative $[Mo^{VI}O_2(HSO_3)(mnt)_2]^{3-}$, giving bound HSO_4^-, that then dissociates.[72] This mechanism was later challenged by Lorber *et al.*,[70] who suggested the direct nucleophilic attack by the sulfur lone pair on a terminal oxo ligand, giving $[Mo^{IV}O(HSO_4)(mnt)_2]^{3-}$, followed by product dissociation. The recent observation that neutral dimethylsulfite fails to react with $[MoO_2(mnt)_2]^{2-}$ supports the mechanism involving oxoanion coordination to Mo prior to OAT.[82] Similar uncertainties surround the mechanism of the enzyme itself (Section 5). The oxidation of $[MoO(mnt)_2]^{2-}$ using $[Fe(CN)_6]^{3-}$ /H_2O results in partial reclamation (ca 10%) of $[MoO_2(mnt)_2]^{2-}$, possibly via CEPT reactions mimicking the regeneration of the active site of sulfite oxidase.[54] The reduction of nitrate by several oxo-Mo(IV) complexes has been described.[54]

11 MODELS FOR THE XANTHINE OXIDASE FAMILY

11.1 Models of the Oxidized Active Enzyme

The Mo hydroxylases are difficult to model because of the general redox incompatibility of the reducing sulfide and oxidizing Mo(VI) moieties found in the enzymes. The outcomes and directions of modeling endeavors up to 1997 have been reviewed by Young.[61]

Pseudotetrahedral complexes, such as $[MoO_{4-n}S_n]^{2-}$ (n = 1–3), $MoOS(ONR_2)_2$ and $Cp^*MoOS(CH_2SiMe_3)$, are well known; their stability may be ascribed to the low effective coordination number and consequently large HOMO-LUMO gap (*see HOMO–LUMO Gap*). Compounds of this type are prepared by sulfidation (oxo → sulfido) reactions but decomposition, upon reduction or attempted biomimetic transformations (e.g. cyanolysis), limits their biomimetic chemistry.[61] The first six-coordinate oxosulfido-Mo(VI) complex, $Tp^*MoOS(S_2P^iPr_2)$, was prepared by sulfur atom transfer to the Mo(IV) precursor, $Tp^*MoO(S_2P^iPr_2)$. Metrical parameters were consistent with an oxosulfido-Mo(VI) formulation, the 'terminal' sulfido ligand being stabilized by a weak interaction with the uncoordinated sulfur of the monodentate dithiophosphinate ligand; regardless, the complex is cleanly reduced to an oxosulfido-Mo(V) species and undergoes cyanolysis/sulfidation reactions that mimic those of the hydroxylases.[83] The complexes, $MoOS(OSiPh_3)_2L$ (L = bpy or phen derivative), prepared by reaction of $K_2[MoO_3S]$, $ClSiPh_3$, and L in basic (NEt_3) acetonitrile, contain an unperturbed oxosulfido unit. The structures of the complexes were defined by X-ray diffraction and EXAFS spectroscopy d(Mo=O ca. 1.71 Å, d(Mo=S) ca. 2.18 Å).[84] Exploitation of

the sterically demanding Tp^{Pr} ligand has now permitted the synthesis of a series of oxosulfido-Mo(VI) complexes of the type $Tp^{Pr}MoOS(OR)$ (OR = phenolate derivative). The parent complex, $Tp^{Pr}MoOS(OPh)$, is monomeric in solution but crystallizes as a dimer, the two units being linked by a S–S bond formed with concomitant reduction of Mo(VI) to Mo(V).[85] Complexes that are monomeric in both the solution and solid states have now been isolated and structurally characterized (Figure 12); these are amenable to a reversible reduction producing Mo(V) species (vide infra). Oxosulfido-Mo(VI) complexes undergo sulfur rather than oxygen atom transfer to phosphines and cyanide.[83–85] This observation argues against enzyme mechanisms postulating direct involvement of the terminal oxo group in OAT.

11.2 Models of Mo(V) States

Oxosulfido-Mo(V) complexes are relevant models of the Very Rapid Mo(V) enzyme center but these too are extremely rare. The in situ generation and EPR characterization of complexes such as $[(L\text{-}N_2S_2)Mo^VOS]^-$ and $[Tp^*Mo^VOSX]^-$ was summarized in *EIC-1*.[1] Identification of $[(L\text{-}N_2S_2)Mo^VOS]^-$ rests upon multifrequency EPR studies employing complexes isotopically labelled with ^{98}Mo ($I = 0$), ^{33}S ($I = 3/2$), and/or ^1H ($I = 1/2$). In particular, the distinctive pattern of anisotropic ^{33}S coupling (dominated by a single direction) observed in the Very Rapid signal of xanthine oxidase is reproduced so convincingly by $[(L\text{-}N_2S_2)^{98}MoO^{33}S]^-$ that there can be little doubt that an $[Mo^VOS]^+$ center (Figure 6) is responsible for the enzyme signal. In addition, the Mo-sulfido interaction is highly delocalized with a spin density of 0.3–0.4 of an electron on the sulfido ligand. The EPR parameters of

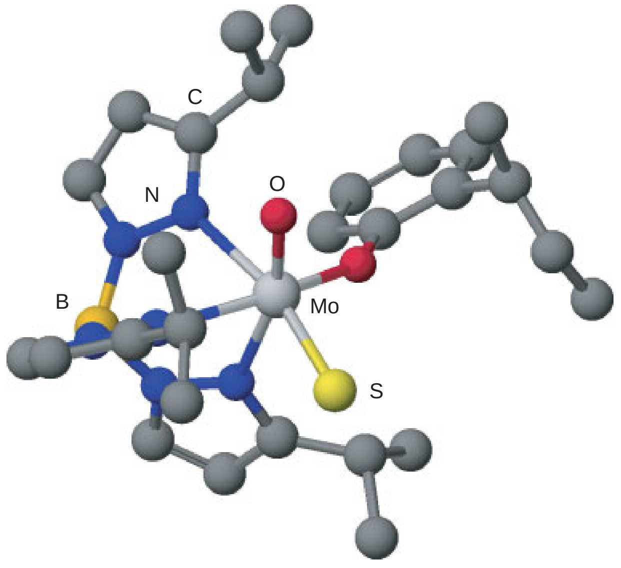

Figure 12 Structure of $Tp^{Pr}MoOS(OC_6H_4{}^sBu\text{-}2)$

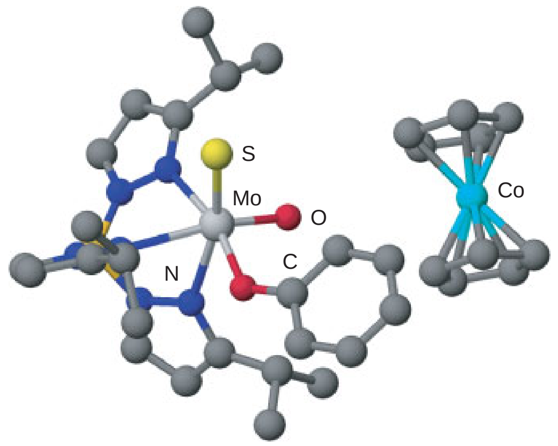

Figure 13 Structure of $CoCp_2[Tp^{Pr}MoOS(OPh)]$

natural abundance $[Tp^*Mo^VOSX]^-$ are very similar to those of $[(L\text{-}N_2S_2)Mo^VOS]^-$.[53]

Protonation of the synthetic species to *cis*-$[MoO^V(SH)]^{2+}$ collapses both the magnitude and the anisotropy of the ^{33}S coupling in addition to inducing the appearance of ^1H coupling.[1,53] These features are characteristic of the centers responsible for the Rapid EPR signals (Figure 6). The delocalized nature of the Mo–S bond in *cis*-$[Mo^VOS]^+$ has been rationalized in terms of a highly covalent Mo(d_{xy})–S(p_y) interaction perpendicular to the strong-field oxo ligand (z). Claims that $(L\text{-}N_2S_2)Mo^VO(SH)$ and salts of $[(L\text{-}N_2S_2)Mo^VOS]^-$ have been isolated are doubtful. In contrast, salts such as $CoCp_2[Tp^{Pr}MoOS(OR)]$ (OR = phenolate derivative) are tractable and a preliminary (O/S disordered) X-ray crystal structure of $CoCp_2[Tp^{Pr}MoOS(OPh)]$ has been achieved (see Figure 13). EXAFS results are indicative of Mo=O and Mo=S distances of 1.72 Å and 2.23 Å respectively, while a strong S K pre-edge XAS feature is associated with the π-bonded sulfido group.

12 CONCLUSION

The Mo-MPT enzymes play vital roles in metabolism and global biogeochemical cycles, their myriad functions being facilitated by the chemical versatility of Mo on one hand and the substrate specificity induced by the structure of the active site and the protein on the other. In recent years, our knowledge of these enzymes has increased dramatically, thanks to insights from advanced structural, spectroscopic, and molecular biological techniques. The intrinsic OAT and CEPT capabilities of Mo appear to be central to the function of many enzymes but complete mechanistic descriptions await the results of ongoing investigations. Model studies have made vital contributions to our appreciation of the enzyme active sites and accurate active-site models are now emerging.

Exploration of the structure and function of Mo-MPT enzymes, from (inter alia) molecular, cellular, environmental, and evolutionary perspectives, promises to fully inform our knowledge of these important and interesting biomolecules.

1 INTRODUCTION

Molybdenum is a transition metal that is found in group 6 of the periodic table and has a ground-state electronic configuration of $4d^5 5s^1$. It has a crustal abundance of ~1.2 ppm. The most important molybdenum ore is molybdenite, MoS_2, with the largest known deposit in Colorado, USA. Other less important ores include wulfenite, $PbMoO_4$, and powellite, Ca(Mo,W)O_4. It was first isolated by P. J. Hjelm in the late eighteenth century by heating the oxide MoO_2 with charcoal. The name molybdenum is derived from the Greek word for lead ($\mu\acute{o}\lambda\nu\beta\delta o\varsigma$, molybdos). This naming arose because of the ancient confusion of soft black minerals that were used for writing. It has an atomic number 42, atomic weight 95.94, mp 2617 °C, and bp 4612 °C. Molybdenum has found extensive use in the steel industry where it is used in high temperature cutting steel, its compounds find use as lubricants, for example, MoS_2, as pigments and catalysts.

Since this article is concerned with molybdenum organometallic chemistry and owing to the immense number of publications each year in this area of science, the author has had to be selective in the areas that are covered. For compounds to be given initial consideration for inclusion, they have to contain a direct molybdenum-to-carbon bond. This article is organized on the basis of the type of carbon-based ligand and the number of atoms directly bound to the molybdenum center. Where there are two or more carbon-based ligands in the compound, the compound is placed in the section perceived to be most relevant. The reader will find that some areas were covered in the Encyclopedia of Inorganic Chemistry, First Edition,[1] and others are new to this edition. The two articles are therefore complimentary. The same referencing policy is used in this article as in the previous edition. Citations are made to review articles wherever possible and where none are available to lead references.

2 σ-LIGAND-CONTAINING COMPLEXES

2.1 Alkyl Complexes

2.1.1 *Homoleptic Complexes*

In 1973, Wilkinson reported the preparation of the homoleptic methyl compounds (*see Homoleptic Compound*) $[W(CH_3)_6]$ and $[Re(CH_3)_6]$. Later, theoretical calculations suggested that these compounds should be based upon trigonal prismatic geometry rather than octahedral as is common in six-coordinate coordination chemistry, and the structure of $[W(CH_3)_6]$ was subsequently shown to be strongly distorted C_{3v} trigonal prismatic.[2] The structure is of particular interest because it contains three long W–C bonds at a narrow angle to each other and three shorter W–C bonds at a larger angle. Recently, the compounds $[Mo(CH_3)_5]$, $[Mo(CH_3)_6]$, and $[Mo(CH_3)_7]$ have been prepared and structurally characterized.[3,4] Blue $[Mo(CH_3)_5]$ is prepared through reaction of $MoCl_5$ with $ZnMe_2$. The compound is paramagnetic and has a square pyramidal geometry with Mo–C_{apical} 2.068(1) Å and Mo–C_{basal} 2.111(1) Å. Orange–brown $[Mo(CH_3)_6]$ is prepared on treatment of MoF_6 with $Zn(CH_3)_2$ and is thermally stable up to 10 °C and very sensitive toward oxygen. Its solid-state structure is similar to its tungsten analog. The structure is strongly distorted trigonal prismatic with three short Mo–C bonds 2.111(3) Å with C–Mo–C 94.9° and three long Mo–C bonds 2.190(3) Å with C–Mo–C 75.7°. Red $[Li\{O(CH_2CH_3)_2\}][Mo(CH_3)_7]$ was prepared on treatment of $[Mo(CH_3)_6]$ with MeLi and is isostructural with its tungsten analog $[Li\{O(CH_2CH_3)_2\}][W(CH_3)_7]$. The structure is best described as a capped octahedron. In none of the reported structures was there any evidence for an agostic interaction (*see Agostic Bonding*), and the relative stability of all these compounds stems from the fact that the methyl group does not contain any β-hydrogen atoms.

2.1.2 *Nonhomoleptic Complexes*

Alkyl-, aryl-, and acetylide-containing compounds that have additional ligands such as phosphines and cyclopentadienyl, amongst others, are far more common than their homoleptic congeners. Examples of this type of compound will be found in other sections of the article.

2.2 Carbonyl Derivatives

2.2.1 Mononuclear Complexes

The starting point for most molybdenum-based carbonyl chemistry is the white crystalline air stable hexacarbonyl $[Mo(CO)_6]$, which is commercially available. Low valent compounds that are derived from this starting material tend to give products that obey the Effective Atomic Number Rule (EAN Rule). Since Mo^0 has a d^6 configuration, six two-electron ligands are required to obey the EAN rule.

Bonding Considerations. $[Mo(CO)_6]$ is stabilized by back bonding of electrons from the d_π orbitals (d_{xy}, d_{xz}, d_{yz}) into the π^*-molecular orbitals of the carbon monoxide ligands (*see **Molecular Orbital Theory***). This back donation of electrons serves to lower the negative charge at the molybdenum center and so strengthens the σ-donation (*see **S-donor Ligands***) from the ligand to the molybdenum atom. The compound $[Mo(CO)_6]$ has strict O_h symmetry (*see Group Theory*) and all six d-electrons are involved in back donation to the π^*-molecular orbitals of the carbonyl ligands. This results in three identical pairs of *trans*-carbonyl ligands that each competes with each other for the available electron density (see Figure 1a). When the first carbonyl is substituted by another two-electron donor ligand that is a poorer π-acceptor (this will generally be the case), then the carbonyl ligand trans to this ligand will obtain a greater share of the electron density with the overall result that the Mo–CO bond trans to the ligand L is strengthened relative to the cis carbonyl ligands (see Figure 1b). The outcome of this strengthening of the bond is that on substitution of a second carbonyl ligand *cis*-$[Mo(CO)_4L_2]$ and a third *fac*-$[Mo(CO)_3L_3]$ respectively are obtained. Facile substitution ceases at this point because all of the remaining carbonyl ligands are trans (generally) to poorer π-acceptor ligands. Further substitution can be facilitated under more forcing conditions or through the use of chelating ligands (*see Chelating Ligands*) and/or good π-acceptors (*see **Carbonyl Complexes of the Transition Metals***).

In $[Mo(CO)_6]$, the Mo–CO bond length is 2.06 Å and the average Mo–CO bond energy (*see **Bonding Energetics of Organometallic Compounds***) is 150 kJ mol^{-1}.

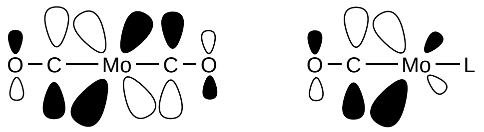

Figure 1 (a) Portion of a molecular orbital that distributes electron density between two *trans*-carbonyl groups. (b) electron density concentrated in M–CO bond trans to poor π-acceptor

Spectral Characteristics. IR spectra (*Infrared Spectroscopy*) are particularly useful for making gross structural assignments in mononuclear carbonyl derivatives. $[Mo(CO)_6]$ is octahedral and has a single carbonyl stretching frequency at 2004 cm^{-1}. The δ–M–C–O bending mode appears at 593 cm^{-1} and the M–C stretch (t_{1u}) occurs at 368 cm^{-1}. Substitution of one carbonyl ligand lowers the effective symmetry to C_{4v} (*see Group Theory*), and three ν(CO) bands become IR active ($2a + e$) in the 2050 to 1850 cm^{-1} range. *cis*-$[Mo(CO)_4L_2]$ has effective C_{2v} symmetry, and four ν(CO) modes ($2a_1 + b_1 + b_2$) are active. *trans*-$[Mo(CO)_4LL']$ has either D_{4h} ($L = L'$) or C_{4v} ($L \neq L'$) symmetry, with one (e_u) or two (a_1(weak) $+ e$) ν(CO) bands respectively. *Tri*-substituted *fac*-$[Mo(CO)_3L_3]$ has C_{3v} symmetry with two ($a_1 + e$) ν(CO) bands. The average ν(CO) frequency decreases with increasing substitution.[5]

In ^{13}C NMR spectra, the carbonyl carbon resonance appears typically in the 200–230 ppm region. If the compound contains phosphine ligands, then the carbonyl signals couple with the spin active phosphorus atom and can be used to complement geometry assignment made using IR spectroscopy. ^{1}H NMR is also useful for characterizing these compounds due to the signals of the organic moieties in the ligands. Typically, the signals are slightly shifted from those observed for the noncomplexed ligand.[6]

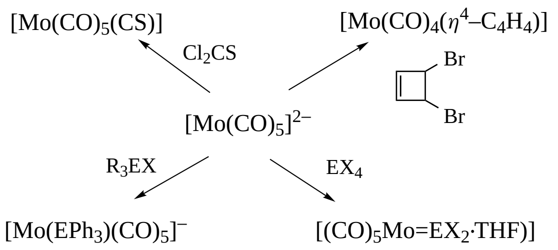
2.2.2 Reductive Substitution

Molybdenum carbonyls react with strong reducing agents to give carbonyl metallates in which the molybdenum is formally reduced.[7] Thus, $[Mo(CO)_6]$ or $[Mo(CO)_5L]$ reacts with strong reducing agents in liquid ammonia or THF to form $[Mo(CO)_5]^{2-}$ and $[Mo_2(CO)_{10}]^{2-}$ respectively. The dimeric dianion is best obtained with sodium in the presence of a catalytic amount of bipyridine or from $NaBH_4$ at 60 °C in ammonia. $[Mo(CO)_5]^{2-}$ is best prepared from the dimer on treatment with CO (equation 1). The $[Mo(CO)_6]$ obtained as a side product is readily removed by sublimation.

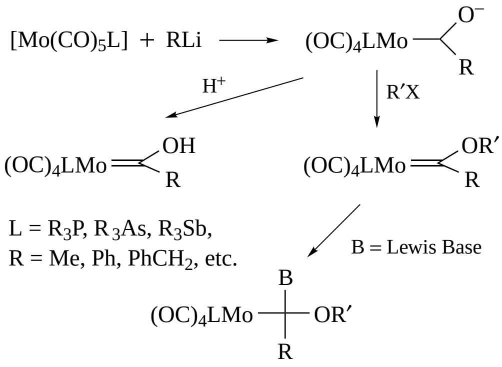
$$[(OC)_5Mo{-}Mo(CO)_5]^{2-} \longrightarrow [Mo(CO)_5]^{2-} + [Mo(CO)_6] \quad (1)$$

Reduction of $[Mo(CO)_4(TMEDA)]$ with sodium in liquid ammonia affords excellent yields of $Na_4[Mo(CO)_4]^{4-}$, which can be isolated as a pyrophoric yellow–orange powder. In this compound, molybdenum shows its lowest formal oxidation state as evidenced by the very low value of ν(CO) 1471 cm^{-1}.

These carbonyl anions are strong nucleophiles (*see Nucleophile*) and can be used to form a diverse range of new compounds. Protonation gives the μ-hydride (*see Bridging Ligand*) $[(\mu\text{-H})\{Mo(CO)_5\}]$. Reactions with other metal carbonyls lead to CO substitution and the formation of metal – metal-bonded heteronuclear anions, for example, $[Mo(CO)_5{-}Fe(CO)_4]^{2-}$ and $[Mo(CO)_5\text{-}Co(CO)_4]^{2-}$. Reaction with main group halides is shown in Scheme 1. The dianion reacts similarly.



Scheme 1 Selected reactions of $[Mo(CO)_5]^-$



Scheme 2 Preparation of fischer carbene complexes

2.3 Carbene and Carbyne Complexes

The carbon atom of the carbonyl ligand in $[Mo(CO)_6]$ or its derivatives may be attacked by strong nucleophiles (*see Nucleophile*) like organo–lithium reagents. The resulting anion from this nucleophilic attack can be quenched with an electrophilic reagent (*see Electrophile*), for example, trialkyloxonium methylfluorosulfonates (Scheme 2). The resultant neural species are known as carbene complexes (*see* ***Carbene Complexes***) or Fischer-type carbene complexes.[8] The related Cr and W analogs and to a lesser extent the Mo analogs have found utility as reagents in organic syntheses (*see* ***Organic Synthesis using Transition Metal Carbonyl Complexes***) and as catalysts for alkene metathesis (*see* ***Metathesis Polymerization Processes by Homogeneous Catalysis***). Alternative routes to Mo–carbene complexes include the treatment of $[Mo(CO)_6]$ with electron-rich alkenes and reaction of the carbonylate anion $[Mo(CO)_5]^{2-}$ with various substrates such as 3,3-dichlorocyclopropenes or iminium salts.[9]

These Fischer-type carbene complexes can be readily converted to Fischer-type carbyne complexes, and this material has been reviewed.[10] Methods to remove the α-alkoxy group include treatment with BBr_3, oxide abstraction from acyl ligands, and electrophilic attack on the β-carbon of metal acetylides (equations 2–4).

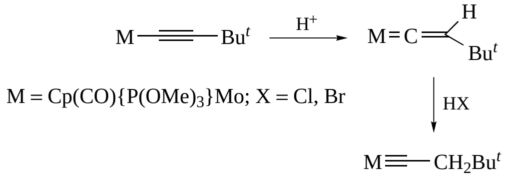
(3)



(4)

2.3.1 *Heavier Group 14 Analogs of Carbene and Carbyne Complexes*

Multiple bonds are readily formed with the 2p elements carbon, nitrogen, and oxygen; however, the heavier main group elements only reluctantly participate in multiple bonding[11] (*see* ***Main Group: Multiple Bonding***) since the mid-1960s, considerable effort has been expended to generate heavier group 14 analogs and investigate their coordination chemistry. Some dated reviews are available.[12,13] On complexation of the divalent group 14 element moiety (Figure 2a), it retains its Lewis acid characteristics and often coordinates a Lewis base (Figure 2b), and there are even examples of the coordination of two Lewis bases (Figure 2c) (*see Lewis Acids & Bases*). The reversal of this process to generate the base-free species has always failed and results in compound decomposition. More recently, attempts to prepare heavier group 14 analogs of carbyne complexes have resulted in the preparation of silylyne- and germylyne-containing molybdenum complexes and a stannylyne-containing complex of tungsten.

Silicon. The first base-stabilized silylene complex $[Cp^*Ru\{=Si(Ph)_2NCMe\}(PMe_3)_2]$ was reported in 1987, and the first base-free silylene-containing complexes $[Cp^*Ru{=}Si(SR)_2(PMe_3)_2]$ (R = Me or Ph) were not synthesized until 1990, much later than for the heavier congeners Ge, Sn, and Pb. Recently, the silylene-containing

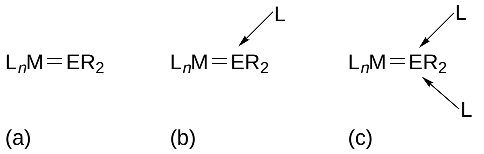


Figure 2 Representation of different classes of double-bonded group 14 fragments

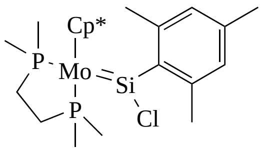
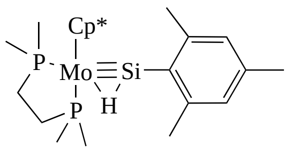
compound [Cp*Mo=SiCl(C_6H_2-2,4,6-Me_3)H(dmpe)] (**1**) has been prepared[14] and structurally characterized. In this compound, the sum of the angles about the silicon atom is 359.8(3)°, which is indicative of a base-free silylene complex that is sp^2 hybridized (*see Hybridization*) at the silicon center. The Mo–Si bond length is short (2.288(2) Å), which confirms its multiple bond character. Compound (**1**) was then treated with Li[B(C_6F_5)$_4$] to facilitate chloride abstraction and generation of the cationic silylyne-containing complex [Cp*Mo≡Si(C_6H_2-2,4,6-Me_3)H(dmpe)][B(C_6F_5)$_4$] (**2**), which has also been structurally characterized. In the solid-state structure of (**2**), the Mo–Si bond length shortened to 2.219(2) Å and the Mo–Si–C angle is 170.9(2)° and is comparable to analogous carbyne-containing compounds.[10]



(**1**)



(**2**)

Another interesting feature in the solid-state structure of (**2**) is the presence of a bridging hydride (*see Bridging Ligand*): Mo–H 1.85(5) Å, Si–H 1.39(5) Å, although in heavy metal structures it is often difficult to make too much comment on the location of a hydrogen atom this close to a metal center (*see* ***Diffraction Methods in Inorganic Chemistry***). Density Functional Theory (DTF) (*see Density Functional Theory*) calculations were carried out and suggest the presence of a nonclassical bridging hydride (*see Bridging Ligand*) and support the position of the hydrogen atom observed in the solid-state structure.

Germanium. The compounds [Mo(CO)$_5$(GeX$_2$·THF)] (X = Cl, Br) were prepared on treatment of the decacarbonyldimolybdate dianion with GeX$_4$ in THF.[12] They were, however, originally erroneously reported as base-free species. Many more examples of this type of germylene-containing complex have been prepared where the central metal is Cr or W. Recently, the *tris*-carbene-containing molybdenum (0) complex [Mo(Ge{N(CH$_2{}^t$Bu)C$_2$H$_2$N(CH$_2{}^t$Bu)})$_3$(CO)$_3$] was synthesized and structurally characterized. The average Mo–Ge bond length is 2.537(2) Å, which is shorter than the sum of the covalent radii.[15] Lengthening of the Ge–N bond lengths and shortening of other bond lengths in the cyclic germylene ligand suggest that it is a good π-acceptor (*see* ***Bond Lengths in Inorganic Solids & Liquids***).

Compounds that contain a germylyne ligand, that is, a metal–germanium triple bond have also been synthesized. Treatment of Na[CpMo(CO)$_3$] with 2,6–Mes$_2$C$_6$H$_3$GeCl at low temperature in THF afforded the germylyne-containing complex [Cp(CO)$_2$Mo≡GeC$_6$H$_3$-2,6-Mes$_2$](**3**), which has been structurally characterized.[16] The Mo–Ge–C angle of 172.2(2)° is similar to what is observed in carbyne-containing complexes and the related silylyne complex (**2**). The Mo–Ge bond length in (**3**) (2.271(1) Å) is significantly shorter (0.35 Å) than the predicted single bond length of 2.62 Å (covalent radii Mo 1.4 Å and Ge 1.22 Å). Unlike in the structure of (**2**), there are no close intramolecular approaches. Another synthetic strategy has also been described[17] for the preparation of the germylyne-containing compounds [(dppe)XMo≡Ge(η^1-Cp*)] (X = Cl, Br, I) (equation 5). The compound [(dppe)BrMo≡Ge(η^1-Cp*)] has also been structurally characterized and found to have a linear Mo–Ge–C geometry 171.6(2)° and a short Mo–Ge bond length 2.310(1) Å, which are comparable to those observed for (**3**).

$$[\mathrm{Mo(N_2)_2(dppe)_2}] + \mathrm{Cp^*GeX} \longrightarrow [\mathrm{(dppe)XMo{\equiv}GeCp^*}] \quad (5)$$

Analogous Cr and W compounds have been prepared by the same methodology; however, in certain cases the tricarbonyl intermediates [Cp(CO)$_2$M(GeC$_6$H$_3$-2,6-Trip$_2$)] (M = Cr **4**, W **5**; Trip = –C$_6$H$_2$2,4,6-^{i}Pr$_3$) that contain a M–Ge single bond were isolated. Both compounds have been structurally characterized and shown to have a stereochemically active lone pair at germanium and a bent M–Ge–C = 117.9(3)° (Cr) 114.7(6)° (W) geometry. Gentle heating of these compounds caused elimination of one carbonyl ligand and the formation of the triply bonded species [Cp(CO)M≡GeC$_6$H$_3$-2,6-Trip$_2$] (M = Cr **6**, W **7**). Compounds (**6**) and (**7**) have both been structurally characterized and shown to have linear M–Ge–C geometry (175.9(6)° Cr; 170.9(3)° W) and significantly shorter M–Ge bond lengths (2.166(4) Å Cr; 2.277(1) Å W respectively).

Tin and Lead. A small number of molybdenum complexes containing stannylene and plumbylene ligands are known.[12,13] The tin and lead compounds [Cp(CO)$_3$Mo-EC$_6$H$_3$-2,6-Mes$_2$] (E = Sn, Pb) have been prepared but do not appear to lose CO and generate the stannylyne[18] or plumbylyne analogs of (**3**).[19] Very recently, however, the preparation of the tungsten complex [W≡Sn(C$_6$H$_3$-2,6-Mes)Cl(dppe)$_2$], that does contain a stannylyne ligand, has been described.[20]

2.4 Halocarbonyl Complexes

2.4.1 *Six- and Seven-Coordinate Complexes*[21,22]

Halocarbonyl complexes of molybdenum have been known since Wilkinson and Piper reported the preparation of [MoX(CO)$_3$Cp] (X = Cl, Br, I) in 1956 with the first dihalocarbonyl donor ligand complex [MoI$_2$(CO)$_3$(diars)] reported by Nyholm and Nigram in 1957. Pioneering work by Colten in the 1960s led to the development of the halide-bridged dimers [{Mo(μ–X)X(CO)$_4$}$_2$] via an oxidative elimination reaction between the halogen and [Mo(CO)$_6$]. In

general, seven-coordinate halocarbonyl complexes have been shown to have one of the following structures: (i) capped octahedral, (ii) capped trigonal prismatic, (iii) pentagonal bipyramidal, (iv) or the so-called 4:3 geometry. Indeed, ^{13}C NMR spectroscopy has been used to correlate the solid-state structures with solution state structures. In the case of capped octahedral structures, there is a shift to low field for the carbonyl in the capping position. Because these compounds are generally fluxional in solution (*see* ***Stability Constants & their Determination***), to observe the capping carbonyl resonance the spectrum needs to be run at low temperature.

An early method for the preparation of a range of six- and seven-coordinate halocarbonyl complexes was the addition of soft donor ligands (*see* ***Hard & Soft Acids and Bases***) to the halide-bridged dimer $[\{Mo(\mu{-}X)X(CO)_4\}_2]$ to give $[MoX_2(CO)_3L_2]$; however, addition of weaker field ligands led to disproportionation and isolation of the non-carbonyl-containing compounds $[MoX_3L_3]$ (L = py, THF, NCMe). An equally effective alternative to this method of preparation was oxidative elimination of the halogen to zero-valent molybdenum precursors such as $[Mo(CO)_4(bpy)]$ to give $[MoX_2(CO)_3(bpy)]$ (X = Cl, Br). The synthesis of the seven-coordinate halocarbonyl complexes $[MI_2(CO)_3(NCMe)_2]$ (M = Mo, W) through the oxidative elimination of I_2 to $[M(CO)_3(NCMe)_3]$ (M = Mo or W) dissolved in acetonitrile has been described.[23] This is a particularly noteworthy observation because, when the compounds $[M(CO)_3(NCMe)_3]$ (M = Mo or W) were originally prepared in 1962 and isolated, I_2 was added to them in refluxing methanol and, under these reaction conditions, only an insoluble non-carbonyl-containing compound was obtained. Recently, the addition of half-a-mole equivalent of I_2 to $[MoI_2(CO)_3(NCMe)_2]$ in refluxing acetonitrile yielded the crystallographically characterized non-carbonyl-containing product $[MoI_3(NCMe)_3]$ and confirms that careful control of reaction conditions is required to prevent significantly different products being obtained. $[MoI_2(CO)_3(NCMe)_2]$ has been crystallographically characterized and shown to have the capped octahedral geometry.[24]

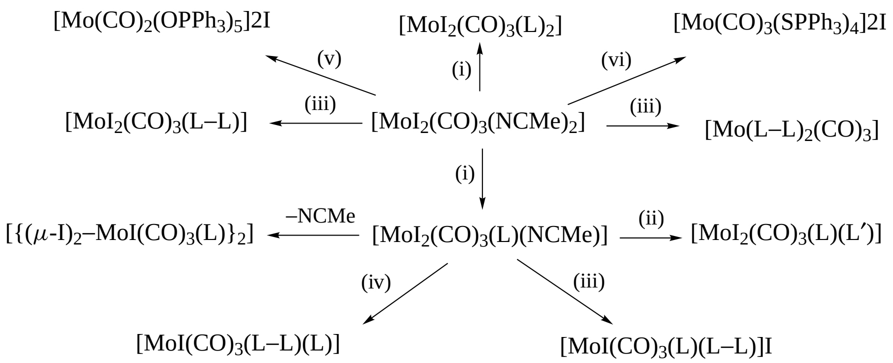
Since its preparation, the compound $[MoI_2(CO)_3(NCMe)_2]$ has been shown to display a diverse range of reactivity. The acetonitrile ligands are particularly labile and are readily substituted by a range of neutral donor ligands. Addition of 1 equivalent of ligand L displaces 1 acetonitrile molecule and yields initially the seven-coordinate complexes of type $[MoI_2(CO)_3(NCMe)L]$ (L = phosphines, arsines, stibines) (**4**), which depending on the steric and electronic properties of the ligand may lose the second NCMe ligand to afford the iodide-bridged dimers $[\{Mo(\mu{-}I)(CO)_3L\}_2]$. A wide range of mixed ligand systems $[MoI_2(CO)_3(L)(L')]$ (L′ = phosphines, arsines, stibines, ureas, thioureas, pyridines etc.) have been prepared through treatment of (**4**) with a second equivalent of a different monodentate ligand L′. $[MoI_2(CO)_3(NCMe)_2]$ also reacts with a wide range of neutral bidentate ligands to yield *bis*-nitrile substituted products $[MoI_2(CO)_3(L{-}L)]$ (phosphines, bpy etc.). The halide ligands can also be substituted through use of anionic ligands such as thiolates, dithiocarbamates, acac, and so on. The reactivity of this compound is summarized in Scheme 3.

The compounds $[M(CO)_3(NCMe)_3]$ have also been shown to undergo oxidative elimination with a range of other halogen-based oxidants including Br_2, ICl, and IBr, to afford analogous seven-coordinate complexes. The reactivity of these compounds has been less extensively investigated than $[MoI_2(CO)_3(NCMe)_2]$.

2.4.2 Group 14–Containing Halocarbonyl Complexes

These compounds are of particular interest as they have been shown to be active Ring Opening Metathesis Polymerization (ROMP) catalysts (*see* ***Metathesis Polymerization Processes by Homogeneous Catalysis***). They are not, however, as effective as imido-based alkylidene systems (see next section).

Routes for the preparation of these types of compound are similar to the dihalo analogs in the previous section. Thus, the heterobimetallic complexes $[MoX(MX_3)(CO)_3(bpy)]$



Scheme 3 (i) L = PR_3, AsR_3, SbR_3, BiR_3, $OPPh_3$, $SPPh_3$; (ii) L′ = PR_3, AsR_3, SbR_3, BiR_3, $OPPh_3$, $SPPh_3$, $SC(NR_2)_2$; (iii) L-L = bpy, 1,10-phen, $Ph_2P(CH_2)_nPPh_2$ ($n = 1{-}6$); (iv) NaS_2CNR_2, KS_2COEt, acac; (v) $OPPh_3$ (vi) $SPPh_3$

($M = Ge$, Sn; $X = Cl$, Br) are prepared through oxidative elimination of MX_4 to the zero-valent precursor $[Mo(CO)_4(bpy)]$. Oxidative elimination of MCl_4 ($M = Sn$, Ge) to $[Mo(CO)_3(NCMe)_3]$ gives the more versatile, as they contain labile readily substitutable acetonitrile ligands, seven-coordinate complexes $[MoX(MX_3)(CO)_3(NCMe)_2]$;[21] these compounds have been shown to undergo a wide range of molybdenum-centered substitution chemistry analogous to that reported for $[MoI_2(CO)_3(NCMe)_2]$. Oxidative elimination has also been shown to be facile with $[Mo(CO)_4(NCEt)_2]$,[25] and the solid-state structure of $[MoX(MX_3)(CO)_3(NCEt)_2]$ has been determined.[26] The structure was shown to contain a chloride ligand bridging the Mo–Sn bond (*see Bridging Ligand*). The reaction between $[Mo(CO)_6]$ and $SnCl_4$ under photochemical conditions has also been described and shown to yield the crystallographically characterized complex $[(CO)_4Mo(\mu\text{-}Cl_3)Mo(SnCl_3)(CO)_3]$.

2.5 Alkylidene Complexes

Alkylidene complexes are typically carbene-containing complexes of transition metals in high oxidation states as opposed to low oxidation state Fischer-type carbenes (*see* ***Carbene Complexes***). They tend to be nucleophilic (*see Nucleophile*) in nature as opposed to the electrophilic (*see Electrophile*) Fischer-type carbenes. By far, the most important alkylidene complexes of molybdenum are the imido-containing complexes $[Mo(CHR')(NAr)(OR)_2]$ originally reported by Schrock, and some good reviews of this chemistry are available.[27–29] The synthetic relevance of these compounds means also that some are now commercially available. These compounds have been used successfully for ROMP and Ring Closing Metathesis Polymerization (RCMP) (*see* ***Metathesis Polymerization Processes by Homogeneous Catalysis***). One of the problems, however, associated with these alkylidene complexes is their lack of tolerance to many functional groups. This problem can often be overcome by using ruthenium-based alkylidene systems (*see* ***Ruthenium: Organometallic Chemistry*** and ***Carbene Complexes***). A significant advance made recently is the preparation of chiral alkylidene complexes (Figure 3) that act as catalysts for asymmetric ring closing metathesis (*see* ***Metathesis Polymerization Processes by Homogeneous Catalysis***).[30,31] Another is that $[Mo\{CH(CMe_2Ph)\}(NC_6H_3\text{-}2,3\text{-}^iPr_2)\{OC(Me)(CF_3)_2\}_2]$ is capable of effecting both ROMP and RCMP in liquid and supercritical CO_2.[32] This approach has particular attractions: the ease with which CO_2 can be removed from the polymer and there is no waste organic solvent that needs to be disposed of.

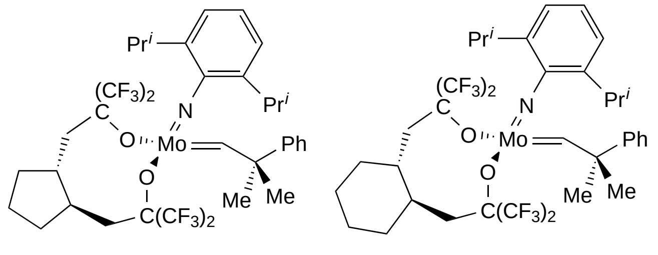


Figure 3 Chiral molybdenum alkylidene complexes used in asymmetric ring closing metathesis polymerization

2.6 Alkylidyne Complexes[33]

$[Mo(CBu^t)(CH_2Bu^t)_3]$ was first prepared in a low yield from the reaction between $^tBuCH_2Li$ and $MoCl_5$. An improved synthesis is available in which MoO_2Cl_2 is added to the Grignard reagent $^tBuCH_2MgBr$ at $-78°$ in diethylether. It is most likely that the alkylidyne ligand is formed through successive α-elimination processes (*see α-Elimination*). Another route to alkylidyne complexes is through alkyne metathesis reactions (*see* ***Metathesis Polymerization Processes by Homogeneous Catalysis***) with the triply bonded dimer $[Mo_2(OBu^t)_6]$ and alkynes to give $[Mo{\equiv}CR(OBu^t)_3]$, however, terminal alkynes are not successfully converted to alkylidyne complexes by this method. This type of complex has been shown to be important as ROMP and RCMP catalysts (*see* ***Metathesis Polymerization Processes by Homogeneous Catalysis***); however, their use has been severely limited as a result of the difficulty in their synthesis. This situation may soon change because of the discovery of a new and effective route to their preparation (equation 6).The ene-dialkylidyne complex 1,2,-di($-C{\equiv}MoL_n$)cyclohex-1-ene has recently been synthesized and crystallographically characterized and the average $Mo{\equiv}C$ bond length was found to be 1.753(5) Å (Figure 4).[34]

3 π-LIGAND-CONTAINING COMPLEXES

3.1 Alkene and Allyl Complexes

Alkene complexes of the type $[Mo(CO)_{(6-n)}(\eta^2\text{-}H_2C{=}CH_2)_n]$ ($n = 1, 2$) have been known since 1963 and are prepared by the photolysis of $[Mo(CO)_6]$ (*see* ***Photochemistry of Transition Metal Complexes***) in the presence of an alkene. The geometry of the *bis*-alkene complexes synthesized is trans, with the alkenes orientated orthogonal to each other. Matrix isolation studies (*see Matrix Isolation*) suggest that on photodissociation of CO from $[Mo(CO)_5(\eta^2\text{-alkene})]$ it is a cis carbonyl ligand that dissociates. This means that there is subsequent rearrangement to the observed trans product. The original assignment of the trans geometry was based upon the observation of a single ν(CO) band in the IR spectrum, which is consistent with gross D_{4h} symmetry (*see* ***Surfaces***); the cis geometry has C_{2v} symmetry and would be expected to give rise to four bands. When butadiene, which is a conjugated diene and has the potential to act as a chelating ligand, is the alkene ligand only one of the double bonds is initially involved in bonding to the metal center and the *bis-trans*-$[Mo(CO)_4(\eta^2\text{-}CH_2{=}CHCH{=}CH_2)_2]$ complex can be prepared. This compound can be transformed into the *bis-cis*-$[Mo(CO)_2(\eta^2\text{-}CH_2{=}CHCH{=}CH_2)_2]$ complex on warming.[35]

The analogous *bis*-ethene-containing complex *trans*-$[Mo(PMe_3)_4(\eta^2\text{-ethene})_2]$ is prepared on bubbling ethene through a solution of $[Mo(PMe_3)_4(N_2)_2]$, and it has been crystallographically characterized (Figure 5).[36] It can be clearly seen that the ethene ligands are trans and orthogonal to each other. This means each ligand accepts electron density from a different metal dπ orbital and so maximizes π-backbonding into its π^*-antibonding molecular orbital. Each ethene ligand also orientates so it eclipses a P–Mo–P vector. The average Mo–C bond length is 2.270(6) Å.

The reactivity of $[Mo(PMe_3)_4(\eta^2\text{-ethene})_2]$ has been much studied and, for example, the *tris*-alkene-containing compound $[Mo(PMe_3)(\eta^n\text{-}H_2C{=}CH\text{-}COOMe)_3]$ is prepared on treatment with $H_2C{=}CH\text{-}COOMe$ and it has been crystallographically characterized (Figure 6). The structure

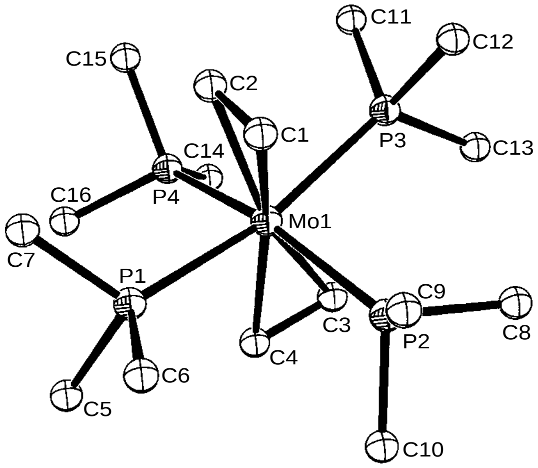

Figure 5 Molecular structure of $[Mo(PMe_3)_4(\eta^2\text{-}H_2C{=}CH_2)_2]$. (Reprinted with permission from Ref. 36. © 2003 American Chemical Society)

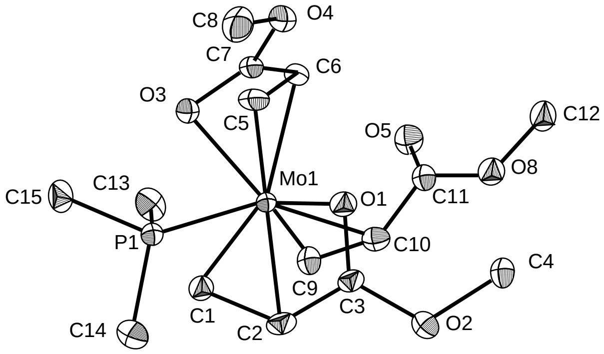

Figure 6 Molecular structure of $[Mo(PMe_3)(H_2C{=}CHCO_2Me)_3]$. (Reprinted from Ref. 37, with permission from Elsevier)

shows two of the methylacrylate ligands coordinate through their C=C and C=O bonds and the third through the C=C bond only. It is noteworthy that in this structure, as in the parent compound, the mutually trans alkene ligands are again orientated orthogonal to each other.[37]

Since its discovery in the 1980s, C_{60} (Buckminsterfullerene) (*see* ***Carbon: Fullerenes***) has captured the imagination. It has been shown to coordinate to many transition metals including molybdenum centers as a two-electron donor alkene ligand. For example, the reaction between *mer*-$[Mo(CO)_3(NCMe)_3]$ with dppb (*bis*-diphenylphosphinobutane) followed by C_{60} gives *mer*-$[Mo(CO)_3(\eta^2\text{-}C_{60})(dppb)]$.[38] C_{60} has been shown to coordinate up to three $[Mo(CO)_2(phen)(dbm)]$ moieties and each of the compounds is electrochemically active at C_{60} (*see* ***Electrochemistry: Applications in Inorganic Chemistry***) and at more negative potentials than for uncoordinated C_{60}. *mer*-$[Mo(CO)_3(\eta^2\text{-}C_{60})(dppb)]$ shows three one-electron reduction potentials associated with the C_{60} ligand. A fourth

one-electron reduction is also observed, which is metal centered and causes dissociation of the C_{60} ligand. Similar behavior is seen when the fullerene C_{70} is coordinated to a metal center.[39]

The reaction between chelating-unconjugated dienes like norbornadiene (NBD) or cycloocta-1,5-diene (COD) yields the compounds *cis*-[Mo(CO)$_4$(η^2, η^2-alkene)]. These products are considerably more stable than their mono-ene analogs due to the chelate effect (*see Chelate Effect*). They are often used as precursors for the preparation of [Mo(CO)$_4$L$_2$] complexes as better yields and purer products are obtained than from the direct reaction between [Mo(CO)$_6$] and L at elevated temperatures. For example, the fluorophosphine complex [Mo(CO)$_4${PF$_2$(CPh$_3$)}$_2$] can be prepared on stirring [Mo(CO)$_4$(NBD)] with PF$_2$(CPh$_3$) at room temperature for 1 h. The solid-state structure of this compound reveals very short Mo–P bonds (2.429 Å) (expected $\approx$ 2.58 Å) and is due to the presence of the electronegative (*see Electronegativity*) fluorine atoms.[40] Dienes are also known to coordinate to molybdenum in higher oxidation states. The seven-coordinate complex [Mo(SnCl$_3$)Cl(CO)$_3$(η^4-NBD)] was prepared on reaction between [(CO)$_4$Mo(μ-Cl)$_3$MoSnCl$_3$(CO)$_3$] with a stoichiometric amount of NBD (equation 7). Its solid-state structure shows some interesting structural features, the most significant being the asymmetry in the bond lengths to the NBD ligand. The alkene trans to the Cl ligand has Mo–C bond lengths of 2.330(3) Å and 2.335(3) Å respectively, which are approximately 0.1 Å shorter than those trans to CO, 2.431(3) Å and 2.423(3) Å. This is consistent with the relative π-acidities of the ligands CO > R$_2$C=CR$_2$ > Cl$^-$ and equally accounts for the differences in the bound C=C bond lengths, 1.388(4) Å and 1.362(4) Å trans to Cl and CO respectively. [Mo(SnCl$_3$)Cl(CO)$_3$(η^4-NBD)] has also been shown to initiate ROMP of NBD when treated with an excess of NBD (*see* ***Metathesis Polymerization Processes by Homogeneous Catalysis***). The propagation step in the polymerization was found to be slower than the initiation step, which requires decomplexation of one alkene moiety of the NBD ligand followed by rearrangement to an alkylidene ligand with subsequent ring opening followed by a 1,2-hydrogen shift.[41,42]

$$[(CO)_4Mo(\mu\text{-}Cl)_3Mo(SnCl_3)(CO)_3] + 2NBD \longrightarrow [Mo(\mu\text{-}Cl)(SnCl_3)(CO)_2(\eta^4\text{-NBD})] + [MoCl_2(CO)_3(\eta^4\text{-NBD})] + CO \quad (7)$$

The compounds [CpMo$^{(II)}$(η^4-C$_4$H$_6$)$_2$]$^+$, [CpMo$^{(III)}$(η^3-C$_3$H$_5$)$_2$], [CpMo$^{(II)}$(η^3-C$_3$H$_5$)(η^4-C$_4$H$_6$)], [CpMo$^{(III)}$(η^3-C$_3$H$_5$)(η^4-C$_4$H$_6$)]$^+$ have all been prepared.[43,44] For [CpMo$^{(III)}$(η^3-C$_3$H$_5$)(η^4-C$_4$H$_6$)]$^{n+}$ (n = 0, 1), four different isomeric forms are possible (Figure 7a–d). The allyl ligand adopts a *prone* or *exo* (Figure 7a and 7d) *supine* or *endo* (Figure 7b and 7c) geometry, whereas the butadiene ligand takes either *s-cis supine* (Figure 7a and 7d) or *s-trans* (Figure 7c and 7d). The *s-cis prone* butadiene ligand geometry has not been observed for this system. Depending upon the oxidation state Mo$^{(II)}$ versus Mo$^{(III)}$ diamagnetic, 18-valence electron or 17-valence electron paramagnetic species are obtained. This change in electronic configuration and metal oxidation state has a profound effect on their reactivity, for example see Scheme 4.[43] The related diene complexes [CpMoCl$_2$(η^4-diene)] (diene = butadiene, isoprene) react with Grignard reagents in a metathetical reaction to yield dialkyl complexes of the type [CpMoR$_2$(η^4-diene)] (R = Me, CH$_2$Ph, CH$_2$SiMe$_3$), note the absence of β-hydrogen atoms, rather than nucleophilic (*see Nucleophile*) attack at the diene ligand. The new Mo–C bonds are stable to weak acids but are cleaved by HCl, HBF$_4$, and CF$_3$CO$_2$H.[45]

An example of nucleophilic attack (*see Nucleophile*) on a π-bound diene is illustrated in Scheme 5. The incoming nucleophile adds on the face exo (*see Exo & Endo Substituents*) to the metal, meaning the metal has an antidirecting effect (*see* ***Organic Synthesis using Transition Metal Complexes Containing π-Bonded Ligands***). The functionalized organic molecule can then be obtained through oxidative cleavage; note the iodide enters on the same face as the nucleophile.[46]

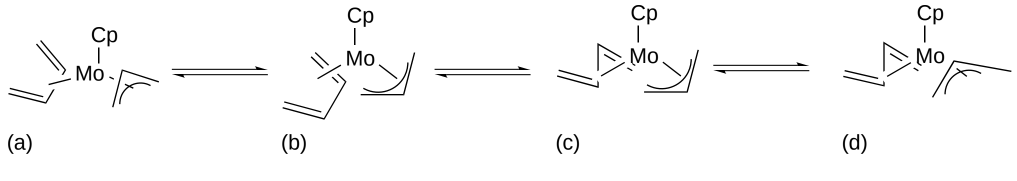

Figure 7 Different isomers of [CpMo(η^3-C$_3$H$_5$)(η^4-C$_4$H$_6$)]

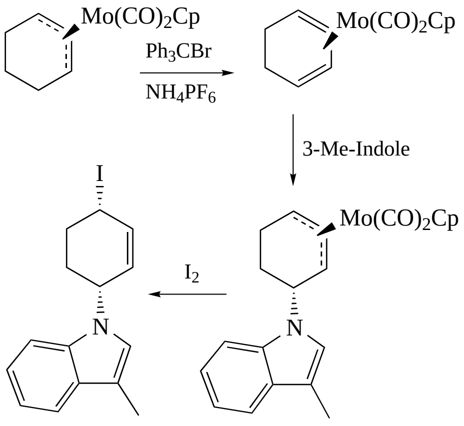

Scheme 5 An example of a nucleophilic attack on a π-bound diene

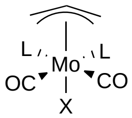

Figure 8 General structure of $[MoX(CO)L_2(\eta^3\text{-}C_3H_5)]$

π-Allyl complexes of the type $[MoX(CO)_2(L)_2(\eta^3\text{-allyl})]$ behave similarly to diene complexes. They show both metal- and ligand-centered reactivity. One method used to prepare this class of compound is by an oxidative elimination reaction between $[Mo(CO)_3(L)_3]$ (L = DMF, NCMe, Py) and a suitable allyl halide or allyl acetate to give $[MoX(CO)_2(L)_2(\eta^3\text{-allyl})]$ (X = Cl, Br, acetate).[47] The ligands L maybe exchanged for a range of monodentate (L′) and bidentate ligands (L-L); nucleophiles (*see Nucleophile*) may also attack the allyl moiety leading to functionalized allylic products.[48] These pseudooctahedral complexes are also known to be fluxional in solution with three different processes having been identified using VT NMR spectroscopy (*see* ***Stability Constants & their Determination***), a pivoted double-switch mechanism, intramolecular trigonal twist, and slow dissociative ligand exchange.[49] They also all generally have the same solid-state geometry (Figure 8). Another interesting use that has recently been found for compounds of the type $[CpMo(CO)_2(\eta^3\text{-allyl})]$ is as robust markers in peptide systems.[50]

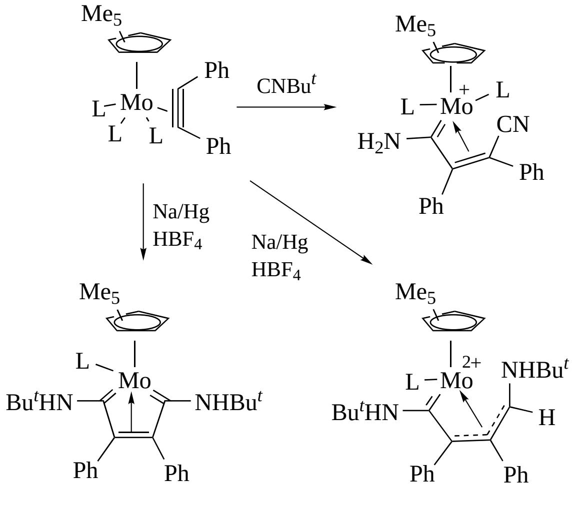
Complexes of cycloheptatriene (C_7H_8) and the tropylium cation $(C_7H_7)^+$ are also known and their chemistry mirrors that of the smaller polyene-containing systems, namely, metal-centered ligand exchange reactions and ligand-centered nucleophilic attack. A detailed review of this chemistry is available.[51]

3.2 Alkyne-containing Complexes

Alkyne complexes of molybdenum are common and there are several approaches to their preparation. They are of particular interest as the alkyne has the potential to act as a variable electron donor to the metal center: 4-e, 3-e or 2-e. The alkyne is able to act as a variable electron donor as it has two orthogonal π-systems, which may participate in bonding to the metal center. This makes them noticeably different from mono-alkene ligands, which can behave only as 2-e donors.

Much work has centered on coordination of alkynes to the $[(\eta^5\text{-}C_5H_5)Mo]$ moiety. *Bis*-alkyne-containing complexes of the type $[CpMo(CO)(\eta^2\text{-alkyne})_2]$ are readily synthesized, for example, on reaction of $[\{CpMo(CO)_3\}_2]$ with 2 Mole equivalents of alkyne in the presence of Ag^+. The alkyne ligands in these complexes are formally 3-e donors, if the complex is to obey the EAN (*see Effective Atomic Number Rule*). The compounds show a wide range of metal-centered ligand substitution reactions with, for example, phosphines and phosphites. It has also been shown that it is possible to react the coordinated alkyne with a range of nucleophiles (*see Nucleophile*). The related mono-alkyne-containing complexes $[CpMoL(\eta^2\text{-}RC_2R)_2]$ (L = phosphine or phosphite) are readily converted to either allyl- or metallacyclopropene-containing complexes on treatment with nucleophiles. The *bis*-alkyne-containing complexes undergo a diverse array of ligand coupling reactions and some reviews with regard to these reactions are available.[19,52,53] $[Mo(CO)(\eta^2\text{-PhC}\equiv\text{CPh})Cp][BF_4]$ reacts with 3 equivalents of $CNBu^t$ to give $[Mo(CNBu^t)_3(\eta^2\text{-PhC}\equiv\text{CPh})Cp][BF_4]$, where the alkyne has switched from a 4-e to a 2-e donor. Addition of a fourth equivalent of $CNBu^t$ causes a coupling reaction to occur ultimately affording a vinylcarbene. Reduction with Na/Hg has been shown to give different products that are condition dependent (Scheme 6).[54] Heptamethylindenyl analogs have also recently been prepared and shown to display similar reactivity to the parent cyclopentadienyl complexes.[55]

Making use of the isolobal analogy (*see Isolobal Analogy*), it has been shown that the imido group (NR) is isolobal with the cyclopentadienyl moiety. Bearing this relationship in



Scheme 6 Isonitrile/alkyne coupling reactions; L = $CNBu^t$

mind, the *bis*-imido alkyne complexes $[Mo(NR)_2(PMe_3)(\eta^2$-$R'C{\equiv}CR'')]$ (R = Ph or adamantyl, R′ = R″ = Ph; R = ^{t}Bu, R′ = Ph, R″ = H) were prepared by displacement of ethene from the analogous alkene complexes $[Mo(NR)_2(PMe_3)(\eta^2$-$H_2C{=}CH_2)]$ in hot heptane. The solid-state structure of $[Mo(N^tBu)_2(PMe_3)(\eta^2$-$PhC{\equiv}CPh)]$ was reported and shows the molecule is pseudo-tetrahedral. The alkyne contact carbon atoms and phosphorus atoms are all coplanar and this plane is perpendicular to the plane defined by N-Mo-N. Analogous structural characteristics are observed in the related solid-state structure of $[Mo(N^tBu)_2(PMe_3)(\eta^2$-$HC{=}CMe)]$ and in zirconocene systems (*see* ***Zirconium & Hafnium: Organometallic Chemistry***). These data add strong support for the isolobal relationship between zirconocenes and four-coordinate *bis*-imido complexes of molybdenum.[56]

The preparation of the *bis*-alkyne complexes $[WI_2(CO)(NCMe)(\eta^2$-$RC{\equiv}CR)_2]$ was reported in 1988 and their reactivity has been reviewed.[21] The analogous molybdenum complexes $[MoXX'_2(CO)(NCMe)(\eta^2$-$RC{\equiv}CR')_2]$ (X = X′ = I, Br; X = I, X′ = Cl; R = R′ = Me, Ph; R = Me, R′ = Ph), which are less stable than the related tungsten analogs, were isolated and structurally characterized in 1998.[57] The structure of $[MoI_2(CO)(NCMe)(\eta^2$-$MeC{\equiv}CMe)_2]$ shows the molecule to be pseudooctahedral, if the alkyne ligands are assumed to occupy one coordination site. The C≡C vectors run parallel to the M–CO axis, which is a common structural feature in compounds of this type. The methyl groups bend away from the linear conformation expected in alkynes due to back bonding from suitable metal dπ orbitals into the π^*-antibonding molecular orbitals of the alkyne ligands. The reactivity of these compounds with regard to ligand substitution reactions has been described and reviewed.[21] For example, on reaction with the monodentate phosphite ligands, initial substitution of an alkyne occurs affording $[MoI_2(CO)\{P(OR)_3\}(NCMe)(\eta^2$-$RC_2R)]$ that on subsequent treatment with a second equivalent gives rise to a mixture of *cis*- and *trans*-phosphite isomers $[MoI_2(CO)\{P(OR)_3\}_2(\eta^2$-$RC_2R)]$; in neither isomer is the alkyne found trans to the carbonyl ligand.[58] The alkyne ligand in *cis*-$[MoI_2(CO)\{P(OMe)_3\}_2(\eta^2$-$MeC_2Me)]$ was shown to be fluxional and undergoing propeller-like rotation, which could be frozen out at low temperature (*see* ***Stability Constants & their Determination***). The barrier to rotation $\Delta G^{\ddagger}$ was calculated to be 55 kJ mol^{-1}.

In the compounds $[CpMoL_2(\eta^2$-$MeC_2Me)]^{z+}$ (L = phosphorus donor, z = 0, 1), the but-2-yne ligand was shown to undergo propeller-like rotation (Figure 9a): at high temperature a single methyl resonance was observed in the ^{1}H NMR spectrum and at low temperatures gave two signals for the methyl groups due to the asymmetric environment. The solid-state structures of this class of compound, that have been determined crystallographically, all have the C≡C vector of the alkyne parallel to an Mo–P vector. This means, if the alkyne propeller-like rotation is frozen out, two signals should be evident in the ^{31}P NMR spectrum due to the presence of inequivalent phosphorus environments. For these compounds, this was found not to be the case and a second associated oscillation was shown to be taking place (Figure 9b) (*see* ***Stability Constants & their Determination***).[59]

3.3 Phosphaalkyne Complexes of Molybdenum

Phosphaalkynes (RC≡P) are phosphorus analogs of nitriles and have been shown to display a diverse range of organic- and inorganic-based chemistry including the preparation of phosphaalkyne-containing-transition metal complexes. This work has been reviewed.[60] Photoelectron spectroscopy has shown that the Highest Occupied Molecular Orbital (HOMO) is the phosphorus-carbon triple bond. It is this that influences the coordination chemistry of these molecules and why π-coordination is found to dominate σ-coordination. As a result, these complexes tend to parallel the well-known π-bound alkyne systems rather than their lighter congeners, the nitriles, which generally prefer the σ-ligation mode, for example, in $[Mo(CO)_3(NCMe)_3]$. However, π-bound nitriles are known and the first crystallographically characterized example was $[Cp_2Mo(\eta^2$-$NCMe)]$ reported by Wilkinson in 1986. The related compound $[(\eta^5$-$C_5H_4Bu^t)_2Mo(\eta^2$-$NCMe)]$ has recently been synthesized and crystallographically characterized. The lone pair at nitrogen has been shown to react with alkyl halides to give the cationic iminoacyl products $[(\eta^5$-$C_5H_4Bu^t)_2Mo(\eta^2$-$RN{=}CMe)][I]$ (R = Me, Et).[61]

End-on σ-coordination of phosphaalkynes has been affected by careful control of the steric environment (*see Steric Effect*) at the metal center or the steric bulk of the phosphaalkyne, thus treatment of $[Mo(N_2)_2\{Et_2P(CH_2)_2PEt_2\}_2]$ with 2 equivalents of ^{t}BuCP afforded the dinitrogen displaced product $[Mo(P{\equiv}CBu^t)_2\{Et_2P(CH_2)_2PEt_2\}_2]$. More recently, the very bulky supermesityl-phosphaalkyne P≡CMes* (Mes* = $-C_6H_2Bu^t_3$) has been reacted with $[Mo(CO)_3(PCy_3)_2]$ to give the η^1-phosphaalkyne bound compound $[Mo(CO)_3(PCy_3)_2(\eta^1$-P≡CMes*$)]$.[62] The crystal structure of the analogous tungsten complex shows that

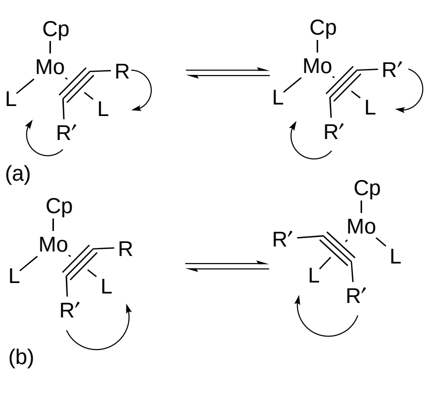


Figure 9 Two fluxional processes present in $[CpMoL_2(\eta^2$-$RC_2R)]$

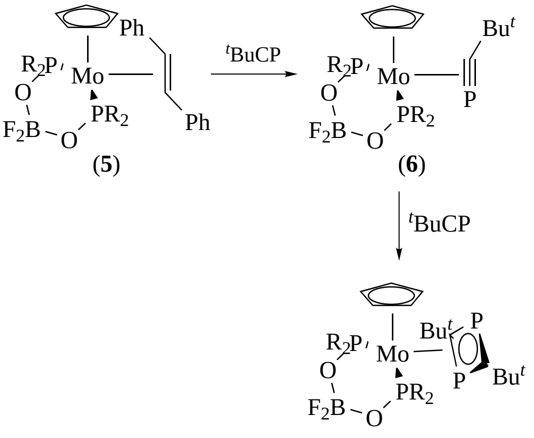
the P–C triple bond length (1.54 Å) is little affected on coordination.

The first example of a π-bond phosphaalkyne complex was $[Pt(PPh_3)_2(\eta^2\text{-PCBu}^t)]$. The lone pair located at the phosphorus atom allows further elaboration. Thus, treatment with $[Mo(CO)_5(THF)]$ afforded the bimetallic complex $[Pt(PPh_3)_2\{\eta^2\text{-Bu}^t\text{CP} \rightarrow Mo(CO)_5\}]$. In other parallels to alkyne chemistry treatment of $[\{CpMo(CO)_2\}_2]$ with ^{t}BuCP affords the four-electron donor phosphaalkyne complex $[\{CpMo(CO)_2\}(\mu\text{-}\eta^2\text{:}\eta^2\text{-PCBu}^t)\{CpMo(CO)_2\}]$. This compound was shown to undergo further reaction at the phosphorus lone pair, including the formation of adducts with $[Fe_2(CO)_9]$, $[W(CO)_5(THF)]$ and $[Os_3(CO)_{11}(NCMe)]$.

In addition to affording analogous products of the alkyne-containing complexes, some significant differences are also noted. Treatment of $[(\eta^5\text{-}C_9H_7)Mo(CO)_2(NCMe)_2][BF_4]$ with 2 equivalents of MeC_2Me affords the *bis*-alkyne complex $[(\eta^5\text{-}C_9H_7)Mo(CO)(\eta^2\text{-}MeC_2Me)_2][BF_4]$ in which the alkynes behave on average as 3e-donors. Whereas treatment of $[(\eta^5\text{-}C_9H_7)Mo(CO)_2(NCMe)_2][BF_4]$ with 2 Molar equivalents of ^{t}BuCP afforded a η^3-ligated 1,3-diphosphacyclobutadiene-containing complex, which in the solid-state has a nonplanar diphosphacyclobutadiene ring. The loss of planarity is caused by one of the phosphorus atoms in the diphosphacyclobutadiene ring interacting with the $[BF_4]^-$ counteranion: P–F 1.536(5) Å (Figure 10a). This interaction leads to the positive charge residing at phosphorus and an elongation of the B–F bond to 1.477(11) Å with the average of the other three B–F bonds being 1.333 Å. It was proposed from the spectroscopic data that in solution the molecule adopts an η^4-ligation of the diphosphacyclobutadiene moiety due to the presence of a singlet resonance in its $^{31}P\text{-}\{^1H\}$ NMR spectrum δ-121.1 ppm.[63]

It is well known that alkynes may behave as variable electron donors to metal centers and efforts have been made to prepare (nonbridging) 4e-donor phosphaalkyne-containing complexes. Treatment of the *trans*-stilbene complex (**5**) with a stoichiometric amount of ^{t}BuCP afforded the low-melting green solid (**6**). Further, treatment of this 4e-donor phosphaalkyne complex with another molar equivalent of ^{t}BuCP afforded the 1,3-diphosphacyclobutadiene-containing complex (**7**) in good overall yield and showed the possibility

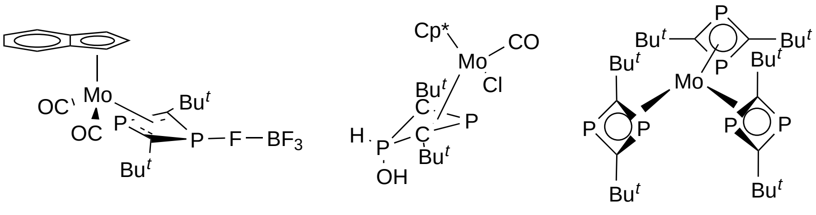


(**5**) (**6**) (**7**)

Scheme 7 Stepwise formation of a diphosphabutadiene ring

of the stepwise formation of 1,3-diphosphacyclobutadiene complexes (Scheme 7).[64]

Using a similar approach, the *bis*-trimethylphosphite-containing complex $[CpMo\{P(OMe)_3\}_2(\eta^2\text{-P}\equiv\text{CBu}^t)]$, analog of (**6**), was obtained in good yield. Unfortunately, a solid-state structure could not be obtained, for what is rare example of a 4e-donor phosphaalkyne complex of Mo^{II}, so a theoretical calculation on the model compound $[(\eta^5\text{-}C_5H_5)Mo\{P(OH)_3\}_2(\eta^2\text{-P}\equiv\text{CMe})]^+$ was carried out and the data obtained were comparable to that obtained for the crystallographically determined solid-state structure of the analogous alkyne-containing complex $[CpMo\{P(OMe)_3\}_2(\eta^2\text{-}HC_2Bu^t)]^+$, where the alkyne is orientated parallel to a Mo–P vector. The short nature of the calculated Mo–C bond distance (2.06 Å) to the ligated phosphaalkyne is consistent with the phosphaalkyne being considered a 4e-donor and indeed is comparable to the structural characterization of a 4e-donor phosphaalkyne in the related tantalum complex $[(\eta^5\text{-}C_5Me_5)TaCl_2(\eta^2\text{-P}\equiv\text{CBu}^t)]$ (*see* ***Niobium & Tantalum: Inorganic & Coordination Chemistry***). Further, treatment of $[CpMo\{P(OMe)_3\}_2(\eta^2\text{-PCBu}^t)][B(C_6F_5)_4]$ with a stoichiometric amount of $PCBu^t$ afforded the 1,3-diphosphacyclobutadiene-containing complex $[CpMo\{P(OMe)_3\}(\eta^4\text{-}P_2C_2Bu^t_2)][B(C_6F_5)_4]$. The mechanism of the reaction was suggested to be associative because of the potential of the 4e-donor phosphaalkyne to switch to



(a) (b) (c)

Figure 10 1,3-Diphosphacyclobutadiene complexes of molybdenum

become a 2e-donor, which is common behavior for 4e-donor alkyne ligands in equivalent alkyne-containing complexes, thus forming a site of attack for the incoming phosphaalkyne. These data add additional support to the stepwise formation of 1,3-diphosphacyclobutadiene rings at molybdenum.[65]

Other routes to 1,3-diphosphacyclobutadiene-containing complexes of molybdenum have been described. Treatment of $[(\eta^5\text{-}C_5R_5)MoCl(CO)_3]$ (where R = H, Me) with $PCBu^t$ afforded the 1,3-diphosphacyclobutadiene-containing complexes $[(\eta^5\text{-}C_5R_5)MoCl(CO)(\eta^4\text{-}1,3\text{-}P_2C_2Bu^t_2)]$ (where R = H, Me) (**8**), (**9**) in reasonable yield. Again this mode of reactivity differs from that of alkynes, where on treatment of $[(\eta^5\text{-}C_5R_5)MoCl(CO)_3]$ (where R = H, Me) with RC_2R affords the 4e-donor alkyne-containing complexes $[(\eta^5\text{-}C_5R_5)MoCl(CO)(\eta^2\text{-}RC_2R)]$. The asymmetry at the metal center gives rise to two Bu^t signals in the ^1H NMR spectrum at room temperature, which on warming begin to coalesce at 60 °C at 400 MHz (*see* ***Stability Constants & their Determination***). Compound (**8**) reacts slowly with water at one of the coordinated phosphorus atoms in an oxidative addition reaction to give compound (**10**) (Figure 10b), which has been crystallographically characterized showing the hydroxyl moiety to be exo (*see Exo & Endo Substituents*).[66]

Metal centers are known to trimerize alkynes to give functionalized arenes and attempts, using molybdenum-based systems, have been made to try and prepare triphosphabenzenes. An early and unsubstantiated report for the preparation of a 1,3,5-triphosphabenzene–containing complex was reported in the 1980s.[67] An alternative approach used was Metal Vapor Synthesis (*see* ***Metal Vapor Synthesis of Transition Metal Compounds***) in which molybdenum atoms were cocondensed with $PCBu^t$ at 77 K. The resulting product was $[Mo(\eta^4\text{-}1,3\text{-}P_2C_2Bu^t_2)_3]$ that contains three 1,3-diphosphacyclobutadiene rings rather than the hoped for $[Mo(\eta^6\text{-}P_3CBu^t_3)_2]$, which would contain two 1,3,5-triphosphabenzene ligands. The compound has been crystallographically characterized and shows that one of the four-membered rings is rotated through 90° relative to the other two, presumably to reduce steric pressure within the coordination sphere, Figure 10(c).[68]

3.3 Cyclopentadienyl-containing complexes

3.3.1 Monocyclopentadienyl Complexes

Molybdenum complexes that contain the cyclopentadienyl ligand $(C_5H_5)^-$ are very common and the cyclopentadienyl ligand (Cp) is often present as a spectator ligand occupying three coordination sites. Precursor compounds that are often used in Cp-containing molybdenum chemistry are the dimeric complex $[\{CpMo(CO)_3\}_2]$, which contains an unsupported metal–metal bond (3.24 Å), $[CpMoX(CO)_3]$ (X = halogen), the anion $[CpMo(CO)_3]^-$, and $[Cp_2MoX_2]$ (X = halogen, hydride etc.).

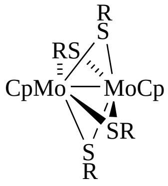
Preparation and Reactivity of $[\{CpMo(CO)_3\}_2]$. $[\{CpMo(CO)_3\}_2]$ can be prepared from the reaction between $[Mo(CO)_6]$ and dicyclopentadiene at 110 to 120 °C; however, this is only really effective for small scale preparations. Better yields are obtained from the reaction between $[Mo(CO)_3(NCMe)_3]$ with C_5H_6 monomer or through oxidation of $[CpMo(CO)_3]^-$ with iron (III) sulfate.[69] These latter routes are particularly effective for substituted cyclopentadienyls and indenyl.

The reactivity of $[\{CpMo(CO)_3\}_2]$ centers around CO substitution by two-electron donors such as phosphines, phosphites, or isonitriles. Typically, one or two carbonyl groups are substituted to give the following compounds $[CpMo(CO)_3\text{-}Mo(CO)_2LCp]$ and $[CpMo(CO)_2L\text{-}Mo(CO)_2LCp]$. These reactions can be affected either photochemically or thermally (*see* ***Photochemistry of Transition Metal Complexes***). A competing reaction that is often present and difficult to predict is heterolytic cleavage (*see Heterolytic Cleavage*) of the Mo–Mo bond (equation 8).

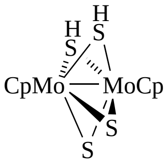
$$[Cp(CO)_3Mo-Mo(CO)_3Cp] \xrightarrow{2L} [CpMo(CO)_3]^- + [CpMo(CO)L_2]^+ \quad (8)$$

One carbonyl ligand can also be lost from each molybdenum center in $[\{CpMo(CO)_3\}_2]$ in the absence of nucleophiles (*see Nucleophile*), affording the compound $[Cp(CO)_2Mo{\equiv}Mo(CO)_2Cp]$, which contains a Mo–Mo triple bond. Analogous systems where the Cp ligand is replaced by indenyl and a variety of substituted cyclopentadienes are known and react similarly.[70] This unsaturated compound is very reactive and adds nucleophiles (*see Nucleophile*) under very mild conditions. For example, alkynes add across the triple bond to give $[Cp(CO)_2Mo(\mu\text{-}\eta^2:\eta^2\text{-}RC_2R)Mo(CO)_2Cp]$ and in turn are reactive species. Recently, heterobimetallic complexes of the type $[Cp(CO)_2Mo(\mu\text{-}\eta^2:\eta^2\text{-}RC_2R)Co(CO)_3]$ (*see* ***Dinuclear Organometallic Cluster Complexes***) have been prepared and shown to undergo the Pauson–Khand reaction (*see* ***Organic Synthesis using Transition Metal Complexes Containing π-Bonded Ligands***) to make cyclopent-2-enones.[71] The chirality (*see Chiral*) of the tetrahedral metal-alkyne core in these compounds has been shown to give good stereocontrol in asymmetric variants.[72] Reaction with sulfur-containing compounds gives rise to compounds of type (**11**), (**12**), and (**13**). This work has been developed because of its relevance to sulfur rich metal centers in enzymes and important industrial desulfurization processes (*see* ***Hydrodesulfurization & Hydrodenitrogenation***) and has been reviewed.[73]

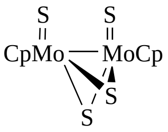
The reducing agents Na/Hg, $[HBEt_3]^-$, or Na/K alloy will reduce $[\{CpMo(CO)_3\}_2]$ to give the anionic complex $[CpMo(CO_3)]^-$, which can also be prepared through reaction between $[Mo(CO)_6]$ and LiCp in THF. Corresponding alkylated cyclopentadiene analogs can also be synthesized in an analogous manner. This anion reacts with a wide range of electrophiles (*see Electrophile*) such as alkyl halides, alkenyl



(**11**)



(**12**)



(**13**)

halides, acyl halides, and other main group element halides to give products of the type $[CpMo(CO)_3E]$. Protonation of $[CpMo(CO_3)]^-$ gives the hydride $[CpMoH(CO)_3]$, which has a pK$_a$ of 13.9 in acetonitrile.[74]

3.3.2 *Preparation and Reactivity of [CpMoX(CO)$_3$]*

The halide compounds $[CpMoX(CO)_3]$ (X = Cl, Br, I) are prepared through treatment of $[\{CpMo(CO)_3\}_2]$ with the halogen or through reaction of $[CpMoH(CO)_3]$ with a halogenating agent such as MeI, CH_2Br_2, or CCl_4. These compounds are good starting materials for the preparation of $[CpMoX(L)_n(CO)_{3-n}]$ through simple CO substitution reactions using two-electron donors such as phosphines. Reaction with additional halogen leads to the higher oxidation state compounds $[CpMoX_3(CO)_2]$. The halide ligand can be replaced by alkyl or allyl groups to give compounds of the type $[CpMoR(CO)_3]$. Photolysis of the σ-allyl complex facilitates the σ-to-π rearrangement of the allyl ligand, due to dissociation of a carbonyl ligand, affording $[CpMo(CO)_2(\eta^3\text{-}C_3H_5)]$. Substitution of the halide may also be affected by carbonylate anions to give Mo-transition metal bonds. The halide atom may also be abstracted by strong Lewis acids (*see Lewis Acids & Bases*), like $AgBF_4$, in the presence of CO to give the cation $[CpMo(CO)_4]^+$ or if the reaction is carried out in the absence of a donor ligand, the $[BF_4]^-$ anion may act as a weekly coordinating ligand to give a masked source of the strong Lewis acid $[CpMo(CO)_3]^+$ (*see Lewis Acids & Bases*).

3.3.3 *Monocyclopentadienylhalide Complexes*

A slightly dated, but exhaustive, review is available on complexes of the type $[CpMoX_n]$. Cyclopentadienyl halide complexes of molybdenum in the +6 and +2 oxidation states are not known.[75]

CpMoX$_n$ and Derivatives. $[CpMoX_4]$ (X = Cl, Br) are best synthesized by oxidation of $[CpMoMe(CO)_3]$ with PCl_5 or PBr_5. The tetrachloride may also be prepared on treatment of $[CpMoO(Cl)_2]$ with HCl. These Mo^V compounds may be reduced to lower valent species. Thus, treatment of $[CpMoCl_4]$ with zinc affords the insoluble molybdenum(III) compound $[(CpMoCl_2)_n]$. Enhanced solubility is obtained through the use of alkylated cyclopentadienyl ring systems. The Mo^{IV} complexes are best prepared by one of two methods: conproportionation of $[CpMoCl_4]$ and $[CpMoCl_2]$ or by oxidation of $[CpMoCl_2]$ with $PhICl_2$ and the reactivity of these compounds has been reviewed.[44]

Cyclopentadienyl Nitrosyl Halides[76]. $[CpMoCl(NO)_2]$ is obtained on treatment of $[CpMo(CO)_2(NO)]$ with NOCl or from the reaction between $[CpMoCl_2]$ and NO. Oxidation of $[CpMo(CO)_2(NO)]$ with halogens affords the compounds $[\{CpMoX_2(NO)\}_2]$, which contain bridging halides (*see Bridging Ligand*). Subsequent reaction with Grignard reagents gives the corresponding mono and dialkyl complexes with hydrolysis of the latter affording the μ-oxo dimer $[\{CpMoR(NO)\}_2(\mu\text{-O})]$ (*see μ-Oxo Bridge*).

3.4 Dicyclopentadienyl Complexes[77,78]

The molybdenum analog of chromocene (*see Metallocene Complexes*) $[Cp_2Mo]$ (molybdenocene) is not stable and has only been isolated using matrix isolation techniques (*see Matrix Isolation*). The IR, magnetic circular dichroism spectra of the matrix isolated $[Cp_2Mo]$ were interpreted in terms of a paramagnetic metallocene, with parallel rings.

The bent metallocenes $[Cp_2MoX_2]$ normally have a Cp–Mo–Cp (Cp = ring centroid) angle near 130°, but the X–Mo–X angle depends upon the number of d-electrons. For d^0 complexes, the angle is approximately 97°, for d^1 it is lowered to 86 to 88° and further still to approximately 82° for d^2 systems. These structural features are consistent with the lone pair of d^2 electrons being in an orbital that lies in the MoX_2 plane with major lobes lying outside the MoX_2 triangle.

3.4.1 *Preparation and Reactivity*

The dihydride $[CpMoH_2]$ was first prepared in 1959 on treatment of $MoCl_5$ and NaCp in the presence of $[BH_4]^-$, and its chemistry has been extensively developed since then.[77] It behaves as a Lewis base (*see Lewis Acids & Bases*) and is readily protonated to give the cation $[Cp_2MoH_3]^+$. This cation has been shown to reduce unsaturated organic fragments such as imines, aldehydes, and ketones.[79] Reaction of $[CpMoH_2]$ with methyl triflate ($CH_3OS(O)_2CF_3$) gives $[Cp_2MoH\{OS(O)_2CF_3\}]$ and CH_4. This compound is water-soluble and undergoes hydride deuteride exchange in D_2O and is capable of readily reducing ketones in water under the mild conditions of 40 °C and pH 7 (*see* ***Organic Synthesis using Transition Metal Complexes Containing π-Bonded Ligands***).[79] $[Cp_2MoH_2]$ also shows its ability to behave as a base by forming adducts with Lewis acids (*see Lewis Acids & Bases*), for example, reaction with $AgBF_4$ in the presence of pseudohalide ligands gives the adducts $[(Cp_2MoH_2)_2AgX]$ (X = SCN^-, OCN^-, CN^-, and $SCF_3{}^-$). The compound $[(Cp_2MoH_2)_2AgSCN]$ has been crystallographically characterized and has an average Mo–Ag bond length of 2.963 Å.[80] Like the parent compound,

$[Cp_2MoH_2]$ substituted cyclopentadienyl ligands can be introduced and the incorporation of alkyl groups onto the Cp ring enhances the complex's solubility in organic solvents. Recently, the compound $[(^tBuCp)_2MoH_2]$ (**14**) has been prepared and its chemistry extensively investigated.[61](**14**) can be converted to $[(^tBuCp)_2MoX_2]$ (X = Cl **15**, Br **16**) on treatment with CCl_4 and CH_2Br_2 respectively. Reaction with MeI gives $[(^tBuCp)_2MoHI]$.

As is generally the case, generation of the dihalides opens up a vast array of chemistry. Thus, treatment of (**15**) with RLi or RMgX gives the dialkyl complexes $[(^tBuCp)_2MoR_2]$ (R = Me, CH_2Ph, CH_2SiMe_3); reaction with LiOH gives the oxo-containing complex $[(^tBuCp)_2Mo{=}O]$; reduction with Na/Hg in the presence of L (L = CO, PMe_3, C_2H_4, C_2H_2, NCMe) gives the formally Mo^{II} adducts $[(^tBuCp)_2MoL]$. Reaction of $[(^tBuCp)_2Mo(CO)]$ with elemental S, Se, or Te gives the compounds $[(^tBuCp)_2Mo(\eta^2\text{-}E_2)]$, where E = S or Se; the compounds have been crystallographically characterized (Figure 11) and both the S–S (2.04 Å) and Se–Se (2.322 Å) bond lengths are close to those in S_8 (2.060 Å) and Se_8 (2.34 Å) suggesting strong back bonding and a Mo^{IV} metallacyclopropane type structure. These reactions mirror those of the parent complex $[Cp_2MoCl_2]$.

$[Cp_2MoCl_2]$ has been shown to hydrolyze phosphoesters under aqueous conditions through the intermediate compound (**16**), which forms from the reaction between $[Cp_2Mo(OH_2)_2]$, generated from the hydrolysis of $[CpMoCl_2]$, and the phosphoester.[81] This work has been further developed and the organophosphate pesticides Paraoxon (**17**) and Parathion (**18**) have also been shown to be hydrolyzed by $[CpMoCl_2]$ with an enhanced rate.[82]

The compounds $[(\eta^5\text{-}C_9H_7)(Cp)MoX_2]$ (C_9H_7 = indenyl) have been prepared and show comparable reaction chemistry to the parent $[Cp_2MoX_2]$ compounds; however, on reduction

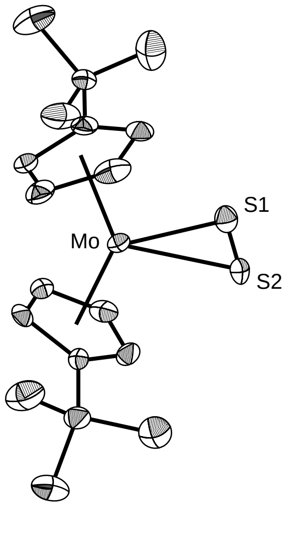


Figure 11 Molecular structure of $[Mo(\eta^2\text{-}S_2)(\eta^5\text{-}^tBuCp)_2]$. (Reproduced by permission of The Royal Society of Chemistry)

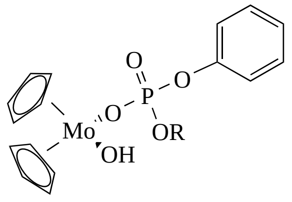
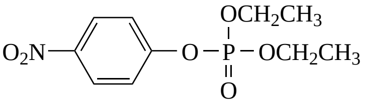
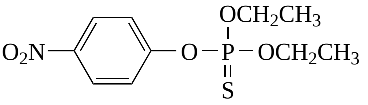


(**16**)



(**17**)



(**18**)

a noticeable difference occurs. The ring-slipped products $[(\eta^3\text{-}C_9H_7)(Cp)MoL_2]$ are obtained rather than the expected $[(\eta^5\text{-}C_9H_7)(Cp)MoL]$. This work has been reviewed[83] and studied theoretically.[84]

3.5 Arene-containing Complexes

There are two different general classes of π-bound arene-containing complexes of molybdenum: the monoarene complexes $[(\eta^6\text{-arene})Mo(CO)_3]$ or the *bis*-arene complexes $[(\eta^6\text{-arene})_2Mo]$. The solid-state structures of both classes of compound show that the bond lengths around the arene ligand are equivalent. This clearly means that the arene does not bond as a triene through localized electron pairs.

The monoarene complexes can be synthesized directly from $[Mo(CO)_6]$, but the reaction of an arene with $[Mo(CO)_3L_3]$ (L = NCMe or py in the presence of BF_3) tend to give better yields and at lower reaction temperatures. The Mo–arene bond strength appears to be greater than for the analogous Cr–arene (280 kJ mol^{-1} vs 191 kJ mol^{-1} (*see* ***Bonding Energetics of Organometallic Compounds***)),[85] however; the molybdenum complexes are thermally less stable and kinetically more labile. The analogous chromium–arene complexes have found much utility in organic synthesis[86] (*see* ***Asymmetric Synthesis by Homogeneous Catalysis*** and ***Organic Synthesis using Transition Metal Complexes Containing π-Bonded Ligands***), in particular utilizing the planar chirality imposed by π-complexation of the $[Cr(CO)_3]$ fragment on one face of the arene ring.[87] The compound $[Mo(CO)_3(\eta^6\text{-}C_6H_3\text{-}1,3,5\text{-}Bu^t_3)]$ and its heteroarene analog $[Mo(CO)_3\ (\eta^6\text{-}1,3,5\text{-}P_3C_3Bu^t_3)]$ were both prepared from $[Mo(CO)_3(NCMe)_3]$ and studied by Photoelectron Spectroscopy (*see* ***Photoelectron Spectroscopy of Transition Metal Systems***) and Density Functional Theory

(*see Density Functional Theory*). It was found that the 1,3,5-triphosphabenzene ligand is more strongly bound to the molybdenum center because the phosphorus atoms cause a lowering of the energy of the π-acceptor orbitals, and hence allow more π-backbonding and so strengthening the molybdenum arene bond.[88]

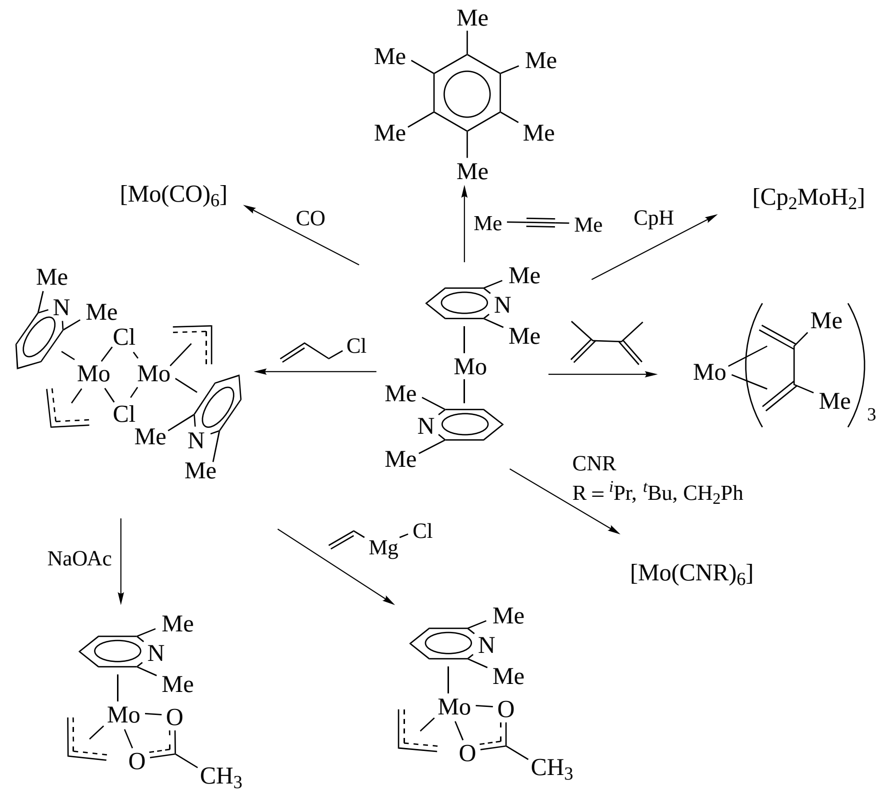
The *bis*-arene complexes $[(\eta^6\text{-arene})_2Mo]$ can be prepared in two principally different ways. The Fischer–Hafner synthesis: The reaction between $MoCl_5$ and an arene in the presence of Al and $AlCl_3$. The problems associated with this method are long reaction times, poor yields, and the limitation on the arenes that may be used. Arenes that have lone pairs such as halobenzenes, anilines, or phenols cannot be used as they form Lewis adducts with $AlCl_3$ (*see Lewis Acids & Bases*). Equally, the use of polyalkylated arenes is not possible due to isomerization catalyzed by $AlCl_3$. The parent compound $[Mo(\eta^6\text{-}C_6H_6)_2]$ is green, very air sensitive, and a diamagnetic 18 valence electron species with a melting point of 115 °C.

An alternative synthetic procedure is to use Metal Vapor Synthesis (MVS) (*see* ***Metal Vapor Synthesis of Transition Metal Compounds***). This method of preparation is hindered by the high boiling point of molybdenum and the expense of the MVS apparatus. It does, however, allow a greater range of functionalized *bis*-arene complexes to be synthesized.[89] *bis*-Heteroarene complexes, like $[Mo(\eta^6\text{-}C_5H_3N\text{-}2,6\text{-}Me_2)_2]$, can also be prepared using this methodology and their reactivity mirrors that of the *bis*-arene molybdenum complexes.[90] The reactivity of $[Mo(\eta^6\text{-}C_5H_3N\text{-}2,6\text{-}Me_2)_2]$ is summarized in Scheme 8. The solid-state structure of $[\{Mo(\mu\text{-}Cl)(\eta^3\text{-}C_3H_5)(\eta^6\text{-}C_5H_3N\text{-}2,6\text{-}Me_2)\}_2]$ has been determined and shows that the 2,6-lutidine ring is not planar. The nitrogen atom and the *para*-carbon bend in toward the metal center and the two-methyl groups bend away, and differs from the arene systems where the ring remains planar on complexation.

4 POLYMETALLIC COMPLEXES

4.1 Multiply Bonded Dimers

Molybdenum(II) and molybdenum(III) form an extensive array of multiply bonded dimers, which contain Mo–Mo quadruple and triple bonds respectively.[91] Much of the organometallic chemistry of this class of compound has come principally from the work of one research group.[92] Homoleptic compounds such as $[Mo_2Me_8]^{4-}$, $[Mo(\eta^n\text{-allyl})_4]$, which contains bridging and terminal allyl ligands (*see Bridging Ligand*), are readily synthesized from $[Mo_2(OAc)_4]$



Scheme 8 Summary of the reactions of $[(\eta^6\text{-}2,6\text{-}Me_2NC_5H_3)_2Mo]$

on reaction with either MeLi or allyl Grignard respectively. Treatment of $[Mo_2(OAc)_4]$ with sources of Cp^- does not generate the expected η^5-Cp coordination rather many compounds that contain bridging (η^5:η^1-)cyclopentadienyl ligands and other coupled Cp bound systems (*see* ***Dinuclear Organometallic Cluster Complexes***).

4.2 Cluster Compounds

As used here cluster refers to molecules that contain at least 3 metal atoms and electron configurations suitable for the formation of metal–metal bonds. Molybdenum readily forms strong homoleptic metal–metal bonds (*see Homoleptic Compound*) and so it is not surprising that molybdenum is readily incorporated into cluster structures (*see* ***Polynuclear Organometallic Cluster Complexes***).

Early work in this area was often serendipitous but as the field has developed, underpinned concepts such as cluster *Electron Counting* rules and Hoffman's *Isolobal Analogy*, rational cluster syntheses have begun to appear.[93]

4.3 Homometallic Complexes

$[M_3(CO)_{12}]$ (M = Fe, Ru or Os) are derived formally from $[M(CO)_5]$ by replacing 1 of the CO ligands with the formation of 2 metal–metal bonds. However, there are no known analogous molybdenum-centered clusters derived from $[Mo(CO)_6]$ in similar fashion. This is likely to be the result of steric congestion (*see Steric Effect*); however, replacement of the CO ligand with smaller groups allows cluster formation as in $[\{MoH(CO)_3\}_4]^{4-}$.

4.4 Clusters with Bridging Ligands

Replacement of CO groups with functionalities that are capable of forming bonds between 2 or 3 metal atoms is an effective strategy in cluster synthesis. Good bridging groups include: P, As, S, Se, Te, PR, RS (*see* ***Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements***). There is particular interest in building clusters that contain sulfur due to their potential importance in processes such as hydrodesulfurization processes (*see* ***Hydrodesulfurization & Hydrodenitrogenation***) important in fossil fuel refining. Additional interest is as models of active sites of metalloenzymes such as nitrogenase (*see* ***Metalloprotein Design & Engineering***).[94–96]

Stone's group have been particularly active in the synthesis of molybdenum- and tungsten-centered heteronuclear complexes making effective use of the Isolobal Analogy (*see Isolobal Analogy*).[97]

METHOD SUMMARY

Acronyms, Synonyms

- Recoilless nuclear resonance absorption of γ-radiation (used by Mößbauer in his Nobel lecture 1961)

Measured physical quantities

- Mössbauer spectroscopy is a nuclear probe and works best with ^{57}Fe. Other Mössbauer-active isotopes are, among many others, ^{61}Ni and ^{67}Zn.
- In case of ^{57}Fe, the resonant absorption of 14.4 keV γ-rays emitted by a radioactive ^{57}Co source is measured. The spectra are determined by the hyperfine interactions (isomer shift, quadrupole splitting, and magnetic hyperfine field) of the Mössbauer nucleus caused by the surrounding electron shell.

Information available

- spin state as well as oxidation state of the Mössbauer atom
- fine structure parameters like zero-field splitting D and rhombicity E/D
- hyperfine coupling tensor $\overleftrightarrow{A}$, respectively magnetic hyperfine field B_{hf}
- phase transitions in solids
- coordination number and geometry
- dynamic properties: mean-square displacement of the Mössbauer atom, Debye temperature of solids.

Information not available, limitations

- Coordination number and geometry cannot be determined directly; comparison with model complexes is necessary.
- If several iron species are present in the sample, deconvolution of signals can be tedious.
- Exchange coupling constants J of polynuclear species can only be estimated, because in addition to D and E/D, at least the hyperfine coupling constants of the single sites have to be determined.

Examples of questions that can be answered

- Is there high-spin Fe(II) in the sample? What is the ratio of Fe(II) to Fe(III)?
- What are the values of D and E/D of a high-spin Fe(II)?
- Is there a $[2Fe{-}2S]^{+}$ or a $[4Fe{-}4S]^{2+}$ center in this protein?

Major advantages

- Method ''sees'' all Mössbauer atoms in the sample and works very well with ^{57}Fe. There is no Mössbauer-silent ^{57}Fe.

Major disadvantages

- For solution studies, enrichment with ^{57}Fe is necessary and relatively high ^{57}Fe concentrations ($\geq$1 mM) are needed.

Sample constraints

- Sample must be in the solid state: powders, foils, and frozen solutions can be studied. Surface layers can be measured by special techniques (CEMS).
- Sample volume of frozen solutions: typically 0.2–1 mL.
- Thickness of iron foils (not enriched in ^{57}Fe): 5–25 µm.

1 INTRODUCTION

This article introduces the reader to basic fundamentals and in quite a general way to applications of Mössbauer spectroscopy within inorganic and bioinorganic chemistry. The idea is to allow scientists dealing with metal sites, especially iron chemistry, to decide whether Mössbauer spectroscopy will help in solving their problems. A huge amount of Mössbauer work on almost all iron-containing materials ranging from iron-containing alloys, oxides, ionic as well as coordination compounds[1–6] and metal sites in proteins does exist.[7–11] Mössbauer spectroscopy has also been applied to study nano-sized particles both in solution and heterogeneous catalysts.[12] Special experimental techniques like conversion electron Mössbauer spectroscopy (CEMS) allow us to study surfaces and thin films even down to the monolayer regime.[13,14] The same sensitivity has been reached very recently in experiments on iron monolayers with Mössbauer spectroscopy with synchrotron radiation, also called nuclear forward scattering (NFS) (*see* ***Nuclear Resonance Vibrational Spectroscopy (NRVS)***).[15]

Because of the broad coverage of this article, we will limit ourselves to the study of structural and electronic properties of iron centers by ^{57}Fe Mössbauer spectroscopy. If the reader is interested in the determination of dynamic properties both by conventional and synchrotron-based Mössbauer spectroscopy, we refer them to the articles by Parak,[16] and Paulsen *et al.*,[17] as well as to the contribution of Scheidt and Sage in this volume (*see* ***Nuclear Resonance Vibrational Spectroscopy (NRVS)***).

2 TECHNICAL BACKGROUND

2.1 Recoil-free Absorption of γ-Rays

The term Mössbauer effect describes the recoil-free resonant absorption of γ quanta by nuclei of the same kind as the emitters. If a free nucleus undergoes a transition from an excited state by emission of a γ quantum, it suffers a recoil. The energy of this quantum in the laboratory frame is given as $E_\gamma^0 = E^0 - E_R$, where E^0 is the nuclear transition energy and E_R is the recoil energy of the nucleus after the emission of the γ quantum. It can be expressed as

$$E_R = \frac{E_\gamma^{0^2}}{2Mc^2} \approx \frac{E^{0^2}}{2Mc^2} \quad (1)$$

with M being the nuclear mass and c the speed of light. The recoil energy of the nucleus E_R is approximately 10^6 larger than the energy width Γ of the excited nuclear state. Thus the lifetime broadening of the nuclear transition cannot exceed the recoil energy and therefore resonance absorption of γ quanta emitted by free nuclei is not possible.

Rudolf Mössbauer found during work on his PhD thesis in 1953 that, if ^{191}Ir nuclei are embedded in a crystal lattice, there is a certain probability for recoil-free emission and absorption of γ quanta.[18] Later he received the Nobel prize because in the meantime it had been found that recoil-free emission and absorption of γ quanta also worked for ^{57}Fe and this boosted the application of the technique in physics, material science, and chemistry. A very instructive description of these investigations can be found in his Nobel lecture.[19]

Qualitatively the effect can be explained by a simple picture: the recoil energy of a single nucleus is taken up by the whole lattice and the expression for the recoil energy (equation 1) does not contain the mass M of the nucleus anymore, but contains the mass of the whole lattice M_{lattice}:

$$E_R^{\text{Moss}} = \frac{E^{0^2}}{2M_{\text{lattice}}c^2} \cong 0 \tag{2}$$

Because M_{lattice} is much larger than the nuclear mass M, the recoil energy is negligible and resonance absorption takes place. In terms of quantum mechanics, there is a probability f for a zero-phonon process, where no lattice vibrations are excited. Rudolf Mössbauer showed that the probability f for a zero-phonon process is given by the subsequently named Lamb–Mössbauer factor:

$$f = \exp\{-k^2\langle x^2\rangle\} \tag{3}$$

The quantity $\langle x^2\rangle$ denotes the mean-square displacement of the Mössbauer nucleus in the direction of the incoming γ-ray and $k = 2\pi/\lambda$ is the wave number of the γ-ray. The decrease of the mean-square displacement $\langle x^2\rangle$ with decreasing temperature leads to an increase of the Lamb–Mössbauer factor f and thus the Mössbauer effect.

2.2 Experimental Setup and Spectral Line Shape

2.2.1 Transmission Geometry

A setup in transmission geometry is the standard implementation of ^{57}Fe Mössbauer spectroscopy. In a transmission experiment, the γ-rays emitted by the radioactive source are registered by a detector after they have passed the absorber. This method works with powders, foils, and frozen solutions. In order to investigate the energy spectrum of the absorber nuclei, the energy of the emitted γ-ray is modulated by moving the source relative to the absorber with a velocity V according to $E_\gamma = \left(1 + \frac{V}{c}\right) E^0_{\text{source}}$. The source is mounted on the Mössbauer drive, which is basically a loudspeaker driven either by a sinusoidal or triangular shaped current (Figure 1).

The magnitude of the observed Mössbauer effect is determined by the effective thickness of the absorber, which is a dimensionless quantity given by

$$t_{\text{eff}} = f\sigma_0 N_A \beta\rho\frac{\Delta x}{A} \tag{4}$$

with f being the Lamb–Mössbauer factor and σ_0 denoting the resonance cross section for absorption of γ quanta. N_A is the Avogadro constant, β is the relative isotopic abundance of the Mössbauer-active element in the absorber, ρ is the mass density of the sample, Δx is the geometric thickness of the absorber, and A is the molar mass of the Mössbauer isotope.

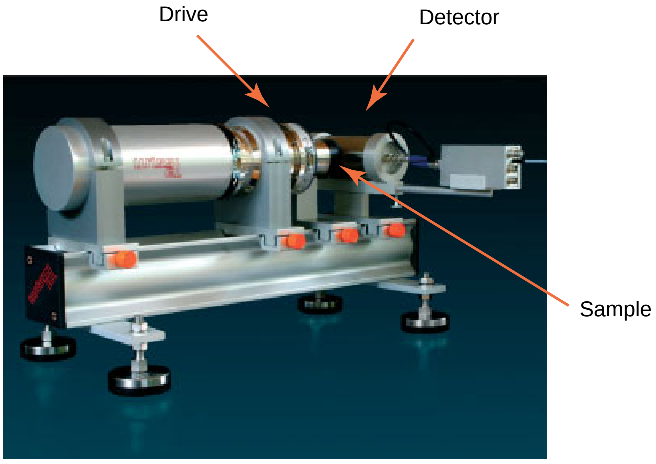

Figure 1 Mössbauer spectrometer with velocity calibrator Mössbauer drive and detector. The sample is placed between drive and detector. For measurements at cryogenic temperatures, the sample is mounted in a cryostat equipped with Mylar or beryllium windows. (Reproduced with permission Wissel Gmbh)

The transmission through an absorber of thickness t_{eff} as a function of the relative velocity V between source and absorber is given by the evaluation of the transmission integral discussed, for example, in Ref. 2. In case of ^{57}Fe Mössbauer spectroscopy for almost all samples which are not enriched in the Mössbauer isotope ^{57}Fe (the natural abundance of ^{57}Fe is 2%), the evaluation of the transmission integral leads to Lorentzian line shape with a minimum linewidth of $0.19\,\text{mm}\,\text{s}^{-1}$, which is twice the natural linewidth of the ^{57}Fe Mössbauer transition. The absorption cross section as a function of source velocity is then given as (with $\sigma_0 = 2.56 \cdot 10^{-18}\,\text{cm}^{-2}$ for ^{57}Fe)

$$\sigma(V) = \frac{\Gamma^2/4}{(V - V_{\text{res}})^2 + (\Gamma/2)^2}\sigma_0 \tag{5}$$

2.2.2 Backscattering Geometry

This technique measures the radiation emitted by the sample after the excited Mössbauer nuclei have returned to their ground state. Backscattered radiation consists of X rays originating from the electron shell, γ-rays from the nucleus, or conversion electrons. Since self absorption prevents γ or X rays from escaping from the inner part of the sample, only a layer at the surface contributes to the backscattered spectrum. The thickness of this layer depends on the energy range and the kind of detected radiation. If one detects γ and/or X rays in backscattering geometry, the escape depth is approximately 10^{-6} m for ^{57}Fe Mössbauer spectroscopy. It is also possible to detect conversion electrons, and in this case the surface layer is even smaller and one can reach monolayer sensitivity. This technique is called *conversion electron Mössbauer spectroscopy* (CEMS). By detecting the

electrons in an energy dispersive fashion, Mössbauer spectra from surface layers of varying thickness can be obtained.

Although chemical and biological samples are routinely measured in transmission geometry, the detection of backscattered Mössbauer radiation may also be considered when thin films of bioinorganic complexes or samples that cannot be moved to a laboratory should be studied. The group of G. Klingelhöver has designed such a transportable miniaturized Mössbauer spectrometer (MIMOS), which contains all necessary mechanical and electronic parts (including a Mössbauer drive and radiation detector) in a box that can be held in one hand (Figure 2). This spectrometer has even been used to perform Mössbauer measurements on the planet Mars.[20,21] Other applications of this spectrometer, which is commercially available, are, for example, the destruction-free examination of artwork and field studies of soil.

2.2.3 Sample Requirements and Pitfalls during Sample Preparation

Metallic foils can be conveniently measured in absorption geometry. An α-Fe foil of 25 µm thickness and an area of $\sim$1 cm^2 is often used as a calibration standard. With such a foil and using a ^{57}Co source with an activity of $\sim$50 mC, it is possible to acquire a decent spectrum at room temperature in less than 1 h.

Powder samples of inorganic iron compounds can be conveniently measured with sample holders that have a sample thickness of $\sim$0.5 mm and an area of $\sim$1 cm^2. This makes a total sample volume of $\sim$50 µL. Some Mössbauer groups prefer to measure pressed pellets, but this decision depends often on history and individual laboratory habits. If sample holders like those displayed in Figure 3 are used, one has to take special care that there are no holes in the sample. This would mean that the γ-rays go through the sample holder

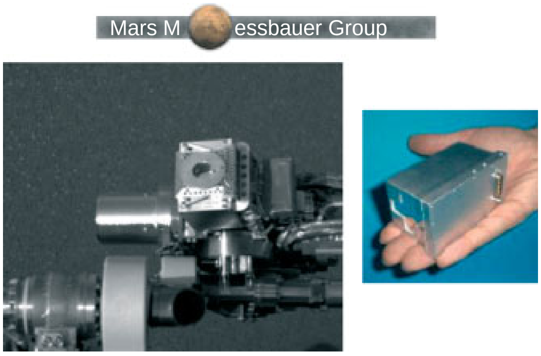

Figure 2 The Mars Exploration Rover Spirit's Mössbauer spectrometer. The hydroxyl containing mineral goethite (FeOOH) has been identified with this spectrometer in the ''Columbia Hills'' of Mars. This finding produced strong evidence for past water activity in the area that Spirit has been exploring.[22] (Reproduced from web page with permission G Klingelhofer)

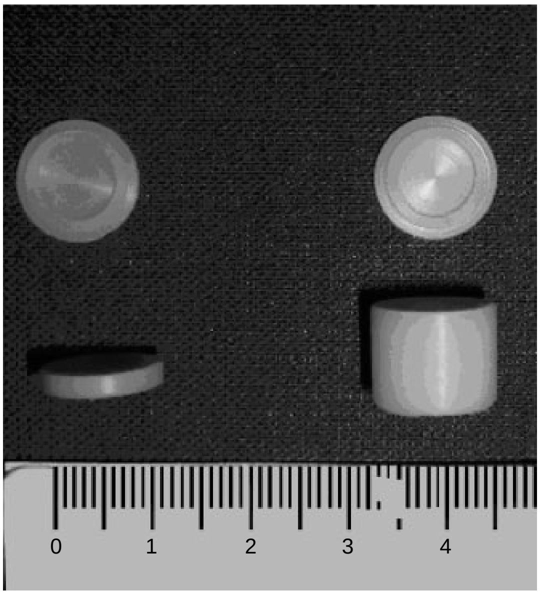

Figure 3 Sample holders made of Delrin© for Mössbauer spectroscopy of powders (left) and frozen solutions (right). The measurement rule has units of centimeters

but do not penetrate sample material and can lead to a drastic decrease in the intensity of the Mössbauer lines. A simple test is to check whether light is shining through the sample holder. This is especially important when only a tiny amount of sample is present. In such a case, it also helps to put a thin sheet of paper in between the sample holder and the sample. If the sample holder is prepared correctly, it is possible that there is only a very weak Mössbauer spectrum at room temperature. In this case, the Mössbauer–Lamb factor f is small and therefore it is advisory to measure at cryogenic temperatures $\leq$120 K. The experience in our laboratory is that measuring a powder sample of an iron compound with an atomic mass of around 500–1000 amu at 77 K in a sample holder made of Delrin©, like those displayed in Figure 3, normally takes not more than 24 h.

For liquid solutions containing iron compounds or proteins, the Mössbauer–Lamb factor goes to zero, and therefore ^{57}Fe Mössbauer spectroscopy on solutions is only possible in the frozen state. Since the natural abundance of ^{57}Fe is only 2%, it is advisable to perform Mössbauer studies on solutions with ^{57}Fe-enriched samples. For protein studies, ^{57}Fe enrichment is essential. Typical sample volumes can range from 0.25–1.0 mL. In some cases, frozen solution studies can be performed down to an ^{57}Fe concentration of $\sim$0.1 mM, but taking a Mössbauer spectrum of such a sample can take weeks depending on the shape of the spectrum and the outcome is uncertain. Therefore, it is strongly recommended that the concentration of ^{57}Fe be at least 1 mM. Samples with ^{57}Fe concentrations of, for example, 10 mM can very conveniently be measured in a couple of hours—such samples the Mössbauer spectroscopists like the most. In any case, for

^{57}Fe-enriched iron proteins a general rule exists: the higher the protein concentration the better.

2.3 Hyperfine Structure of ^{57}Fe Mössbauer Spectra

Mössbauer spectroscopy senses the hyperfine interactions, which are present at the nucleus of the Mössbauer isotope. The electrical monopole interaction causes the isomer shift and the electric quadrupole interaction leads to the quadrupole splitting, which in the case of ^{57}Fe causes a two-line Mössbauer pattern. The magnetic dipole interaction leads to a magnetically split six-line pattern (Figure 4). In the following text, these interactions and their deduction from Mössbauer spectra will be discussed.

2.3.1 *The Isomer Shift δ*

The electric monopole interaction is proportional to the s-electron density at the iron nucleus $|\varphi(0)|^2$ and can be expressed by

$$E = \frac{2}{3}\pi \cdot Z^2 e^2 |\varphi(0)|^2 \cdot \langle r^2 \rangle \qquad (6)$$

with $\langle r^2 \rangle$ being the mean-square nuclear radius and *Ze* being the nuclear charge. In general, source and absorber nuclei are embedded in different matrices, which leads to different *s*-electron densities at the source and the absorber nuclei. As a consequence, the energy of the Mössbauer nuclei in the source and in the absorber have slightly different energy

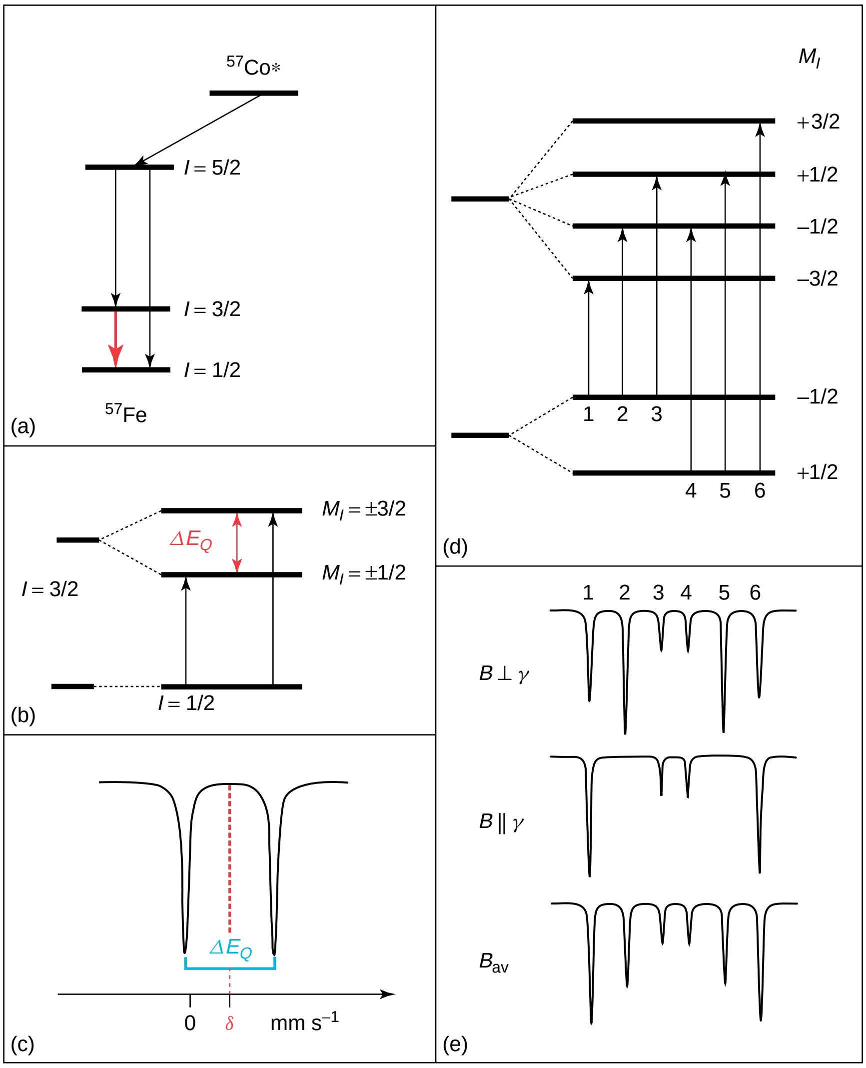

Figure 4 (a) Decay scheme of ^{57}Co. The 14.4-keV transition used for ^{57}Fe Mössbauer spectroscopy is shown in red. (b) Mössbauer transitions without magnetic field. (c) Mössbauer spectrum with quadrupole doublet. (d) Energy levels of the ^{57}Fe states and Mössbauer transitions in the presence of a magnetic field. (e) Magnetic Mössbauer spectra for different orientations of the magnetic field relative to the propagation direction of γ-ray. The quadrupole interaction has been neglected in (d) and (e). shifts of δE_{source} and $\delta E_{\text{absorber}}$. Therefore, the isomer shift δ is expressed as

$$\delta = \delta E_{\text{source}} - \delta E_{\text{absorber}} \tag{7}$$

For a homogenous charge distribution, the isomer shift is given as

$$\delta = \frac{4}{5}\pi Z e^2 R^2 \frac{\delta R}{R}[|\varphi(0)_{\text{absorber}}|^2 - |\varphi(0)_{\text{source}}|^2] \tag{8}$$

with $R = \frac{1}{2}(R_e + R_g)$ and $\delta R = R_e - R_g$, where R_g and R_e are the nuclear radii of the ground and excited state, respectively.

For iron, $\delta R = R_e - R_g$ is negative and therefore a more positive isomer shift implies a lower value of $|\varphi(0)_{\text{absorber}}|^2$. This may be caused either from a decrease in the total s-electron population or from shielding of s electrons by the 3d electrons. The isomer shift is sensitive to the oxidation state of the iron and typical values against metallic iron at 300 K are given in Figure 5.

The experimentally observed isomer shift can be expressed as a sum of the temperature-independent term δ_0 and the temperature-dependent second-order Doppler shift δ_{SOD}

$$\delta = \delta_0 + \delta_{\text{SOD}} \quad \text{with} \quad \delta_{\text{SOD}} = -\frac{E_\gamma \langle v^2 \rangle}{2c^2} \tag{9}$$

with $\langle v^2 \rangle$ denoting the mean-square velocity of the iron atom and c denoting the speed of light.

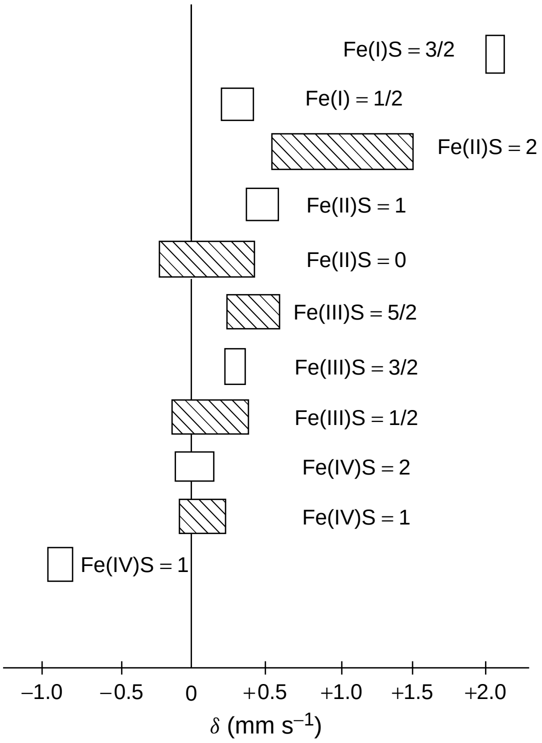

Figure 5 Ranges of isomer shifts observed in various oxidation and spin states of iron (given relative to α-iron at 300 K). Shadowing indicates the most frequently observed configurations. (From Greenwood and Gibb.[3] With kind permission from Springer Science & Business Media)

2.3.2 *The Electric Quadrupole Splitting ΔE_Q*

The electric quadrupole interaction is described by the Hamiltonian

$$\hat{H}(E2) = \frac{eQV_{zz}}{4I(2I-1)}\left[3\hat{I}_z^2 - I(I+1) + \eta(\hat{I}_x^2 - \hat{I}_y^2)\right] \tag{10}$$

with Q being the nuclear quadrupole moment and I being the nuclear spin of the nuclear state. $\hat{I}_x^2$, $\hat{I}_y^2$, and $\hat{I}_z^2$ being the corresponding spin operators. The coordinate frame of the electric field gradient (EFG) tensor $\overleftrightarrow{V}$ is conventionally chosen in such a way that $|V_{xx}| \leq |V_{yy}| \leq |V_{zz}|$. The asymmetry parameter η is generally defined as

$$\eta = \frac{V_{xx} - V_{yy}}{V_{zz}} \tag{11}$$

Since the electric quadrupole moment of the nuclear ground state of iron ^{57}Fe with $I_g = 1/2$ is zero, the quadrupole interaction does not affect the ground state, but splits the first excited nuclear state with $I_e = 3/2$ into two sublevels. As a result, it produces, in the case of ^{57}Fe, a two-line Mössbauer absorption pattern (Figure 4) with a corresponding quadrupole splitting ΔE_Q given by

$$\Delta E_Q = \frac{1}{2}eQV_{zz}\sqrt{1 + \frac{\eta^2}{3}} \tag{12}$$

The largest component of the EFG tensor V_{zz} and the asymmetry parameter η can only be determined separately when a magnetic interaction is present in addition. They reflect the population of the iron 3d orbitals as well as the ligand charges surrounding the iron. For a more detailed description, see Ref. 2 as well as a review on iron porphyrins by Debrunner.[24]

2.3.3 *The Magnetic Splitting B_{hf}*

The third term of the nuclear Hamiltonian contains two contributions. The nuclear Zeeman term couples the magnetic moment of the nucleus to the external magnetic field $\vec{B}_0$. Furthermore, there is a term that describes the interaction of the nuclear spin with the internal magnetic hyperfine field. For paramagnetic samples this is often done in terms of the hyperfine coupling tensor $\overleftrightarrow{A}$, which multiplied by the spin

expectation value $\langle\vec{S}\rangle$ of the corresponding electronic state of, for example, the iron ion, that produces the internal magnetic hyperfine field

$$\vec{B}_{\text{hf}} = -\langle\vec{S}\rangle \cdot \overleftrightarrow{A}/(g_N\mu_N) \tag{13}$$

Therefore the hyperfine coupling $\overleftrightarrow{A}$ tensor is often given in units of Tesla ($\overleftrightarrow{A}/g_N\mu_N$; 1T $\hat{=}$1.36 MHz for ^{57}Fe). The magnetic Hamiltonian is given as

$$\hat{H}(M1) = \langle\vec{S}\rangle \cdot \overleftrightarrow{A} \cdot \vec{I} - g_N\mu_N\vec{B}_0 \cdot \vec{I} = -g_N\mu_N(\vec{B}_{\text{hf}} + \vec{B}_0) \cdot \vec{I} \tag{14}$$

where g_N is the nuclear g factor and μ_N is the nuclear magneton. If the internal hyperfine field is zero as is the case of diamagnetic ions, the energy eigenvalues of a nuclear spin I in a magnetic field B_0 are given as

$$E_M(m) = -mg_N\mu_N B_0 \tag{15}$$

This leads to the energy differences between nuclear ground and excited state

$$\Delta E_M(m_e; m_g) = B_0(m_e g_N^e \mu_N - m_g g_N^g \mu_N) \tag{16}$$

For ^{57}Fe with a ground state nuclear spin of $I_g = 1/2$ and $I_e = 3/2$ for the excited state and taking into account the dipole selection rules $\Delta M = 0, \pm 1$, one gets six transitions of different energy, which means a six-line pattern as shown in Figure 4.

For most cases, the internal field is much higher than the external magnetic fields. Metallic iron for example exhibits a magnetic hyperfine field (−33 T at 300 K) that is oriented opposite to the magnetization of the sample. The internal hyperfine field contains particularly valuable information about the electronic configuration of the iron atom and is determined by four contributions:

$$\vec{B}_{\text{hf}} = \vec{B}_{\text{fc}} + \vec{B}_{\text{ls}} + \vec{B}_{\text{dd}} + \vec{B}_{\text{latt}} \tag{17}$$

$\vec{B}_{\text{fc}}$ is due to the Fermi-contact interaction, which is caused by the core polarization of the s-electron density at the nucleus. The sign of $\vec{B}_{\text{fc}}$ is negative, which can qualitatively be rationalized in the following way: in the case of iron, the unpaired 3d electrons attract the spin parallel s electrons via exchange interaction. This leaves an excess of antiparallel s-electron spin density at the nucleus, which leads to the negative sign of $\vec{B}_{\text{fc}}$. $\vec{B}_{\text{fc}}$ dominates, for instance, in high-spin ferric Fe(III), whereas low-spin ferric iron shows a considerable contribution of $\vec{B}_{\text{ls}}$ due to spin-orbit interaction. The dipole field $\vec{B}_{\text{dd}}$ originating from the electron shell as well as lattice contributions $\vec{B}_{\text{latt}}$ are normally of the order of 1 T and therefore negligible in most cases.

2.3.4 *The Spin Hamiltonian Formalism: Determination of Zero-Field Splitting D and Rhombicity E/D of Paramagnetic Iron Centers by Mössbauer Spectroscopy*

Mössbauer spectroscopy can also be used to obtain information about fine structure parameters like zero-field splitting D and rhombicity parameter E/D. The zero-field splitting is a second-order effect, which can be classically visualized as resulting from the circular currents generated in the atomic shell by the electron spin. In Section 3.10.5, we describe how D and E/D can be calculated.

The spin Hamiltonian formalism, which is also needed to interpret, for example, electron paramagnetic resonance or magnetic circular dichroism spectra (*see* ***Magnetic Circular Dichroism (MCD) Spectroscopy***), was first applied to the interpretation of magnetic Mössbauer spectra by Wickmann, Klein and Shirley[25] and was implemented into a computer program by Münck *et al.* in the early 1970s.[26] For most studies of mononuclear iron centers with electron spin quantum number S, the following electronic Hamiltonian is used:

$$\hat{H}_{\text{fs}} = D\left[\hat{S}_z^2 - \frac{1}{3}S(S+1) + \frac{E}{D}(\hat{S}_x^2 - \hat{S}_y^2)\right] + \mu_B\vec{S}\overleftrightarrow{g}\vec{B} \tag{18}$$

Here $\hat{S}_x^2$, $\hat{S}_y^2$, $\hat{S}_z^2$, and $\vec{S}$ are the corresponding quantum mechanical spin operators, $\vec{B}$ is the external magnetic field, and $\overleftrightarrow{g}$ denotes the electronic g tensor. After diagonalization of equation (18) in the spin space, the spin expectation values $\langle\vec{S}_i\rangle$ can be calculated for every fine structure sublevel i. The fine structure levels are separated by energy gaps, which are a function of D, E/D, and the external field $\vec{B}$. The energy gaps between the fine structure sublevels are of the order of some wave numbers. According to equation (13), the spin expectation values $\langle\vec{S}_i\rangle$ lead to a characteristic magnetic hyperfine field B_{hf} at the iron nucleus, which manifests itself in a magnetic splitting of the spectrum. In order to simulate spectra of frozen solutions or powder samples by the spin Hamiltonian formalism, spectra for all orientations of the molecule with respect to the external field have to be calculated and summed up (powder average). Details of this procedure will not be discussed here, but can be found in Refs. 7, 8, 11, and 24. Nowadays several program packages are available. We are using the package VINDA, which runs under Windows environments and is available free of charge via the web site of Palle Gunnlaugson.[27] While working at the laboratory of Prof. Alfred X. Trautwein, Dr. Gunnlaugson had included the code that had been used at that time in the Trautwein group in VINDA. Some Mössbauer groups use the package WMOSS, which is distributed by Web Research Co.,[28] and others use their own codes. Unfortunately, the broadly used software package NORMOS does not have the option to evaluate paramagnetic Mössbauer spectra by full diagonalization of the

spin Hamiltonian matrix to date, but this might be included in the future.

3 APPLICATIONS

3.1 Metallic Iron, Iron Nanoparticles, and Thin Films

3.1.1 Metallic Iron

The Mössbauer spectrum of metallic α-iron at room temperature is used as a velocity calibration standard in almost every Mössbauer laboratory. Therefore most isomer shift values published to date are given relative to metallic iron at room temperature.[a] The ferromagnetism of α-Fe is caused by unpaired spin density in its electronic band structure. The unpaired electronic spin density is able to couple to the nucleus via magnetic hyperfine interactions. This leads to a magnetic six-line pattern which reflects a very high magnetic hyperfine field of $B_{\rm hf} = -33\,\rm T$ at the iron nucleus. In the case of metallic iron and iron-containing alloys as well as minerals, the interaction between electron spin $\vec{S}$ and nuclear spin $\vec{I}$ proceeds predominantly via isotropic Fermi-contact interaction. Therefore, the magnetic hyperfine field at the iron nucleus $B_{\rm hf}$ is proportional to the magnetization of the sample and temperature-dependent measurements of $B_{\rm hf}$ can be regarded as complementary to magnetization measurements. The determination of the temperature dependence of the magnetic hyperfine field of α-Fe and its saturation magnetization (Figure 6) was one of the very first applications of ^{57}Fe-Mössbauer spectroscopy.

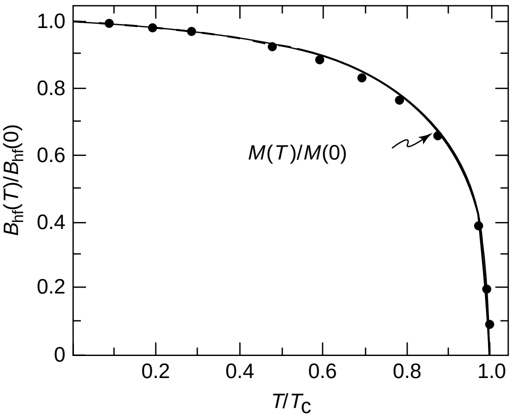

Figure 6 Temperature dependence of the magnetic hyperfine field $B_{\rm hf}(T)$ of α-Fe as a function of $T/T_{\rm c}$ with $T_{\rm c}$ being the Curie Temperature. Note that $B_{\rm hf}(T)$ is scaled with the value extrapolated to 0 K which is denoted as $B_{\rm hf}(0)$. The dots represent Mössbauer data and the solid line represents saturation magnetization data. (Redrawn after Greenwood and Gibb.[3] With kind permission from Springer Science & Business Media)

Figure 6 shows that the magnetic hyperfine field does indeed scale very nicely with data from magnetic measurements. It should be noted that such measurements can be performed on any magnetic material to investigate magnetic phase transitions no matter whether the iron atom is present in an alloy, in an oxide or as an impurity in normally non-iron-containing materials. This is always true if the Fermi-contact interaction is the dominant contribution to the magnetic hyperfine field, which holds for metallic iron and ferric high-spin iron having $S = 5/2$.

3.1.2 Iron Nanoparticles

If the dimension of a metallic α-Fe-particle (or any ferro-, antiferro-, or ferrimagnetic material) reaches the dimensions of magnetic domains, the particle turns into a single-domain particle. Owing to thermal excitation, the magnetization of the single-domain particle can relax between the axes of easy magnetization. Such a magnetic behavior of small single-domain particles is called *superparamagnetic*. If the relaxation rate of a superparamagnetic particle is fast with respect to the lifetime of the excited state of the ^{57}Fe nucleus ($\sim 10^{-7}$ s), the nucleus sees on average no magnetic field and only a quadrupole doublet occurs.[12] This is often the case if small nanoparticles of metallic iron or iron oxides are measured at room temperature. In order to unambiguously identify the magnetic phase of these systems, measurements at cryogenic temperatures are helpful. By lowering the temperature, the relaxation rate of the superparamagnetic particles is slowed down and a magnetically split pattern occurs (Figure 7).[29]

In the simplest case of uniaxial relaxation, a relaxation process where the magnetization flips around an angle of 180°, the relaxation rate of a single-domain particle with the saturation magnetic moment $\vec{\mu}$ in a magnetic field $\vec{B}$ at a given temperature T is expressed as

$$\nu = \nu_{\rm o} \cdot \exp\left(-\frac{KV + \vec{\mu} \cdot \vec{B}}{k_{\rm B}T}\right) \qquad (19)$$

The energy barrier $E_a = KV$ is called the *anisotropy energy* and describes the strength of the pinning of the single-domain particle magnetization. The anisotropy energy KV can be determined by analyzing temperature-dependent Mössbauer measurements in zero magnetic field with suitable relaxation models (Figure 8).[30] A simpler approach is the determination of the superparamagnetic blocking temperature $T_{\rm B}$. For this temperature one assumes $k_{\rm B}T_{\rm B} \cong KV$. By definition the blocking temperature of an ensemble of superparamagnetic particles is the temperature where half of the spectral area of the Mössbauer spectrum shows magnetic splitting and the other half of the spectrum shows a doublet or a single line depending on the size of the quadrupole splitting. An approach to determine $T_{\rm B}$ is to fit the temperature-dependent spectra with at least two components: a simple quadrupole doublet with Lorentzian line shape and a spectrum

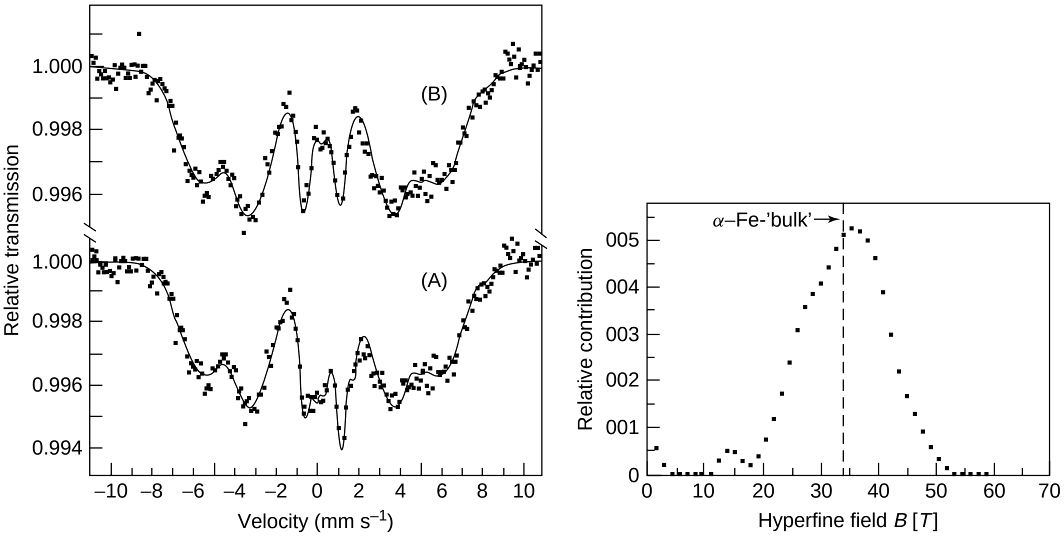

Figure 7 Mössbauer spectrum of nanometer-sized metallic iron particles in zeolite NaX obtained at $T = 4.2\,\mathrm{K}$ before (A) and after (B) subtraction of two Fe(II) contributions with $\delta_1 = 0.75\,\mathrm{mm\,s^{-1}}$ and $\Delta E_{Q1} = 0.8\,\mathrm{mm\,s^{-1}}$ (5% relative contribution) and $\delta_2 = 0.85\,\mathrm{mm\,s^{-1}}$ and $\Delta E_{Q2} = 1.85\,\mathrm{mm\,s^{-1}}$ (6% relative contribution). The analysis of the magnetic hyperfine field distribution identifies metallic α-Fe-nanoparticles. (From Schünemann, Winkler, Butzlaff and Trautwein.[29] With kind permission from Springer Science & Business Media)

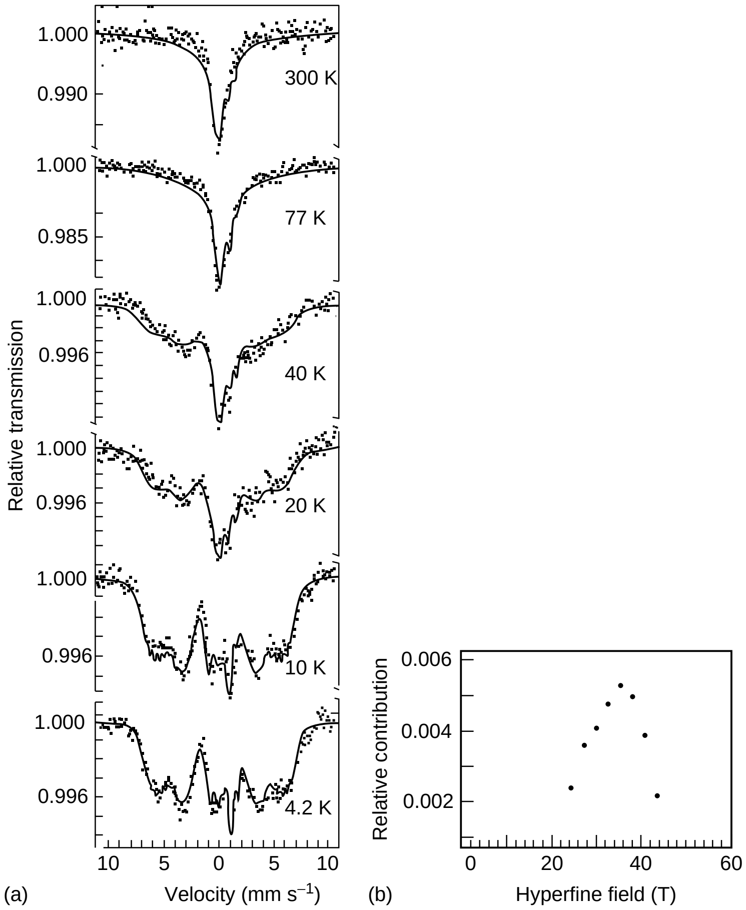

Figure 8 Temperature-dependent Mössbauer spectra of metallic iron nanoparticles in zeolite NaX (a). The superparamagnetic blocking temperature T_c is around 40 K. The solid lines have been calculated by a relaxation formalism[30] assuming a hyperfine field distribution as shown in (b) with a bimodal size distribution of metallic iron particles. (Reprinted from Schünemann, Winkler, Butzlaff and Trautwein.[29] With kind permission from Springer Science & Business Media)

generated by a hyperfine field distribution that represents the magnetically blocked particles. Fitting of Mössbauer spectra with hyperfine field distributions has been pioneered by Le Caer *et al.*[31] Nowadays the software packages NORMOS and VINDA allow us to calculate hyperfine field distributions.[27]

As an example, temperature-dependent Mössbauer spectra of nanometer-sized metallic iron particles prepared by thermal decomposition of $Fe(CO)_5$ on a zeolitic support are shown in Figure 8(a). The analysis of the 4.2 K spectrum by a distribution of hyperfine fields (Figure 7) according to the method of Le Caer *et al.*[31] shows that 90% of the iron is in a magnetically ordered state, with the maximum of the distribution corresponding to metallic iron, whereas 10% remained paramagnetic Fe(II). The spectra could be simulated by an algorithm for uniaxial relaxation[30] assuming two particle fractions with different anisotropy energies and different isomer shifts (0.1 and $0.25\,\mathrm{mm\,s^{-1}}$ at 4.2 K for the larger and smaller particle fraction, respectively) but with the same hyperfine field distribution (Figure 8b). This analysis has been motivated by ferromagnetic resonance results.[32] The anisotropy energies $E_{ai} = K_i V_i (i = 1, 2)$ were determined from the temperature-dependent relaxation rates $\nu(T)$ by assuming the Neel equation (equation 19). Values of $(2.7 \pm 0.4) \cdot 10^{-22}$ J and $(9.8 \pm 1.5) \cdot 10^{-22}$ J were obtained. Using the values of $K_1 = (1.45 \pm 0.2) \cdot 10^5\,\mathrm{J\,m^{-3}}$ and $K_2 = (1.21 \pm 0.18) \cdot 10^5\,\mathrm{J\,m^{-3}}$ obtained from ferromagnetic resonance measurements one obtains, under the assumption that the particles are spherical and have the saturation magnetization of the bulk α-Fe, the diameters of $d_1 = (1.53 \pm 0.15)$ nm and $d_2 = (2.50 \pm 0.25)$ nm. Obviously, one fraction of particles is in the large zeolite cavities, which have a diameter of 1.3 nm. The other fraction of particles is located in defect sites of the zeolite lattice and/or on the surface of the microcrystalline zeolite support.

Another very elegant method to determine the magnetic moment μ of superparamagnetic particles involves Mössbauer spectroscopic measurements above the blocking temperature T_c in varying external magnetic fields, a method that had been first introduced by Steen Morup.[12] In this case, the magnetic energy of the particles μB is much larger than the anisotropy energy, so $\mu B \gg KV$ holds. The observed magnetic hyperfine field $\vec{B}_{obs}$ at the iron nucleus is expressed as

$$\vec{B}_{obs} = \vec{B}_0 L\left(\frac{\mu B}{k_B T}\right) + \vec{B} \qquad (20)$$

Here $\vec{B}_0$ is the saturation hyperfine field, L is the Langevin function, and k_B is the Boltzmann constant. If the condition $\mu B / k_B T \gg 1$ is fulfilled (e.g., for particles having particle magnetizations of 1000–10 000 μ_B and external fields B on the order of 1 T as well as temperatures around 80 K), equation (20) simplifies to

$$|\vec{B}_{obs} - \vec{B}| = B_0 \left(1 - \frac{k_B T}{\mu B}\right) \qquad (21)$$

Figure 9 shows a plot of $|\vec{B}_{obs} - \vec{B}|$ against $1/B$ for metallic α-Fe particles in zeolite NaX.[32] From the slope of the curve, a mean magnetic moment of $\mu = 916 \pm 180\,\mu_B$ has been obtained. With the saturation magnetization of α-Fe and assuming spherical particle sizes with body-centered cubic structure, one obtains a mean diameter of $d = 2.1 \pm 0.1$ nm.

3.1.3 Thin Films

Some bioinorganic chemists may also be interested in the characterization of bioinorganic or inorganic complexes on surfaces or in thin films. Such studies are rare to date, but we refer to reviews by Shinjo and Przybylski, which deal with the characterization of iron monolayers and multilayers by CEMS.[13,14] During the last two decades Mössbauer spectroscopy with synchrotron radiation has also been developed, which gives information about the magnetization of thin iron films with a sensitivity down to the monolayer range.[15]

3.2 Covalent Iron Compounds

Iron organometallic compounds are diamagnetic and highly covalent. The parent compounds of this class of molecular compounds are $Fe(CO)_5$ and the cyclopentadienyl complex ferrocene $(\pi\text{-}C_5H_5)_2Fe$. Since no internal hyperfine field is present owing to the diamagnetism of the compounds, indications of the type of sterochemistry and bonding can be inferred only from their isomer shifts and quadrupole splittings. Their isomer shifts range from $-0.18\,\mathrm{mm\,s^{-1}}$ to $+0.54\,\mathrm{mm\,s^{-1}}$ and the quadrupole splittings from 0 up to $2.8\,\mathrm{mm\,s^{-1}}$.[3]

Since iron carbonyls are not only involved in chemical synthesis (of e.g., iron nanoparticles) but also can occur in heterogenous iron catalysts during reaction conditions (e.g., Fischer–Tropsch reactions), we will briefly discuss the Mössbauer parameters of this class of compounds.

Iron pentacarbonyl has $\delta = -0.35\,\mathrm{mm\,s^{-1}}$, which reflects the strong covalency of the Fe–CO bonds. The high value of the quadrupole splitting ($\Delta E_Q = 2.57\,\mathrm{mm\,s^{-1}}$) is explained by the noncubic iron site geometry. The $Fe(CO)_4^{2-}$ anion has a perfect tetrahedral coordination of CO and therefore no detectable quadrupole splitting is observed in $Na_2[Fe(CO)_4)]$. The isomer shift of this compound is $\delta = -0.45\,\mathrm{mm\,s^{-1}}$, which reflects the empirical rule that decreasing the coordination number of the iron center by one leads to a decrease of the isomer shift by $\Delta\delta \approx 0.1\,\mathrm{mm\,s^{-1}}$. $Fe_2(CO)_9$ has axial symmetry with three bridging CO groups and an Fe–Fe bond. The two iron sites are equivalent and

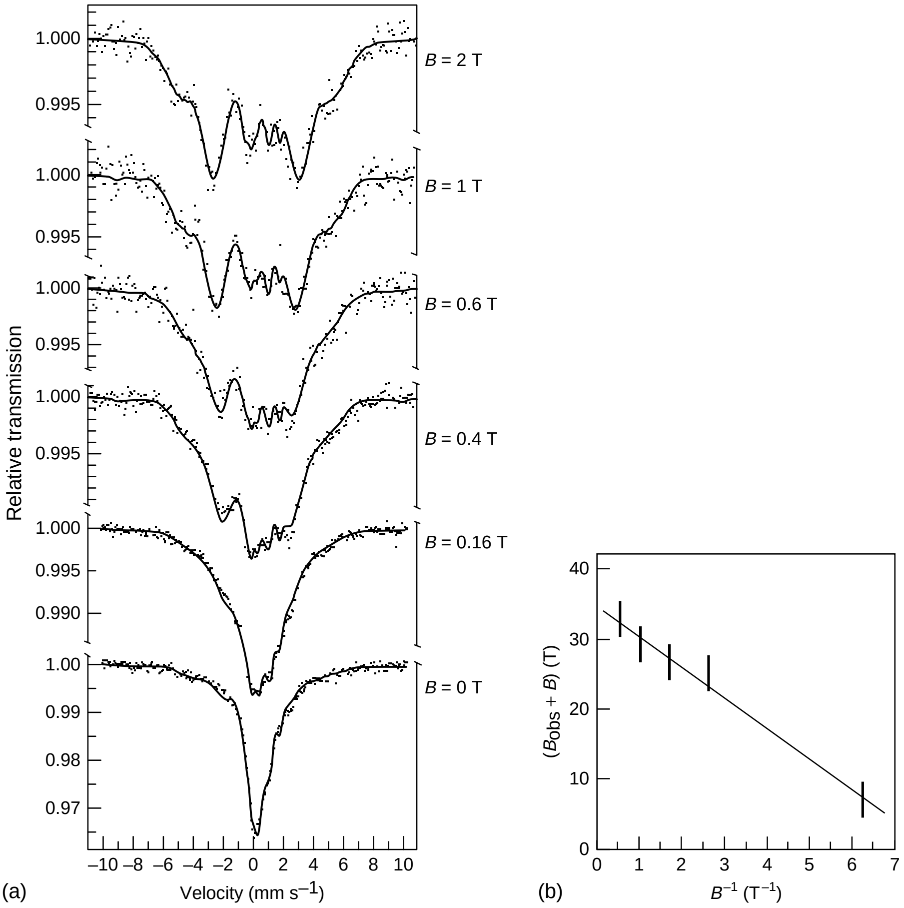

Figure 9 Mössbauer spectra of metallic iron nanoparticles in zeolite NaX taken at T = 77 K and different external fields (a). The analysis of the field dependence of the magnetic hyperfine field according to equation (21) yields a mean particle size of $d = 2.1 \pm 0.1$ nm (b). (Reprinted from Schünemann[32])

Table 1 Isomer shifts δ and quadrupole splittings ΔE_Q of some selected iron carbonyls. These compounds are diamagnetic and therefore do not have an internal magnetic hyperfine field. (From Greenwood and Gibb.[3] With kind permission from Springer Science & Business Media)

Compound	δ [mm s^{-1}]	ΔE_Q [mm s^{-1}]
$Fe(CO)_5$	−0.35	2.57
$Fe_2(CO)_9$	−0.42	0.42
$Fe_3(CO)_{12}$	−0.15	1.13(64%)
	−0.21	0.13(33%)
$Na_2[Fe(CO)_4]$	−0.45	0

the axial symmetry leads to a low quadrupole splitting of $\Delta E_Q = 0.42\,\mathrm{mm\,s^{-1}}$ (Table1).

The Mössbauer spectrum of $Fe_3(CO)_{12}$ shows two distinct iron sites, with a relative ratio of 2:1. In fact, this result led to the refinement of a crystal structure that had reported three equivalent iron sites. Although this happened in the early days of Mössbauer spectroscopy, that is, the 1960s, it is an example of how Mössbauer spectroscopy can help refine crystal structure data. Later the correct structure of $Fe_3(CO)_{12}$ had also been determined by X-ray diffraction and can be pictured as a Fe_2 $(CO)_9$ where a CO-bridge is replaced by a $Fe(CO)_4$ group.[3]

3.3 Iron(I) Compounds

Iron(I) compounds are quite rare. Münck *et al.* have recently reported a Mössbauer study of the mononuclear low-coordinate iron(I) compound LFe(HCCPh).[33] They show by a combined Mössbauer and electron paramagnetic resonance (EPR) study that the complex has a high-spin $3d^7$ configuration ($S = 3/2$) with near orbital degeneracy. The complex shows a sharp magnetic six-line pattern at 4.2 K and an external field of 50 mT. It exhibits an extraordinarily high hyperfine field of $B_{hf} = +68.8$ T. The positive sign of B_{hf} has been determined from the observation that the magnetic splitting increases with increasing external fields. This behavior is completely different from the situation of most iron compounds and shows

that, in the case of LFe(HCCPh), B_{hf} is clearly dominated by orbital contributions.

3.4 Iron(II) Compounds

3.4.1 Low-Spin Iron(II)

Low-spin iron(II) ions are d^6 with no unpaired electrons and are diamagnetic. The t_{2g} subshell is fully occupied, which leads to a symmetric charge distribution around the iron nucleus. Therefore, the electronic contribution to the electric field gradient should diminish and as a consequence low-spin iron(II) complexes are expected to have a very small or even undetectable quadrupole splitting. However, this is not always the case. Note that some low-spin ferrous heme proteins as well as heme model complexes have $\Delta E_Q > 1\,\mathrm{mm\,s^{-1}}$. For example, for the heme model complex [TMPFe(II)(1,2-Me_2Im)$_2$], $\Delta E_Q = 1.73\,\mathrm{mm\,s^{-1}}$ has been reported.[34]

Because the shielding of the nucleus by the fully occupied t_{2g} subshell of low-spin iron(II) is less effective than in the case of high-spin iron(II) compounds (*see* Section 3.4.2), the charge density at the nucleus caused by the s electrons is increased compared to high-spin iron(II). This leads to isomer shifts ranging from $-0.258\,\mathrm{mm\,s^{-1}}$ at 298 K for sodium nitroprusside $Na_2[Fe(CN)_5NO] \cdot 2H_2O$ up to $0.31\,\mathrm{mm\,s^{-1}}$ for $[Fe(phen)_3](ClO_4)_2$ or even $0.46\,\mathrm{mm\,s^{-1}}$ for several ferrous low-spin heme models and cytochromes.[34]

The very low isomer shift of $Na_2[Fe(CN)_5NO] \cdot 2H_2O$, a compound that has been often used as calibration standard, can be understood on the basis of the strong covalent effects present in the Fe–NO bond. The ground state of the iron in the nitroprusside molecules is $(d_{xz}, d_{yz})^4(d_{xy})^2$. The electrons in the orbitals with (d_{xz}, d_{yz}) character are delocalized by back donation to the 2p orbitals of the NO ligand. In addition, as in the cyanides shown in Table 2, there is also some slight delocalization from the d_{xy} orbital to the equatorial cyanides. Since there is also considerable 4s population, the electron density at the nucleus is much higher than usual, which manifests itself in the unusually low isomer shift.[3]

For the identification of low-spin iron(II), a low value of the quadrupole splitting is generally not enough. As an example, the Mössbauer spectrum of the reduced low-spin ferrous form of cytochrome c_{552} is shown in Figure 10. The reduced heme iron has $\delta = 0.46\,\mathrm{mm\,s^{-1}}$ and $\Delta E_Q = +1.30\,\mathrm{mm\,s^{-1}}$.[35] These values are characteristic for the low-spin ferrous forms of several electron transfer heme proteins like cytochromes *c* and *b*.[34]

Measurements at 4.2 K and large external fields are the experimental choices to unambiguously identify diamagnetic iron species. A diamagnetic iron species exhibits a splitting of the Mössbauer spectrum in a high-field experiment, which is due only to the external field since the internal magnetic hyperfine field at the iron nucleus is zero. The Mössbauer spectrum of ^{57}Fe-enriched cytochrome c_{552} obtained at 7 T is displayed in Figure 10(b). Note that the spectrum originates from a frozen protein solution. Therefore, the distribution of the molecules with respect to the direction of the external field is random (or powderlike) and hence the distribution of the electric field gradient tensor of the iron centers is also random. This fact has to be regarded if one wants to simulate high-field Mössbauer spectra of diamagnetic complexes. Such a situation can conveniently be handled in spin Hamiltonian simulations by setting all elements of the hyperfine coupling tensor $\overleftrightarrow{A}$ to zero for an arbitrary spin S.

3.4.2 High-Spin Iron(II) Compounds

High-spin iron(II) compounds with the iron in the $S = 2$ state have rather high isomer shifts up to $1.3\,\mathrm{mm\,s^{-1}}$ at room temperature (Table 3), depending on the coordination

Table 2 Mössbauer parameters of some six-coordinate low-spin Fe(II) ions. Note that the isomer shift decreases if the Fe–ligand bonds become more covalent in character. Mössbauer parameters for the cyanide complexes, as well as those for the phenanthroline complex, were taken from Greenwood and Gibb,[3] which the reader may consult for further references

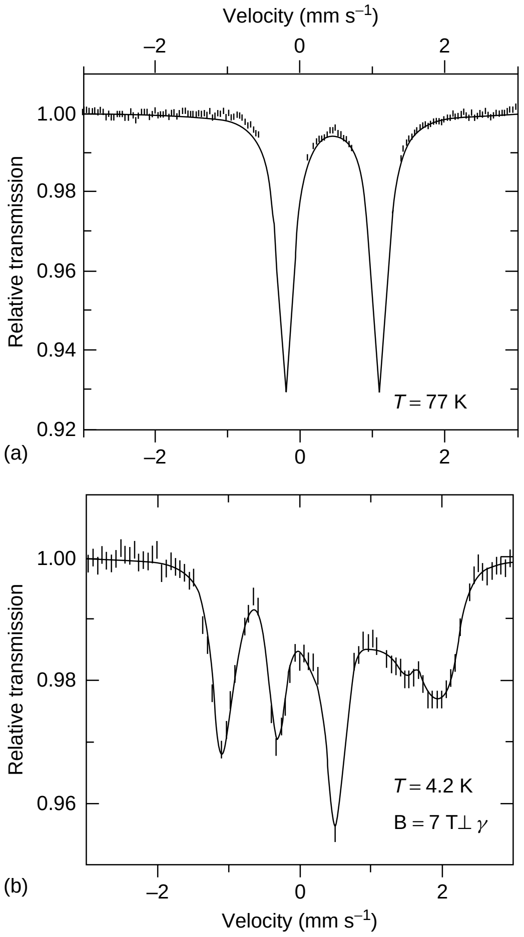

Figure 10 Mössbauer spectra of ferrous cytochrome c_{552} (a) Mössbauer spectrum of reduced cytochrome c_{552} obtained at $T = 77\,\mathrm{K}$. The solid line represents a Lorentzian fit with $\delta = 0.46\,\mathrm{mm\,s^{-1}}$, $\Delta E_Q = 1.30\,\mathrm{mm\,s^{-1}}$, and $\Gamma = 0.27\,\mathrm{mm\,s^{-1}}$. (b) Field-dependent Mössbauer spectrum of reduced cytochrome c_{552} obtained at $T = 4.2\,\mathrm{K}$ in a field of 7 T perpendicular to the γ beam. The shape of the spectrum is characteristic of a diamagnetic powder or frozen solution sample with a positive sign of ΔE_Q. For a negative ΔE_Q, a reversed pattern would be observed. The solid line corresponds to a simulation with $S = 0$, $\delta = 0.46\,\mathrm{mm\,s^{-1}}$, $\Delta E_Q = 1.30\,\mathrm{mm\,s^{-1}}$, $\eta = 0.3$, and $\Gamma = 0.24\,\mathrm{mm\,s^{-1}}$. (From Zoppellaro, Teschner, Harbitz, Schünemann, Karlsen, Arciero, Ciurli, Trautwein, Hooper and Andersson.[35] Reprinted by permission of Wiley-VCH)[35]

number and the type of ligand. The high isomer shift is caused by the shielding of the outer s-electron charge density (mostly of 2s type) by the inner 3d electron charge density. In addition, the spin-down electron in the doubly occupied 3d orbital contributes significantly to the EFG. This leads to the fact that most high-spin iron(II) compounds have quadrupole splittings of around 2–3 $\mathrm{mm\,s^{-1}}$.

The identification of high-spin iron(II) is one of the most straightforward problems to solve with Mössbauer spectroscopy. As an example, we will discuss the native form of human tyrosine hydroxylase (hTH), which catalyzes the rate-limiting reaction in the biosynthesis of dopamine, noradrenaline, and adrenaline. The enzyme contains a nonheme iron center that is required for enzymatic function. All isoforms of hTH exhibit a quadrupole doublet with isomer shift $\delta(1.6–77\,\mathrm{K}) = 1.26–1.24\,\mathrm{mm\,s^{-1}}$ and temperature-independent quadrupole splitting $\Delta E_Q = 2.68\,\mathrm{mm\,s^{-1}}$.[37] These values are characteristic of high-spin Fe(II) in six-coordination with oxygen or nitrogen ligands. Shorter bond lengths in four-coordination with respect to six-coordination, as well as the presence of covalent ligands like sulfur as opposed to oxygen or nitrogen, would increase the s density at the Fe nucleus. This in turn would reduce the isomer shift. For four-coordination with ionic ligands, one would expect isomer shifts $\leq 1\,\mathrm{mm\,s^{-1}}$ below 77 K while alternatively six-coordination yields isomer shifts $> 1.2\,\mathrm{mm\,s^{-1}}$. The empirical rule that reduction of the coordination number by one leads to a decrease of the isomer shift by an amount of $\sim$0.1 $\mathrm{mm\,s^{-1}}$ as discussed in Section 3.2 for covalent iron(0) compounds also holds here. In the same way, a substitution of one oxygen or nitrogen by one sulfur ligand would reduce the isomer shift by about 0.1 $\mathrm{mm\,s^{-1}}$.

An X-ray crystallography study, on the related enzyme from rat reported a five-coordinate iron center. Since nuclear magnetic resonance (NMR) studies indicated the presence of a water molecule loosely bound to the iron, a Mössbauer study of dehydrated hTH was undertaken. Indeed, it has been found that 63% of the spectral area can be attributed to five-coordinate high-spin Fe(II) ($\delta = 1.07\,\mathrm{mm\,s^{-1}}$). After rehydration of hTH the spectroscopic changes were completely reversed.[38] The X-ray absorption spectra (*see* ***X-Ray Absorption Spectroscopy***) of hTH corroborate the findings derived from the Mössbauer spectra. Thus, it was concluded that the active-site iron can exist in different coordination states, which can be interconverted depending on the hydration state of the protein, indicating the presence or absence of a water molecule as a coordinating ligand to the iron.

As a second example, Mössbauer spectra of a rubredoxin-type protein mutant from *Pyrococcus abyssi* are shown in Figure 11. This protein contains a tetrahedral sulfur-coordinated high-spin ferrous site. Owing to the covalent character of the Fe–S bond, an isomer shift of $\sim$0.70 $\mathrm{mm\,s^{-1}}$ is observed at 4.2 K. This value is characteristic for almost all tetrahedral sulfur-coordinated high-spin ferrous sites.

Although the high-spin ferrous site with $S = 2$ is paramagnetic, no magnetic splitting is observed at 4.2 K. The reason is that the ground state spin expectation value of ions having integer spin in small magnetic fields goes to zero. The application of a moderate field of 1 T induces significant spin expectation values and therefore a magnetically split pattern is observed (Figure 11).[39]

The spin Hamiltonian analysis of the field-dependent Mössbauer spectra has been performed by a simultaneous fitting procedure of all spectra displayed in

Table 3 Mössbauer parameters of some high-spin Fe(II) compounds (taken from Greenwood and Gibb[3]) in comparison to the ferrous high-spin site of human tyrosine hydroxylase. Note the decrease in isomer shift with decreasing coordination number

Compound	Iron coordination	δ [mm s^{-1}]	ΔE_Q [mm s^{-1}]	T [K]
Human tyrosine hydroxylase[37]	6N and/or O	1.26	2.68	4.2
Dehydrated human tyrosine hydroxylase[38]	5N and/or O	1.07	2.89	77

Figure 11. The best fit has been found for $\delta = 0.7 \pm 0.01\,\text{mm s}^{-1}$, $\Delta E_Q = -3.25 \pm 0.01\,\text{mm s}^{-1}$, $\overleftrightarrow{g} = (2.11, 2.19, 2.00)$, $\overleftrightarrow{A}/g_N\mu_N = (-45, 10, 19)\,\text{T}$, $\eta = 0.74 \pm 0.1$, $D = 7.2 \pm 0.5\,\text{cm}^{-1}$, and $E/D = 0.16 \pm 0.02$. The zero-field splitting parameter $D = 7.2 \pm 0.5\,\text{cm}^{-1}$ is comparable to that found for rubredoxin from *Clostridium pasteurianum* ($D = 7.6\,\text{cm}^{-1}$).[40] Surprisingly, the rhombicity parameter $E/D = 0.16 \pm 0.02$ differs somewhat from that of rubredoxin from *C. pasteurianum* ($E/D = 0.28$). The hyperfine coupling tensor has been determined to be $\overleftrightarrow{A} = (-14.5, -9.2, -27.5)\,\text{T}$. The anisotropy of the hyperfine coupling tensor is caused by spin-orbit contributions to the internal magnetic hyperfine field.

It should be noted here that a correct determination of fine and hyperfine structure parameters should be done in such a way that spectra taken under different experimental conditions (variable external fields and/or variable temperatures) are reproduced with the same parameter set. This reproduction of the experimental data is often a bit less accurate than when one fits only a single experimental spectrum. However, owing to the many parameters involved in the simulation it makes absolutely no sense to deduce a complete spin Hamiltonian parameter set of a paramagnetic iron center from just one Mössbauer spectrum.

3.5 Iron(III) Compounds

3.5.1 Low-Spin Iron(III) Compounds

Low-spin iron(III) ions have an electron hole in the t_{2g} orbitals. Therefore, these centers have $S = 1/2$ and spin-orbit interaction contributes considerably to the magnetic hyperfine field. Low-spin iron(III) compounds in solution always show a rather complicated magnetic Mössbauer pattern at temperatures around 4.2 K and low external fields, which means that the relaxation rate of these centers is lower than the nuclear precession rate of $\sim 10^{-7}$ s. Sometimes a magnetic splitting is observed even at 77 K. Therefore, in order to pin down δ and ΔE_Q, it is advisory to measure between 100 and 200 K, where the electronic relaxation rate becomes fast with respect to the Mössbauer time window and the limit of fast relaxation applies. Spin–spin interaction in microcrystals can also enhance the electronic relaxation rate and therefore some low-spin iron(III) compounds show quadrupole doublets even at 4.2 K.[41]

Since the iron 4s orbitals are involved in covalent bonding with the ligands, the s-electron density at the iron nucleus is increased compared to high-spin iron(II) compounds. This is even more true if π-accepting ligands like CN^- are present. Therefore the difference in isomer shift between low-spin iron(II) and low-spin iron(III) is much less pronounced than between high-spin iron(II) and high-spin iron(III).

As an example of how to determine the electronic ground state of a low-spin iron(III) compound, we present work on the ferric low-spin heme complex $[TPPFe(NH_2PzH)_2]Cl$, which has been shown to have a $(d_{xy})^2(d_{xz}, d_{yz})^3$ electronic ground state.[42] The field-dependent Mössbauer spectra of $[TPP^{57}Fe(NH_2PzH)_2]Cl$ displayed in Figure 12 are well reproduced by simulations, which yield $\delta = 0.25\,\text{mm s}^{-1}$, $\Delta E_Q = (+)2.50\,\text{mm s}^{-1}$, an asymmetry parameter $\eta = -3$, and an anisotropic A tensor of $\overleftrightarrow{A}/g_N\mu_N = (-47.6, 6.7, 18.3)\,\text{T}$. The g values necessary for the $S = 1/2$ spin Hamiltonian ($g_{zz} = 2.39$, $g_{yy} = 2.28$, and $g_{xx} = 1.87$) have been taken from a combined EPR and electron spin echo envelope modulation spectroscopy ESEEM analysis.

The calculation of the corresponding A tensor according to the model of Oosterhuis and Lang[43] in the reference frame chosen by Taylor[44] yields $\overleftrightarrow{A}/g_N\mu_N = (-47.6, 11.7, 18.3)\,\text{T}$, which is in very good agreement with the experimental values. The fact that the electronic ground state predominantly exhibits d_{yz} character also allows determination of the anisotropy parameter η, if one neglects the ligand contribution to the EFG.[24] A value of $\eta \cong -3$ has been obtained, which is in excellent agreement with the experiment. The EFG is nearly axially symmetric around the x axis of the molecular frame. The coordinate system of the EFG tensor (x', y', z') is commonly chosen in such a way

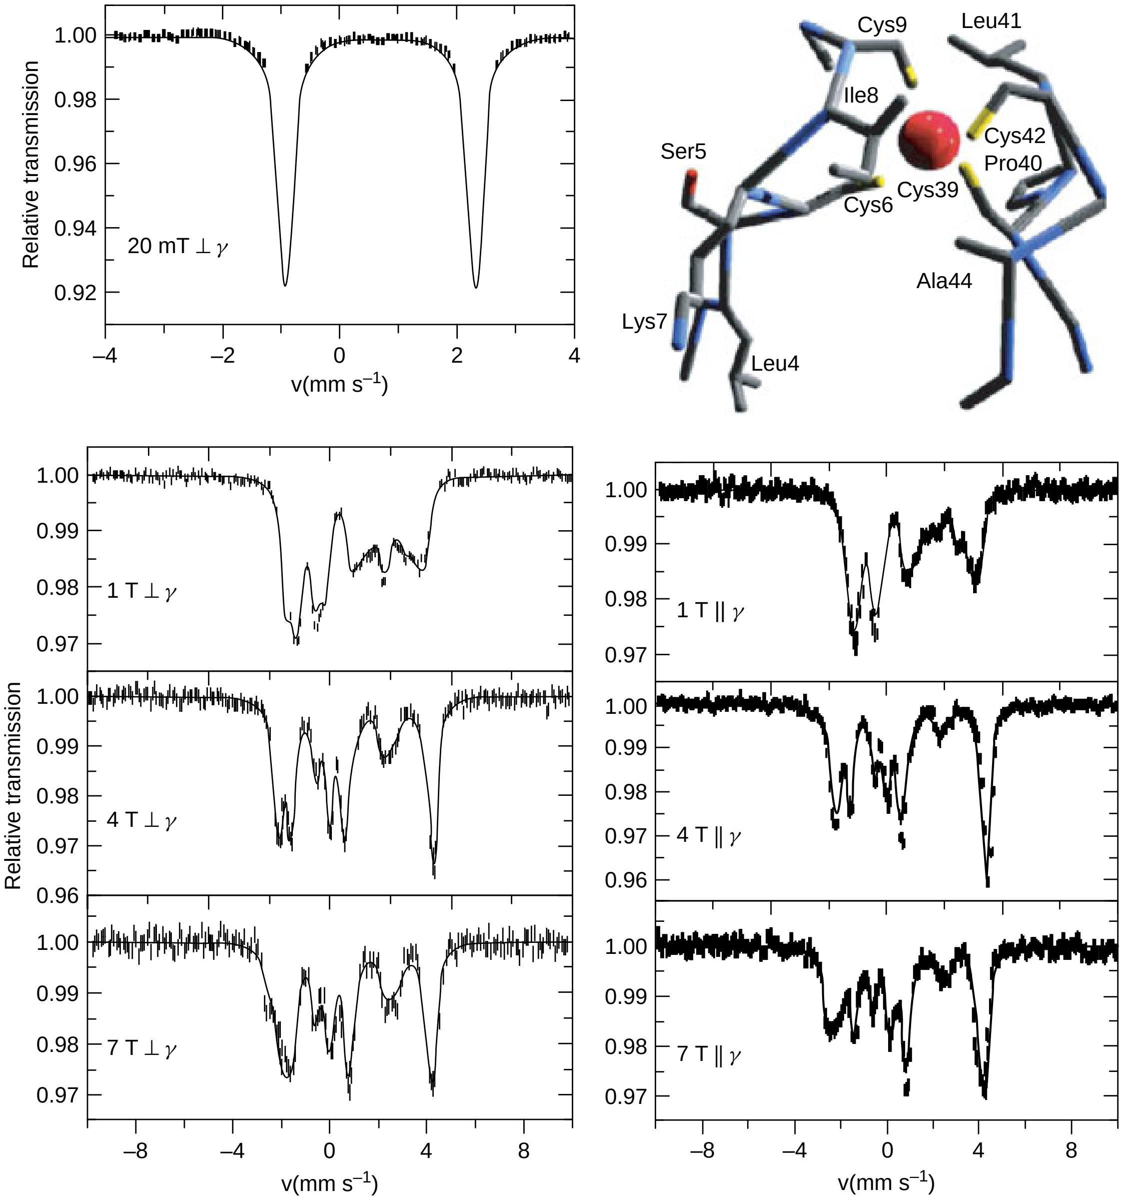

Figure 11 Mössbauer spectrum of the rubredoxin-type protein mutant RM-2−4 from the archaeon *P. abyssi* taken at 4.2 K and fields indicated. The structure of the iron site is shown at top right. The solid lines have been obtained by simultaneous fitting of the Mössbauer spectra with the software package VINDA for an $S = 2$ ground state. The parameters obtained are described in the text. (From Wegner *et al.*[39] With kind permission from Springer Science & Business Media)

that $|V_{z'z'}| \geq |V_{y'y'}| \geq |V_{x'x'}|$, which means that the coordinate system of the EFG tensor is turned around the y axis of the molecular frame by the Euler angle $\beta = 90°$. In this coordinate system, $\eta' \approx 0$ and $\Delta E'_Q = (-)2.50\,\mathrm{mm\,s^{-1}}$. A hole in the t_{2g} orbitals contributes to the quadrupole splitting by an amount of $\sim 3\,\mathrm{mm\,s^{-1}}$.[24] The experimental value of $\Delta E_Q = 2.50\,\mathrm{mm\,s^{-1}}$ for [TPP^{57}Fe(NH$_2$PzH)$_2$]Cl confirms this empirical observation.

Thus, Mössbauer spectroscopy corroborates the results of the ESEEM studies, which give $\overleftrightarrow{g} = (2.39, 2.28, 1.87)$ and clearly show an electronic ground state with major d_{yz} character. The hyperfine coupling constants of the bis-3-aminopyrazole complex are, in fact, very similar to those of the low-spin form of cytochrome P450$_{\mathrm{cam}}$, for which Debrunner *et al.* reported $\overleftrightarrow{A}/g_N\mu_N = (-45, 10.2, 19.1)$ T.[45] In spite of the similarity in A values, the g values of the P450$_{\mathrm{cam}}$ species are 2.45, 2.26, and 1.91, somewhat different from those of the 3-aminopyrazole complex discussed here. The largest component of the electric field gradient tensor with respect to the molecular frame is the x component and is negative. The z component of the hyperfine coupling tensor is positive and only about half the magnitude of the

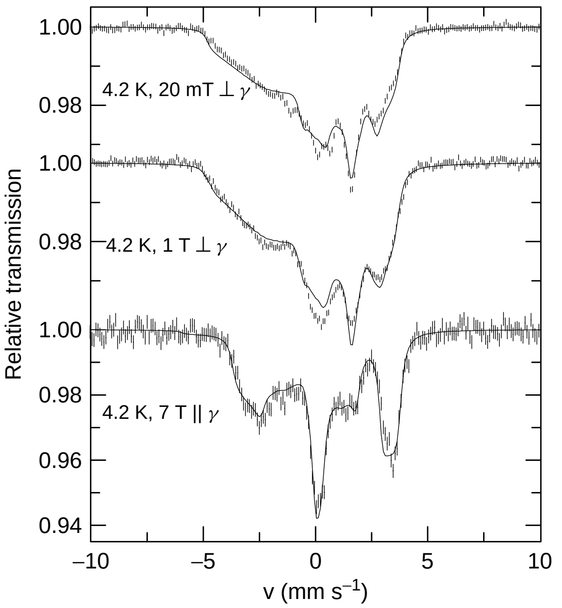

Figure 12 Field-dependent Mössbauer spectra of the ferric low-spin heme complex $[TPPFe(NH_2PzH)_2]Cl$. The solid lines are spin Hamiltonian simulations for $S = 1/2$ with parameters discussed in the text and given in Ref. 42 (From Schünemann *et al.*[42] With kind permission from Springer Science & Business Media)

x component. This is also consistent with a singly occupied d_{yz} orbital, although most other $(d_{xy})^2(d_{xz}, d_{yz})^3$ electronic ground state systems except for cytochrome $P450_{cam}$ have A_{zz} as the largest component.

3.5.2 High-Spin Iron(III) Compounds

The iron centers of high-spin iron(III) compounds have a half-filled 3d electron shell with each 3d orbital singly occupied. This electron configuration leads to a symmetric charge distribution around the iron nucleus. Therefore, highly symmetric high-spin iron(III) compounds in general exhibit low values of the quadrupole splitting. This holds specially for highly symmetric octahedral halogen iron compounds like FeF_3 and $FeCl_3$ which have almost zero quadrupole splittings. The isomer shifts of octahedrally coordinated high-spin iron(III) complexes are in general around $0.5\,mm\,s^{-1}$ at cryogenic temperatures except if sulfur ligands are present, which tends to decrease the isomer shift.

Octahedral iron(III) complexes with nitrogen and/or oxygen as ligand have isomer shifts ranging from 0.4 to $0.6\,mm\,s^{-1}$. Tetrahedral coordination enhances the electron density at the nucleus and therefore leads to slightly reduced isomer shifts but this effect is not as pronounced as in high-spin iron(II) complexes. Therefore, it is not straightforward to distinguish between different coordination numbers of ferric high-spin iron. An exception is tetrahedral ferric high-spin centers in iron–sulfur proteins. They exhibit an isomer shift of $0.24\,mm\,s^{-1}$ at 4.2 K, and it has been shown that a 2N2S coordination leads to a slight increase in isomer shift by about $0.08\,mm\,s^{-1}$. For example, the Mössbauer spectrum of the oxidized Rieske cluster from *Thermus thermophilus*[46] consists of two doublets, which reflects the difference in ligand geometry of the two tetrahedral high-spin iron(III) sites. One doublet has $\delta_1 = 0.24\,mm\,s^{-1}$ and $\Delta E_{Q1} = 0.52\,mm\,s^{-1}$ and the other has $\delta_2 = 0.32\,mm\,s^{-1}$ and $\Delta E_{Q2} = 0.91\,mm\,s^{-1}$ at 4.2 K. The former values are practically identical with those found for oxidized rubredoxin, which has a tetrahedral sulfur-coordinated ferric high-spin iron site. The latter values are still comparable with $S = 5/2$ ferric irons and represent a tetrahedral iron(III) site with 2N2S coordination. This was proposed on the basis of the Mössbauer data and was confirmed by X-ray crystallography almost a decade after the initial Mössbauer study by Münck *et al.*[46]

In the following text, we discuss the extraction of D from field-dependent Mössbauer spectra recorded at $T = 4.2\,K$ by means of the spin Hamiltonian formalism for a single iron center in the Fe(III) $S = 5/2$ state. The variation of parameters was carried out by simultaneous simulation of the spectra shown in Figure 13 and of spectra recorded at 4.2 K in a field of 20 mT (data not shown). It should be noted that the rhombicity parameter E/D has been determined from a complementary EPR measurement, which is advisory if spin Hamiltonian simulations of $S = 5/2$ systems are performed to decrease the number of parameters. The EPR spectrum of oxidized RM-2–4 exhibits a broad distribution of effective g values around 4.3 consistent with $E/D = 0.28$. Therefore, this value was taken as initial input parameter for the simulations of the Mössbauer spectra. The best fit has been found for $\delta = 0.24 \pm 0.01\,mm\,s^{-1}$, $\Delta E_Q = -0.36 \pm 0.01\,mm\,s^{-1}$, $\overleftrightarrow{g} = (2.0, 2.0, 2.0)$ (fixed), $\overleftrightarrow{A}/g_N\mu_N = (-17.7, -15.7, -16.4)\,T$, $\eta = 0.80 \pm 0.2$, $D = 2.13 \pm 0.6\,cm^{-1}$, and $E/D = 0.23 \pm 0.03$. The hyperfine coupling tensor $\overleftrightarrow{A}$ is almost isotropic, which means that the isotropic Fermi-contact interaction is dominant and spin-orbit interaction contributes only marginally to the anisotropy of $\overleftrightarrow{A}$. The mean value of the hyperfine coupling tensor $A/\mu_N g_N = -16.6\,T$ (corresponding to $B_{hf} = -41.5\,T$) is characteristic for iron in tetrahedral sulfur coordination. This value is considerably smaller than $A/\mu_N g_N = -22\,T$ (corresponding to $B_{hf} = -55\,T$) typically found for ferric high-spin ions with oxygen and/or nitrogen coordination.

3.6 Iron(IV) Compounds

Four-valent iron centers are well known as catalytic intermediates in enzymatic heme catalysis. The catalytic cycles of, for example, catalase, peroxidase, and cytochrome P450, all have in common an intermediate that is comprised of a ferryl Fe(IV) and a further oxidation equivalent located either on the heme ring or on the protein moiety. This reaction intermediate is called compound I (cpd I) and has a system spin of $S = 1/2$ (e.g., in chloroperoxidase) or $S = 3/2$ (e.g.,

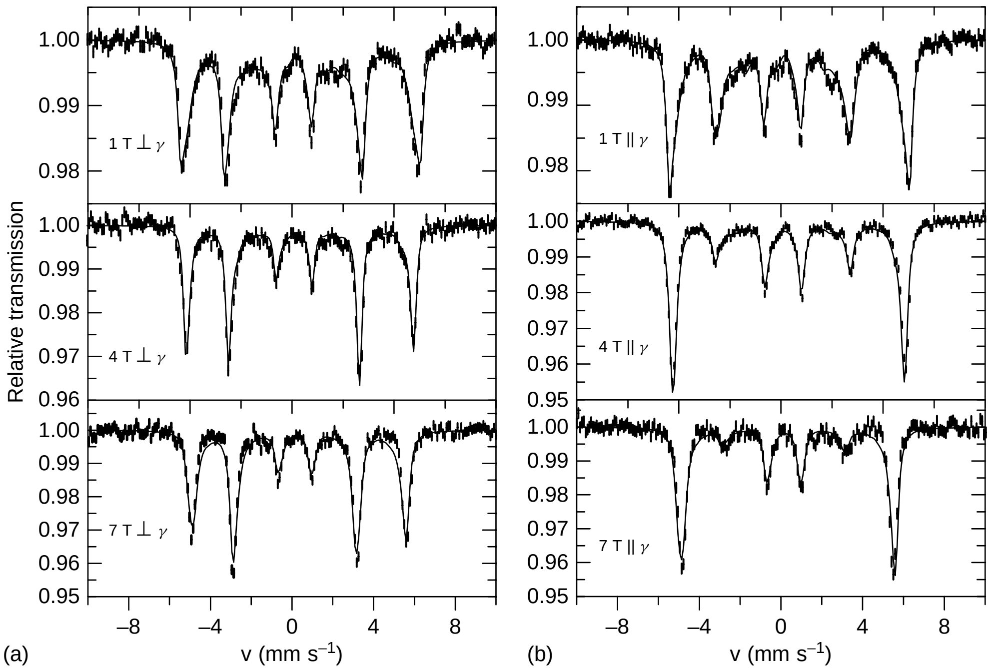

Figure 13 Mössbauer spectra of the oxidized rubredoxin-type protein mutant RM-2−4 from the archaeon *Pyrococcus abyssi* taken at 4.2 K in applied field perpendicular (a) and parallel (b) to γ-ray. The solid lines have been obtained by simultaneous fitting of the Mössbauer spectra with the software package VINDA assuming an $S = 5/2$ ground state.[27] The parameters are described in text. (From Wegner *et al.*[39] With kind permission from Springer Science & Business Media)

in catalase and many heme model compounds). Mössbauer spectroscopy continues to contribute to the understanding of the formal oxidation state of these intermediates. The reduction of cpd I by one electron equivalent leads to a ferryl Fe(IV) heme complex with almost the same isomer shift as cpd I. Heme iron(IV) compounds are characterized by their low isomer shifts around 0 mm s^{-1}. Ferryl heme iron has a d^4 configuration with the lowest lying d_{xy} orbital being doubly occupied and the d_{yz} and d_{xz} orbitals being singly occupied. This leads to a total spin of $S = 1$. As an overview, the isomer shifts and quadrupole splittings of some Fe(IV) hemes are displayed in Table 4.

The situation in the case of nonheme Fe(IV) intermediates is somewhat different. It has been recently shown by Krebs and coworkers that a catalytically competent Fe(IV) intermediate in the α-ketoglutarate-dependent dioxygenase TauD has a high-spin $S = 2$ configuration.[48] TauD is a member of a large family of enzymes that catalyze reactions in the biosynthesis of antibiotics, collagen, degradation of xenobiotics, and biosynthesis of antioxidants. Mössbauer spectroscopy of rapid-freeze-quenched (RFQ) samples identified an intermediate named J upon the reaction of a TauD–Fe(II): α-ketoglutarate–taurine complex in the time regime from 20 to 200 ms. The time dependence of the concentration of J correlates with a UV-absorption band at 320 nm. The intermediate J showed a quadrupole doublet with $\delta = 0.31$ mm s^{-1} and $\Delta E_Q = 0.88$ mm s^{-1} even at $T = 4.2$ K in a weak field of 40 mT (Figure 14).[49]

The application of external fields up to 8 T induced a magnetic splitting, which has been analyzed assuming an $S = 2$ ground state. This example is a very nice piece of work illustrating how the spin and oxidation state can be deduced from Mössbauer spectroscopy. Therefore, we will explain these assignments in more detail by raising some questions:

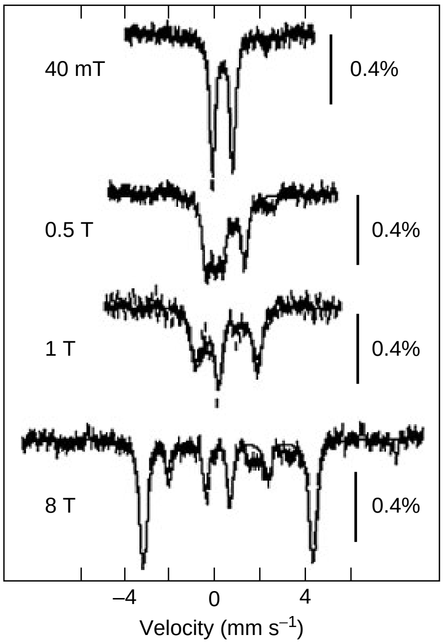

Figure 14 Mössbauer spectra of intermediate J of α-ketoglutarate-dependent dioxygenase TauD obtained at 4.2 K and fields indicated. The solid line represents a simulation using an $S = 2$ spin Hamiltonian and the parameters $\delta = 0.31\,\mathrm{mm\,s^{-1}}$, $\Delta E_Q = -0.88\,\mathrm{mm\,s^{-1}}$, $\eta = 0.0$, $\overleftrightarrow{A}/g_N\mu_N = (-18, -18, -18)$ T, $g = (2.3, 2.3, 2)$, $E/D = 0.03$, and $D = 10.5\,\mathrm{cm^{-1}}$. (Reprinted with permission from Krebs, Price, Baldwin, Saleh, Green and Bollinger.[48] © 2005 American Chemical Society)

Question 1: Both δ and ΔE_Q are within the range of Fe(III) species with an $S = 5/2$ ground state. Could J have this kind of ground state?

Answer: No! The Mössbauer spectrum of J does not show magnetic splitting at $T = 4.2$ K and weak external field, which would be expected for an isolated ferric high-spin iron.

Question 2: Why does J have an integer spin?

Answer: Spin expectation values (and therefore the magnetic hyperfine field) of half-integer spin systems can be saturated in low fields (*see* Section 3.5.2). This is not the case here. In order to drive the magnetic splitting to its saturation, fields of up to 8 T have been applied. In addition, J is EPR silent, which points to an integer-spin species.

Question 3: Can J be an exchange-coupled Fe(III) dimer? These are EPR silent and also show only a doublet at 4.2 K and weak field.

Answer: Although this may be ruled out from the biochemistry perspective, it is worth considering this question from the Mössbauer spectroscopic point of view: Strongly exchange-coupled ferric iron dimers like those in methane monooxygenase, ribonucleotide reductase, and Fe_2S_2 iron–sulfur proteins all have a diamagnetic ground state. The magnetic splitting of J clearly exceeds that of the applied external fields. Therefore J cannot be diamagnetic.

Question 4: Ultrasmall superparamagnetic particles can relax faster than the time window of Mössbauer spectroscopy even at 4.2 K and such ferric nanoparticles also show similar δ and ΔE_Q values.

Answer: The relaxation rate of superparamagnetic particles would be slowed down by the application of large external fields. What one normally observes is a magnetically split spectrum with broad lines and almost negligible quadrupole splitting (see e.g., Figure 7). The reason is that the main axis of the electric field gradient tensor of the surface atoms of such clusters is oriented in all directions with respect to the direction of the magnetic hyperfine field. This is often observed in reconstitution experiments of iron–sulfur proteins. If the reader is interested, Figure 4 of the work on anaerobic ribonucleotide reductase by Ollagnier *et al.*,[50] which serves as an example of small superparamagnetic iron–sulfur agglomerates, may be referred to.

Question: How can a spin state of S = 1 be ruled out from the spectra?

Answer: The authors did indeed evaluate the Mössbauer data by spin Hamiltonian simulations assuming an $S = 2$ as well as an $S = 1$ ground state. In this way they could deduce two sets of hyperfine and fine structure parameters: simulations assuming an $S = 1$ ground state yield an axial hyperfine tensor $\overleftrightarrow{A}_{x,y}/g_N\mu_N = -33.3$ T. Such a high hyperfine coupling tensor has never been observed for ferryl iron species having $S = 1$. The isotropic hyperfine coupling tensor $\overleftrightarrow{A}/g_N\mu_N = -18$ T which has been obtained assuming an $S = 2$ ground state is in the range of hyperfine coupling tensors observed for ferryl iron species.

The groups of Que and Münck have reported the synthesis of the nonheme Fe(IV)=O model compound $[(Fe(IV){=}O)(TMC)(NCCH_3)](OTf)_2$, which contains a nonheme macrocyclic ligand.[51] In zero applied field, the complex exhibits a Mössbauer spectrum consisting of a doublet with $\delta = 0.17\,\mathrm{mm\,s^{-1}}$ and $\Delta E_Q = 1.24\,\mathrm{mm\,s^{-1}}$. The spin Hamiltonian analysis of the Mössbauer spectra in high fields between 4.2 and 100 K shows that $[(Fe(IV){=}O)(TMC)(NCCH_3)](OTf)_2$ has integer electronic spin. Spectral simulations using an $S = 1$ spin Hamiltonian yield $\delta = 0.17(1)\,\mathrm{mm\,s^{-1}}$, $\Delta E_Q = +1.24\,\mathrm{mm\,s^{-1}}$, $\eta = 0.5$, $\overleftrightarrow{A}/g_N\mu_N = (-25, -20, -3)$ T, $g = (2.3, 2.3, 2)$, $E/D = 0$, and $D = 29\,\mathrm{cm^{-1}}$. In their analysis, the z component of the g tensor was set to 2.0 and the x and y components were calculated according to $g_{x,y} = 2.0 + 4D/\zeta$, with ζ being the single-electron spin-orbit coupling constant. This parameter set compares well with those of Fe(IV)=O complexes having $S = 1$, which show $A_{x,y} \sim 17 - 25$ T and a relatively large zero-field splitting $D \sim 20–37\,\mathrm{cm^{-1}}$.

It is instructive to compare the Mössbauer properties of $[(Fe(IV){=}O)(TMC)(NCCH_3)](OTf)_2$ with those of the

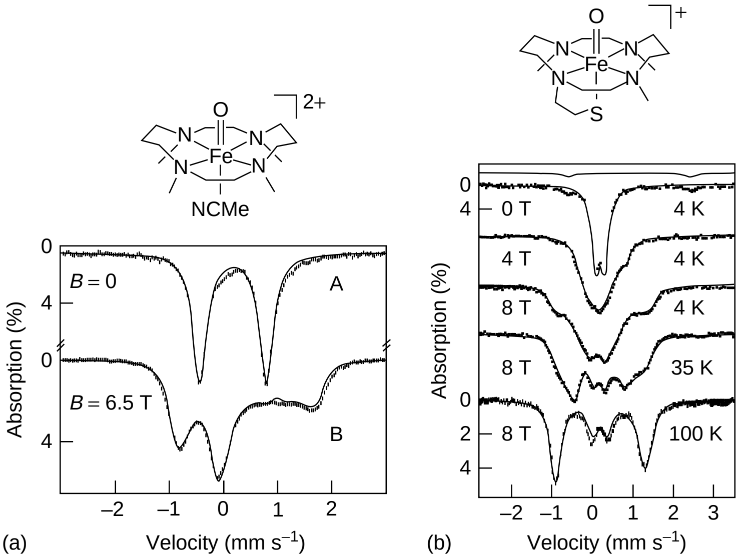

Figure 15 (a) The 4.2 K Mössbauer spectra of [(Fe(IV)=O)(TMC)($NCCH_3$)]$(OTf)_2$ in acetonitrile recorded in (A) zero field and (B) a parallel field of 6.5 T. The solid line represents a spin Hamilton simulation with the parameters described in the text. (b) Mössbauer spectra of [Fe(IV)=(O)(TMCS)] recorded at temperatures and applied fields that are indicated. The solid lines represent spin Hamiltonian simulations with parameters described in the text. The spectra were simulated in the slow (at 4.2 K) and fast (at 30 K) spin fluctuation limit. The applied field was directed parallel to the observed γ radiation. The doublet drawn above the topmost experimental spectrum (0 T, 4 K) represents a 7% Fe(II) contribution from the starting complex. (From J. U. Rohde *et al*. (2003) *Science* **299**:1037–1039. Reprinted with permission from AAAS)

complex [Fe(IV)=(O)(TMCS)].[52] TMCS, the monoanion of 1-mercaptoethyl-4,8,11-trimethyl-1,4,8,11-tetraaza cyclotetradecane, is a pentadentate ligand that provides a square pyramidal N4(SR) ligand environment about the iron center, which is similar to that of cytochrome P450, containing an axial RS^- ligand. At zero field, [Fe(IV)=(O)(TMCS)] exhibits a doublet with $\delta = 0.19\,\mathrm{mm\,s^{-1}}$ and $\Delta E_Q = 0.22\,\mathrm{mm\,s^{-1}}$. A spin Hamiltonian analysis of the high-field Mössbauer spectra (Figure 15) assuming $S = 1$ yields a negative sign for the quadrupole splitting and an asymmetry parameter $\eta = 0$. The hyperfine coupling tensor has been determined as $\overleftrightarrow{A}/g_N\mu_N = (-23, -22, -5)$ T and the fine structure parameters as $E/D = 0$ and $D = 35\,\mathrm{cm^{-1}}$. Surprisingly, the isomer shift of [Fe(IV)=(O)(TMCS)] is comparable with that of [(Fe(IV)=O)(TMC)($NCCH_3$)]$(OTf)_2$ within the experimental error of $\pm 0.01\,\mathrm{mm\,s^{-1}}$. However the quadrupole splitting is significantly smaller and even reverses its sign in the thiolate complex ($\Delta E_Q = -0.22\,\mathrm{mm\,s^{-1}}$ for [Fe(IV)=(O)(TMCS)] versus $\Delta E_Q = +1.25\,\mathrm{mm\,s^{-1}}$ in [(Fe(IV)=O)(TMC)($NCCH_3$)]$(OTf)_2$).

3.7 Iron(V) Compounds

Iron(V) complexes are very rare, but recently two examples involving the characterization of these compounds with Mössbauer spectroscopy have been reported in the literature. Meyer *et al*. reported on the spectroscopic characterization of a nitridoiron(V) species prepared by photolysis of [Fe(III)(cyclam)$(N_3)_2$]$^+$ complexes.[53] Mössbauer spectroscopy of this species yields $\delta = -0.04\,\mathrm{mm\,s^{-1}}$ and $\Delta E_Q = -1.90\,\mathrm{mm\,s^{-1}}$ at 80 K and it has a spin state $S = 3/2$ (determined by EPR). The spin Hamiltonian parameters obtained by Mössbauer spectroscopy are consistent with this picture. The analysis yields $D = -0.37\,\mathrm{cm^{-1}}$, $E/D = 0.095$, $g = 2.0$ (isotropic), $\overleftrightarrow{A}/g_N\mu_N - 13.3, -10.6, 2.5)$ T and $\eta = 0.6$.

Very recently, chemical and spectroscopic evidence for an Fe(V)-oxo-complex has been reported by de Oliveira *et al.*[54] Field- and temperature-dependent Mössbauer as well as X-ray absorption (*see* ***X-Ray Absorption Spectroscopy***) and EPR spectroscopies in combination with density functional theory DFT calculations show that [Fe(TAML)(O)]$^-$ with TAML being a macrocyclic tetraamide ligand is a d^3 system with spin $S = 1/2$ and $\delta = -0.42\,\mathrm{mm\,s^{-1}}$, $\Delta E_Q = +14.25\,\mathrm{mm\,s^{-1}}$, $\eta = 0.65$, $A/\mu_N g_N = (-49.3, -1.5, -16.3)$ T and $g = (1, 99, 1.97, 1.74)$. The hyperfine parameters have also been determined by DFT using Gaussian with the functional B3LYP and the basis set G-311G with admirable accuracy ($\delta = -0.39\,\mathrm{mm\,s^{-1}}$, $\Delta E_Q = +4.51\,\mathrm{mm\,s^{-1}}$, $\eta = 0.72$, $\overleftrightarrow{A}_{\mu_N} g_N = (-43.6, -0.5, -15.0)$ T).

3.8 Iron(VI) Compounds

Until very recently, only a single Fe(VI) species, the ferrate ion [Fe(VI)O_4]$^{2-}$, was known. This species is a

strong oxidant and used not only in organic synthesis but also in waste water treatment, batteries, and disinfectants. The Fe(VI) compound K_2FeO_4 has a single-line resonance at $-0.78\,mm\,s^{-1}$ at 78 K.

Very recently, a photochemical synthesis of an Fe(VI) compound has been reported by the Wieghardt group.[55] The octahedrally coordinated iron in $[(Me_3cy\text{-}ac)FeN](PF_6)_2$ has a Fe≡N triple bond of 1.57 Å as shown by X-ray absorption spectroscopy. Mössbauer spectroscopy in a field of 7 T shows that the iron is diamagnetic and that the sign of ΔE_Q is positive (Figure 16).

DFT calculations reproduce the positive sign of ΔE_Q and indicate that $[(Me_3cy\text{-}ac)FeN](PF_6)_2$ has a doubly occupied nonbonding d_{xy} orbital and a strong covalent iron−nitrogen bond. Surprisingly the isomer shift of this complex ($\delta = -0.29\,mm\,s^{-1}$) is much higher than that of $[Fe(VI)O_4]^{2-}$, which has δ values between −0.79 and $-0.85\,mm\,s^{-1}$, depending on the type of salt.

In such a situation, the only clear cut strategy that leads to a definite answer concerning the valence state of the iron is not only to apply spectroscopic methods complementary to Mössbauer spectroscopy but also to investigate complexes with similar ligands but different electronic configurations. In order to clarify the electronic configuration of $[(Me_3cy\text{-}ac)FeN](PF_6)_2$, X-ray absorption spectroscopy (XAS) has been chosen as a method complementary to Mössbauer spectroscopy and the spectroscopic signatures of a series of iron complexes with valence states ranging from Fe(II) to Fe(VI) have been studied. Figure 17 displays a plot of the isomer shifts versus iron oxidation states for a series of low-spin iron complexes with cyclam-related ligands having oxidation states from II to VI. Not only the isomer shift scales beautifully with the oxidation number, but also the XAS pre-edge-energy, which is also an indicator for iron oxidation states, exhibits a linear correlation with the iron oxidation states of the complexes.

Together with the reproduction of δ and ΔE_Q values by DFT calculations, this piece of work is a beautiful example of how Mössbauer spectroscopy can be used to determine spin and oxidation states of high-valent iron. The authors do claim that in fact Fe(VI) intermediates that are undetected until now might exist in chemical and/or enzymatic reactions.

3.9 Molecules with Iron Centers of Higher Nuclearity

There are many iron proteins and corresponding model complexes that have more than one iron site. Dinuclear iron centers are present in 2Fe−2S electron transfer proteins or in enzymes like methane monoxygenase and ribonucleotide reductases. Even high-valent reaction intermediates have been detected by the RFQ Mössbauer studies of Huynh *et al.*[56] A broad variety of 3Fe−4S and 4Fe−4S proteins exist and enzymes like hydrogenases and nitrogenases have even more complex iron centers. Mössbauer spectroscopy detects all ^{57}Fe in the sample, which is a big advantage if compared, for example, with EPR, and therefore all the systems mentioned above have been and are still investigated using this technique.[7,8,11]

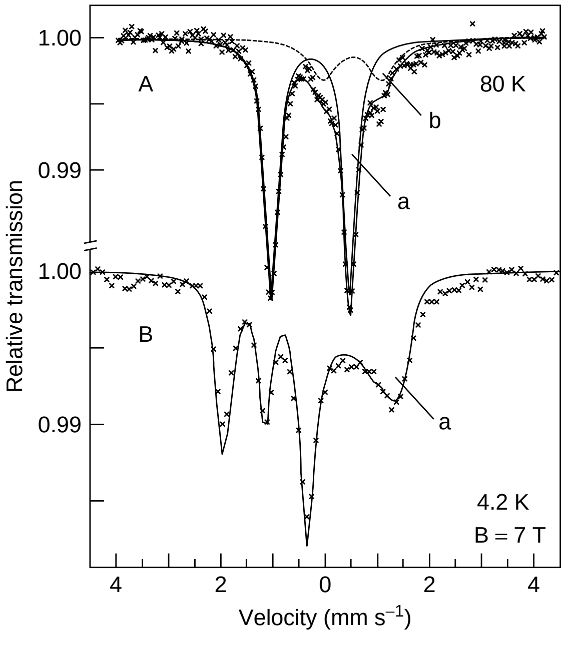

Figure 16 Mössbauer spectra of a acetonitrile solution of $[(Me_3cy\text{-}ac)Fe(VI)N](PF_6)_2$ measured at 80 K (A) and at 4.2 K in a magnetic field of 7 T (B). The magnetic splitting in B corresponds to the external field. The simulation has been performed by assuming a diamagnetic species. Subspectrum (a) corresponds to a stable $[(Me_3cy\text{-}ac)Fe(IV)N_3](PF_6)_2$ and was the only subspectrum that was fitted in (B). (From J. F. Berry *et al.* (2006) *Science* **312**:1937−1941. Reprinted with permission from AAAS)

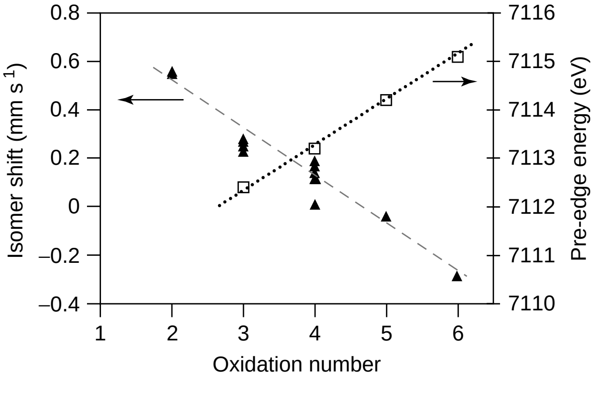

Figure 17 Plot of the isomer shifts versus Fe oxidation state of a series of low-spin Fe(III) Fe(IV), Fe(V), and Fe(VI) complexes with cyclam-related ligands. A plot of the Fe X-ray absorption spectroscopy (XAS) pre-edge peak energies of some complexes versus Fe oxidation state is also shown (open squares). The lines with dashes and dots represent least squares fits. (From J. F. Berry *et al.* (2006) *Science* **312**:1937−1941. Reprinted with permission from AAAS)

Mössbauer spectra of exchange-coupled iron centers having a paramagnetic ground state are almost exclusively evaluated in the strong-exchange limit. This implies that all exchange interactions are assumed to be strong and that no excited states are populated under the conditions at which the Mössbauer spectra are recorded. Only in this case is it justified to assume that the center can be described by a system spin S. Therefore, it is possible to evaluate the Mössbauer spectra in terms of the conventional spin Hamiltonian (equation 18). This procedure yields the system spin S as well as the parameters D, E/D, g, and A. The parameters of the single iron sites can be obtained by the spin-projection technique, which is also used in evaluating EPR spectra of strongly exchange-coupled systems. Instructive examples of this procedure can be found in Ref. 57.

Here we limit ourselves to an example of a 4Fe–4S center from the radical *S*-adenosyl-L-methionine (SAM) enzyme oxygen-independent coproporphyrinogen III oxidase HemN.[58] This enzyme catalyzes the oxidative decarboxylation of coproporphyrinogen III to protoporphyrinogen IX during bacterial heme biosynthesis. The crystal structure of *Escherichia coli* HemN revealed the presence of an unusually coordinated iron–sulfur cluster and two molecules of SAM.

The Mössbauer spectra of HemN without further additions are shown in Figure 18(a) and the parameters obtained are summarized in Table 5. The corresponding three iron atoms are ligated by cysteines ($\delta_1 = 0.43(1)\,\mathrm{mm\,s^{-1}}$, $\Delta E_{Q1} = 1.17(1)\,\mathrm{mm\,s^{-1}}$) whereas the fourth is not ($\delta_2 = 0.57(3)\,\mathrm{mm\,s^{-1}}$, $\Delta E_{Q2} = 1.23(2)\,\mathrm{mm\,s^{-1}}$). A value of $\delta \sim 0.45\,\mathrm{mm\,s^{-1}}$ is typical for valence-delocalized $Fe^{2.5+}$–$Fe^{2.5+}$ pairs with one electron being delocalized over the two iron sites. The value $\delta_2 = 0.57(3)\,\mathrm{mm\,s^{-1}}$ is clearly outside this range. Therefore, the ligand of the fourth iron site is unknown in the absence of SAM. Possible candidates could be either an amino acid residue of the polypeptide other than cysteine or alternatively any molecule contained within the buffer solution. These results are consistent with the finding that only the three cysteine residues C62, C66, C69 within the CXXXCXXC motif of *E. coli* HemN are involved in iron–sulfur cluster coordination.

Figure 18(b) shows the Mössbauer spectra of HemN plus SAM. As in the case of HemN, two different iron sites of a $[4Fe–4S]^{2+}$ cluster were identified for the HemN spectra in the presence of SAM. However, for the latter spectra, a change in the isomer shift of the non-cysteine-ligated iron atom (from $\delta_2 = 0.57(3)\,\mathrm{mm\,s^{-1}}$ to $\delta_2 = 0.68(3)\,\mathrm{mm\,s^{-1}}$) was observed, which indicates that SAM only binds at one iron of the cluster, namely this unique, non-cysteine-ligated iron atom. This is consistent with the observed coordination of SAM to the iron–sulfur cluster in the crystal structure of *E. coli* HemN, in which it was observed that SAM binds at the iron by means of the carboxy and the amino group of the methionine part of SAM. Thus SAM coordination to the fourth iron site of the cluster is analogous in solution and in the crystalline state of HemN. The isomer shift value for the SAM ligated iron site can be directly correlated with specified distances between the iron and the ligand atoms in the case of HemN. Thus, the observed isomer shift of $\delta_2 = 0.68(3)\,\mathrm{mm\,s^{-1}}$ is

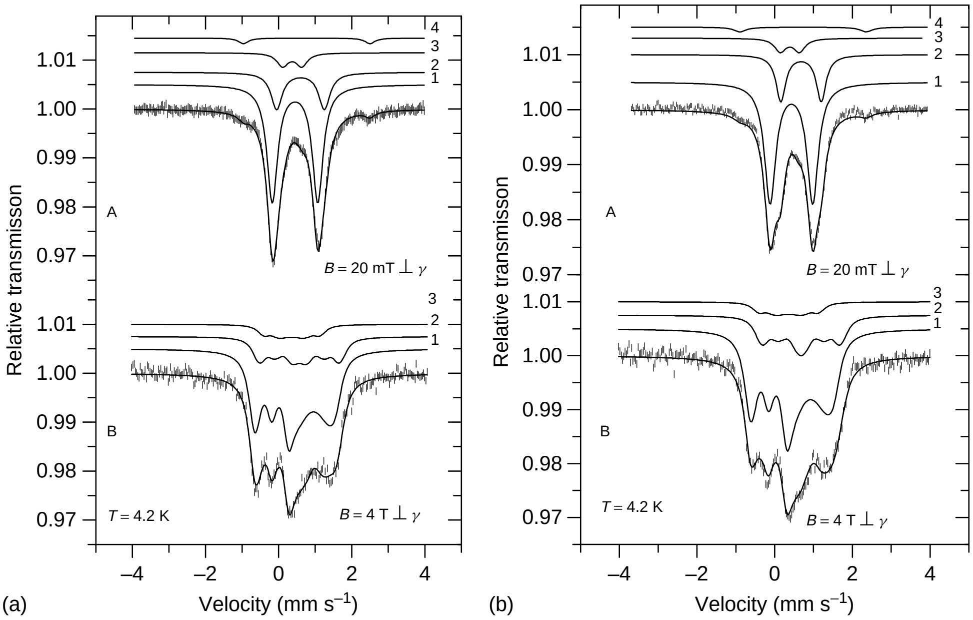

Figure 18 Mössbauer spectra of HemN in the absence (a) and in the presence of SAM (b). Spectra were obtained at $T = 4.2\,\mathrm{K}$ in an external magnetic field of (A) 20 mT and (B) 4 T perpendicular to the γ beam. The parameters are given in Table 5. associated with the iron site, which is ligated by the O- (2.3 Å) and the N-ligand (2.6 Å) of the methionine part of SAM as observed in the crystal structure of HemN. Therefore, the Mössbauer results provide essential information in correlation with the structural data, namely the possibility to combine the structural features (distances between the atoms) with the electronic properties (Mössbauer parameters) of the [4Fe–4S] cluster of HemN.

3.10 Prediction of Mössbauer Parameters by Density Functional Calculations

Since the early days of application of Mössbauer spectroscopy in solid state physics and inorganic chemistry, electronic structure calculations have been performed to rationalize and predict the Mössbauer parameters obtained. In the beginning, calculations were applied to single ions, but later semiempirical methods could be applied to small molecules, too. Early density functional theory (DFT) methods, like the self-consistent charge (SCC)-Xα method could be successfully applied to larger molecules. For more than a decade, DFT methods with all-electron basis sets have also been applied to large bioinorganic molecules. These methods allow the determination of Mössbauer parameters with impressive accuracy and have become a valuable tool for the interpretation of Mössbauer spectra.

3.10.1 Density Functional Calculations

Density functional theory is based on the Hohenberg–Kohn theorems,[59] which state (i) that there is a one-to-one mapping between the electronic charge density ρ_0 and the wavefunction Ψ_0 of the ground state and (ii) that there is a functional $E[\rho]$ that maps the density on the molecular energy and that is minimized by the ground state density ρ_0. In this way, the solution of the Schrödinger equation for an N-particle wavefunction is reduced to the problem of minimizing the energy functional $E[\rho]$ by a one-particle charge density. The price for this reduction of complexity is that only approximations for the functional $E[\rho]$ are available, the exact form being unknown. Actually, Before the formulation of the Hohenberg–Kohn theorems, Slater had already proposed the SCC-Xα method,[60,61] which is now regarded as the first DFT method. For most of the problems that are addressed by electronic structure calculations, DFT methods became the method of choice. Although ab initio methods can, in principle, give results with any desired accuracy, they are at the current stage for most purposes computationally too demanding to compete with DFT methods in the field of transition metal compounds.

3.10.2. Electric Field Gradient and Quadrupole Splitting

The quadrupole splitting ΔE_Q is the first Mössbauer parameter that could be predicted with reasonable accuracy by electronic structure calculations. The quadrupole splitting can be related to the EFG at the Mössbauer nucleus according to equation (12). Since the nuclear quadrupole moment Q is very difficult to determine by experiment alone, the combination of Mössbauer spectroscopy and density functional calculations is currently the most accurate approach to estimate Q. A linear regression of measured quadrupole splittings and calculated electric field gradients has been performed by Blaha *et al.*[62] for a large series of compounds

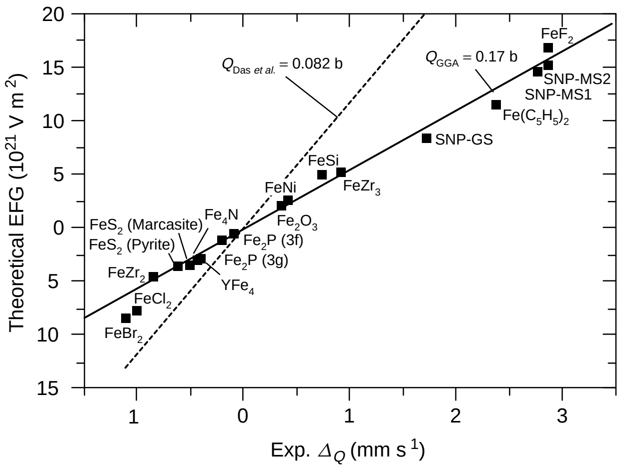

Figure 19 Calculated electric field gradients versus observed quadrupole splittings ΔE_Q. The solid line represents a linear regression with a ^{57}Fe nuclear quadrupole moment of 0.17 barns. (From Blaha, Schwarz, Faber and Luitz.[62] With kind permission from Springer Science & Business Media)

covering a wide range of different quadrupole splittings (Figure 19). According to these calculations, a value of the nuclear quadrupole moment of the ^{57}Fe nucleus of 0.15–0.17 barn is commonly accepted, with an uncertainty of about 10%.

Successful calculations of the quadrupole splitting have been performed with a variety of density functional methods. Among the currently most popular functionals—like the gradient corrected functionals BP86 or BPW91 or the hybrid functional B3LYP—there are no apparent differences in the quality of the predicted field gradients. Zhang and Oldfield[63] demonstrated that wrong iron–ligand bond lengths are a major source of error for calculated field gradients. Methods employing the local density approximation, which are notorious for underestimating metal–ligand bond lengths, are in principle expected to give less accurate field gradients than corrected gradient functionals. However, this effect may be canceled by other sources of error working in the opposite direction.

Several studies[63–65] have shown that the calculated field gradients are sensitive to the quality of the size of the basis set. The type of basis set, for example, Gaussian-type orbitals (GTOs) or Slater-type orbitals (STOs), does not seem to influence the field gradient, provided the basis set is large enough.[63] For this reason, the computationally more efficient GTOs are usually preferred to STOs, which give a better representation of the cusp of the charge density at the nucleus. Since relativistic calculations give no significant improvement of the calculated electric field gradients,[66] most of the reported EFG calculations have been performed with nonrelativistic methods.

3.10.3 *Isomer Shift*

According to equation (8), the absolute value of the isomer shift, δ_{abs}, depends linearly on the electronic charge densities $\rho_S(0) = e|\varphi(0)_{source}|^2$ and $\rho_{\text{A}}(0) = e|\varphi(0)_{absorber}|^2$ at the Mössbauer nuclei in the source and in the absorber, respectively.[67] Usually, nonrelativistic electronic structure calculations are performed, giving an electronic charge density $\rho_{\text{nr}}(0)$ that is smaller than the true value (nonrelativistic $\sim 1.2 \cdot 10^4$ au as compared to relativistic $\sim 1.5 \cdot 10^4$ au in case of ^{57}Fe). Fortunately, the relativistic charge density $\rho(0)$ can in good approximation be retrieved from the nonrelativistic charge density $\rho_{\text{nr}}(0)$ by multiplication with a so-called relativity factor $S(Z)$:

$$\rho(0) = S(Z)\rho_{\text{nr}}(0) \tag{22}$$

This factor is about 1.32 in the case of iron and about 2.48 in the case of tin. One may conclude that—like for the quadrupole splitting—for the prediction of the isomer shift also nonrelativistic calculations are fully sufficient. Since it is quite difficult to determine the absolute isomer shift as defined in equation (8), it is common practice to give the isomer shift as the difference, $\delta = \delta_{\text{abs, sample}} - \delta_{\text{abs, standard}}$, compared to a given standard (e.g., α-iron foil or sodium nitroprusside in case of iron). In principle, one could try to predict the isomer shift directly, using equation (8) and the relativity factor $S(Z)$. However, it turns out that the accuracy of the calculated charge densities as well as the accuracy of the experimentally observed radii of the Mössbauer nuclei in the ground and excited state is not sufficient for this approach. Therefore, it is common to use linear regression on a large data set containing measured isomer shifts and calculated charge densities. For this purpose, the isomer shift can be written as

$$\delta = \alpha[\rho_{\text{A,nr}}(0) - b] \tag{23}$$

where α and b are parameters that have to be determined by linear regression. A large number of studies have been performed to estimate α and b by semiempirical molecular orbital, ab initio and DFT calculations, first for free atoms[68–73] (see also Ref. 74 for a review), and also later for molecules.[64,65,75–79] A detailed description of the technical details of the calculation of charge densities and an extensive review of previously published work on this subject have been given by Neese.[80]

With increasing computational resources, the correlation between calculated charge densities and measured isomer shifts has improved significantly. A benchmark for the calibration of the parameters α and b in equation (24) has been given by Neese,[80] who compiled data for 15 iron-containing compounds that cover a range of the isomer shift from $-0.87\,\text{mm s}^{-1}$ to $+1.39\,\text{mm s}^{-1}$. The linear regression of the measured isomer shifts with respect to nonrelativistic charge densities calculated with B3LYP gives a remarkable correlation and a standard deviation between measured

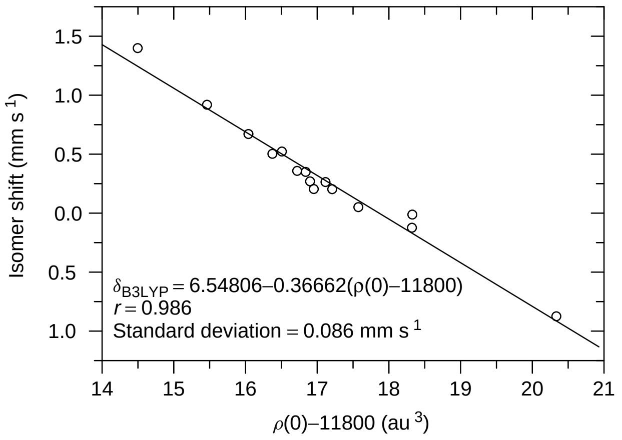

Figure 20 Calibration of the B3LYP method for the prediction of ^{57}Fe isomer shifts. The calculated electron density at the iron nucleus is plotted versus the experimentally determined isomer shift for a series of 15 iron-containing compounds. (Reprinted from Neese.[80] © 2002, with permission from Elsevier)

and predicted isomer shifts of about 0.1 mm s^{-1} (Figure 20). Similar results were obtained with the BP86 method.[80]

It is important to note that, although different DFT and ab initio methods can be used for the prediction of the isomer shift with comparable accuracy, these methods nevertheless give quite different values for the charge densities at the Mössbauer nucleus. The linear regression parameters α and b obtained with a particular method are therefore not useful for charge densities that have been calculated with any other method.

There is a long-standing tradition to correlate the measured isomer shifts with calculated orbital populations of the Mössbauer isotope, especially with the populations of the valence orbitals. The first reason for this tradition is the restricted computational resources that did not allow full electron basis sets. A second reason is the intention to rationalize the relation between physical and chemical concepts like spin and oxidation state of the Mössbauer atom. While the first argument is becoming obsolete even for large bioinorganic molecules, the second argument is as appealing as ever, since the prediction of isomer shifts by DFT methods has to some extent the character of a ‘‘black box’’, despite its remarkable accuracy. However, the correlation of orbital populations and isomer shifts is hindered by several problems. The first problem is that orbital populations may significantly depend on the basis set employed. A second problem is that the relation between the orbital populations and the charge density at the nucleus is fairly complex since core and valence orbitals change their shape owing to shielding and covalency effects. An authoritative analysis of these complex relations has been given by Neese.[80] Vrajmasu *et al.* have combined DFT calculations with a semiempirical model that is able to predict the influence of redox states on the isomer shift in iron proteins.[81]

Instructive examples for the possible benefit of isomer shift calculations using DFT are some recently investigated high-valent iron complexes like those that are described in Sections 3.7 and 3.8. For instance, the Fe(VI) complex [(Me_3cy-ac)FeN](PF_6)$_2$, reported by Berry *et al.*[55] (*see* also Section 3.8), exhibits a surprisingly high isomer shift. For this reason, a series of similar complexes with different electronic configuration was investigated by spectroscopic and by theoretical methods in order to confirm the oxidation state VI of this complex. DFT calculations were able to accurately reproduce the spectroscopic results for the investigated series of complexes and they confirmed that the electronic configurations that have been assigned to the complexes as a result of the spectroscopic data were consistent with the calculated electronic structures.

3.10.4. Lamb–Mössbauer Factor

The Lamb–Mössbauer factor f_{LM}, which is difficult to determine experimentally as well as computationally, does not belong to the most common Mössbauer parameters in the field of inorganic chemistry. It can be of importance, however, when Mössbauer spectra are used to determine for a given sample the fractions of different species containing the same Mössbauer isotope. This is the case, for instance, for iron spin-crossover complexes where Mössbauer spectroscopy can be used to measure the temperature- or pressure-dependent fraction of different spin isomers.[82] The first approach to estimate the change of the Lamb–Mössbauer factor upon spin crossover has been restricted to molecular vibrations, neglecting the important contribution that arises from intermolecular vibrations.[83,84]

3.10.5 Spin Hamiltonian Parameters

In case of paramagnetic compounds in high magnetic fields, it is common to use the spin Hamiltonian formalism to interpret the Mössbauer spectra (compare Section 2.3.4). This formalism employs adjustable parameters like the g tensor, the hyperfine coupling tensor $\overleftrightarrow{A}$, the zero-field D splitting, and the rhombicity E/D, in order to simulate the measured spectra. The interpretation of these parameters in terms of geometric and electronic structure can be supported by DFT calculations. In general, g tensors can be calculated quite accurately by DFT methods. Unfortunately, in the case of transition metal complexes sometimes only qualitative agreement can be achieved. Currently, the best results seem to be obtained by a combination of nonrelativistic DFT methods and second-order perturbation theory.[85] The calculation of the hyperfine coupling tensor $\overleftrightarrow{A}$ (consisting of the Fermi-contact contribution, a spin dipolar contribution, and an orbital contribution) of iron is currently less advanced than the g tensor. The first results have been published by Neese.[85] In the meantime, algorithms for the calculation of the hyperfine coupling tensor are implemented in many quantum chemistry program packages. A recent application to an oxoiron(IV)

complex is described in Ref. 52. In order to calculate the zero-field splitting D and the rhombicity E/D, the ground state wavefunction has to be mixed with wavefunctions of different multiplicities. This has first been achieved at the semiempirical level.[86] Only recently, very accurate calculations of the zero-field splitting using DFT have been presented.[87–89] While the zero-field splitting parameter D is currently systematically underestimated by DFT calculations,[87,88] more accurate results have been obtained by ab initio methods.[90]

4 ACKNOWLEDGMENTS

We would like to dedicate this contribution to our academic teacher Ali Trautwein, who introduced us to the fascinating field of Mössbauer spectroscopy.

5 END NOTE

a. In the older literature isomer shifts are often reported relative to $Na_2[Fe(CN)_5NO]$ (Table 2) sodium nitroprusside. The values are related by $\delta_{\mathrm{NP}} = \delta_{\alpha-Fe} + 0.26\,\mathrm{mm\,s^{-1}}$.

1 INTRODUCTION

The nickel enzymes covered in this article can be divided into two groups: redox enzymes and hydrolases. The five Ni redox enzymes are hydrogenase, CO dehydrogenase (CODH), acetyl-CoA synthase (ACS), methyl-Coenzyme M reductase (MCR), and superoxide dismutase (SOD). Glyoxalase-I and urease are Ni hydrolases. Ni proteins that are not enzymes are not covered, because they have been recently reviewed.[1,2] These include regulatory proteins (NikR) and chaperonins and metal uptake proteins (CooJ, CooE, UreE, and ABC transporters). A recent crystal structure of NikR, shown in Figure 1(i), is a notable recent achievement in this area.[3]

1.1 Biology of Nickel

Derived from the German word meaning Devil's copper, Ni is an essential element that, at elevated levels, is toxic, causing skin allergies, lung fibrosis, and cancer of the respiratory tract (*see* ***Metal Ion Toxicity***).[10,11] While the total Ni concentration in most natural environments is in the low nM range (e.g. ∼20 nM in freshwater or seawater and 0.5 nM in the human bloodstream),[12] industrial workers like welders are exposed to atmospheric Ni levels that have been determined to be a cancer risk ($>1\,\mathrm{mg\,m^{-3}}$). Ni becomes toxic at relatively high levels (oral LD50 in rats for nickel acetate = $350\,\mathrm{mg\,kg^{-1}}$). Based on studies of Ni depletion in rats as early as 1920, it was suggested that Ni is an essential element for higher animals;[11] however, the source of the Ni requirement has not yet been uncovered. Following the initial discovery of a microbial Ni requirement for hydrogenase activity in 1965,[13] a Ni requirement for many microbes as an essential prosthetic group in key enzymes has been described. The diverse structures of Ni active sites are shown in Figure 1 and summarized in Table 1. Some general properties of the Ni enzymes are described in Table 2. Reviews on the bioinorganic chemistry of Ni are available.[2,14]

1.2 Chemistry of Nickel

Nickel (relative atomic mass = 58.69) is a first-row transition metal in group VIIIb of the periodic table. Although there are five natural isotopes, ^{58}Ni (68.3%) and ^{60}Ni (26.1%) are the most abundant. Proteins are often labeled with ^{61}Ni (nuclear spin, I, is 3/2) to identify the nickel site by EPR spectroscopy, since paramagnetic species with significant spin on ^{61}Ni exhibit a four-line splitting. ^{63}Ni, which is a beta emitter with a relatively long half-life of 100 years, can be used to identify Ni-containing proteins and to measure Ni uptake in cells.

Nickel can exist in oxidation states from 0 to +4 and all but the +4 state have been observed in biology. Although the 2+ state ($3d^8$) is most common, the Ni redox enzymes described here appear to access either the 2+/1+ and/or the 3+/2+ redox couples. It has been proposed that the 0 state is important during catalysis by acetyl-CoA synthase. The hydrolases appear to only use Ni^{2+}, which is a Lewis acid. Since Ni^{1+} and Ni^{3+} are paramagnetic, electron paramagnetic resonance (EPR) and related advanced methods like electron nuclear double resonance (ENDOR) and electron spin echo envelope modulation (ESEEM) are valuable spectroscopic methods used to study Ni redox enzymes. Some Ni enzymes have rather strong UV-visible and magnetic circular dichroism (MCD) bands that are redox- and coordination-dependent. X-ray absorption spectroscopic (XAS) methods are often used to assess the oxidation state and geometry of the Ni active site in proteins.

Table 1 Reactions covered in this review

Urease	Urea + $H_2O \rightarrow 2NH_3 + H_2CO_3$	(1)
Hydrogenase	$2H^+ + 2e^- \leftrightarrow H_2$	(2)
CO Dehydrogenase	$CO + H_2O \leftrightarrow 2H^+ + CO_2 + 2e^-$	(3)
Acetyl-CoA Synthase	CH_3–CFeSP + CoASH + CO → CH_3–CO–SCoA + CFeSP	(4)
Methyl-CoM Reductase	Methyl-SCoM + CoBSH → CH_4 + CoBS-SCoM	(5)
Superoxide Dismutase	$2O_2^- + 2H^+ \rightarrow H_2O_2 + O_2$	(6)
Gloxylase I	Methylglyoxal + glutathione ↔ GS-derivative	(7)
Aci-reductone dioxygenase	Aci-reductone + O_2 → methylthiopropionate	(8)

Table 2 Nickel Enzymes

Enzyme	Source	Composition	Ni center	Other groups
Urease	Plants	6 × 91 kDa	High-spin Ni^{II} dimer	
	K. pneumoniae	60.3 + 11.7 + 11 kDa	High-spin Ni^{II} dimer	
Hydrogenase	*D. gigas*	61 + 28 kDa	NiFe Center	2[4Fe−4S] + [3Fe−4S]
	Wolinella succinogenes	64 + 32 + 19 kDa		2[4Fe−4S] + cytochromeb
CO dehydrogenase	*M. thermoacetica*	71 kDa	$NiFe_4S_4$ cluster	2[4Fe−4S] + 1 *bridged* [4Fe−4S]
	Rhodospirillum rubrum	61.8 kDa	$NiFe_4S_4$ cluster	2[4Fe−4S] + 1 *bridged* [4Fe−4S]
	C. hydrogenoformans	64.5 kDa (CODHII)	$NiFe_4S_5$ cluster	2[4Fe−4S] + 1 *bridged* [4Fe−4S]
Acetyl-CoA Synthase	*M. thermoacetica*	78 kDa	$NiNiFe_4S_4$ cluster	
	C. hydrogenoformans	73.3 kDa (CODHIII)	$NiNiFe_4S_4$ cluster	
Methyl-CoM reductase	Methanogenic bacteria	65 (Ni protein), 46, and 35 kDa	Ni tetrapyrrole (hydrocorphin)	
Superoxide Dismutase	Streptomyces		4−5 coordinate Ni site	
Gloxylase I	*E. coli*	14.9 kDa	6-coordinate Ni site	
Aci-reductone dioxygenase	*K. pneumonia*	20.2 kDa	6-coordinate Ni site	

Ni^{2+} generally adopts octahedral or tetragonally distorted octahedral geometry, but square-planar (diamagnetic) and tetrahedral (high-spin) geometries are well known. It forms tight complexes with histidine ($\log K_f = 15.9$), a property exploited in affinity tagging of engineered proteins for easy purification, and, among the first-row transition metals, is second only to Cu(II) in its ability to complex with acidic amino acids ($\log K_f = 6–7$).[15] Square-pyramidal and trigonal bipyramidal Ni^{2+} complexes have also been reported. Ni^{1+} generally contains distorted octahedral or square-planar geometry, while Ni^{3+} is usually low spin, with distorted octahedral or trigonal bipyramidal geometry. Redox changes in Ni during redox activation and catalysis are often accompanied by changes in the geometry and spin state.

2 UREASE (EC 3.5.1.5)

Urease, which catalyzes the reaction described by equation (1) (Table 1), was the first Ni enzyme to be identified.[16] A relatively recent review on urease is available.[17] Ironically, although urease was the first enzyme to be crystallized, it was not recognized at that time to be a metalloenzyme. A di-Ni hydrolase, urease catalyzes the

Figure 1 Nickel centers in Enzymes. (a) dinuclear center of urease (1EJX). The two nickel ions are bridged by a hydroxide bridge and the two oxygens from K217*, which is a carbamylated lysine residue. Each Ni ion binds an additional water ligand. (b) The dinuclear NiFe center of the reduced active state of the NiFe–Se hydrogenase from *desulfomicrobium baculatum* (1CC1).[4] The Se–Cys residue corresponds to C543 in *D. fructosovorans* and appears to be the general base in the heterolytic H_2 cleavage reaction. The Fe site contains 2 CN and 1 CO ligands. Besides the NiFe dinuclear center, this enzyme contains 3 [4Fe−4S] clusters. (c) The Ni tetrahydrocorphinoid active site of MCR (1HBN).[5] The oxygen from the side chain of glutamine-147 axially coordinates to the Ni. (d) The [2Ni−4Fe−4S] site of the *M. thermoacetica* ACS (1MJG).[6] A tetragonally distorted Ni ion, called the proximal Ni (Ni_p) bridges the [4Fe−4S] cluster and the square-planar Ni, called the distal Ni (Ni_d). Although Cu was present in the original structure, Ni has been shown to be the active metal at the Ni_p site (see text). (e) The [Ni−4Fe−5S] site of the *C. hydrogenoformans* CODH (1JJY).[7] In the *R. rubrum* CODH, the sulfur from the homolog of C526 replaces the sulfide bridge in the Ni–Fe subsite (1JQK).[8] (f) The Ni active-site of E. coli glyoxylase-I (1F9Z) (g) The square-planar Ni active site of superoxide dismutase (1G0D). (h) The octahedral Ni site of aci-reductone dioxygenase (1M4O).[9] (i) The Ni-bound regulatory domain of NikR (1Q5Y).[3] The Ni ions are shown in cyan, sulfur in yellow, and iron in red

hydrolysis of urea to yield two moles of ammonia and carbonic acid. The ammonia can then serve as a nitrogen source. Urease also is a virulence factor that participates in GI tract infection by *Helicobacter pylori*. Urease is found in bacteria, plants, fungi, and invertebrates. Jack bean urease has a 545 kDa hexameric quaternary structure, with six identical 91 kDa subunits, while the *Klebsiella aerogenes* urease consists of three copies each of three smaller subunits (UreABC) (i.e. it is a homotrimer of the heterotrimeric unit), in which the larger UreC subunit (60.3 kDa) contains the dinuclear active site.

The structures of the ureases from *Klebsiella aerogenes*,[18,19] *Bacillus pasteurii*,[20] *H. pylori*,[21] and jack bean are known. The active site contains a dinuclear Ni–Ni center bridged by a carbamylated lysine residue and a hydroxy group (Figure 1(a)). Based on MCD and magnetic susceptibility measurements, the two Ni ions appear to be high spin Ni(II) ($S = 1$) and become strongly antiferromagnetically coupled when the inhibitor β-mercaptoethanol is bound ($J = -40\,\mathrm{cm}^{-1}$).[22] Synthesis of this metallocenter is a multistep process that has been recently reviewed[1,2] in which several accessory proteins (UreDFG) form a complex with apourease (UreABC in bacteria like *K. aerogenes*) and promote assembly of the Ni ions into the urease apoenzyme by UreE, carbamylation of lysine with carbon dioxide, and GTP hydrolysis by UreG. In bacteria, the accessory proteins are encoded adjacent to the urease structural genes, and, in some organisms, the gene cluster contains a Ni permease. The following complexes have been characterized: UreABCD, UreABCDF, and UreABCDFG. UreE, whose structure is known,[23,24] appears to be the metallochaperone that donates Ni to apourease. UreE contains a metal-binding domain and a Hsp40 chaperone domain. In *H. pylori*, there is evidence that the hydrogenase accessory proteins HypA and HypB are involved in urease assembly.

What features of the active site are responsible for the 10^{14}-fold rate enhancement over the uncatalyzed reaction? Urease can hydrolyze 3500 molecules of urea per second.[25] The bridging electrophilic carbamate group on the modified lysine residue stabilizes the dinickel center, which appears to be mechanistically significant since the enzyme is only active when both Ni are present in the active site. The Ni_2 ion has a nearly perfect octahedral coordination while Ni_1 shows a slightly distorted square-pyramidal coordination. The two Ni are bridged by the carbamate of lysine and by a hydroxide bridge. A proposed bimetallic mechanism (Figure 2) is based on computational studies,[26,27] model studies,[28] on the 2.0 Å X-ray structure of the diamidophosphoric acid-inhibited form of the enzyme (regarded as a transition state analogue),[20] and the 1.85 Å structure of the phosphate-inhibited form.[29] It appears that urea binds in a bidentate manner based on the X-ray crystallographic structure of the DAP-inhibited urease and on computational studies as shown in Figure 2. The urea carbonyl group is expected to bind to the most electrophilic Ni_1 while one amino group of urea would coordinate to Ni_2. The hydroxide bridge between Ni_1 and Ni_2 is apparently parallel to the bound urea, which would facilitate nucleophilic attack of the bridging hydroxide on urea carbonyl carbon atom to give a tetrahedral intermediate. Replacement of the hydroxide bridge by fluoride inhibits urease, suggesting that the bridging hydroxide is responsible for hydrolysis of urea. Either the bridging hydroxide or His320 would then protonate the leaving ammonia molecule. However, it remains possible that a metal bound water molecule (W2) would act as the nucleophile. Figure 2 shows attack by the bridging OH to generate an OH^- nucleophile that attacks bound urea, liberating NH_2, which is protonated by an active-site histidine residue (or perhaps the proton release to form ammonia, and carbamate, which spontaneously and nonenzymatically hydrolyzes to another mol of ammonia and carbonic acid. Alternatively, it has been suggested that one of the bound water molecules facilitates the hydrolysis of the first product, carbamate.

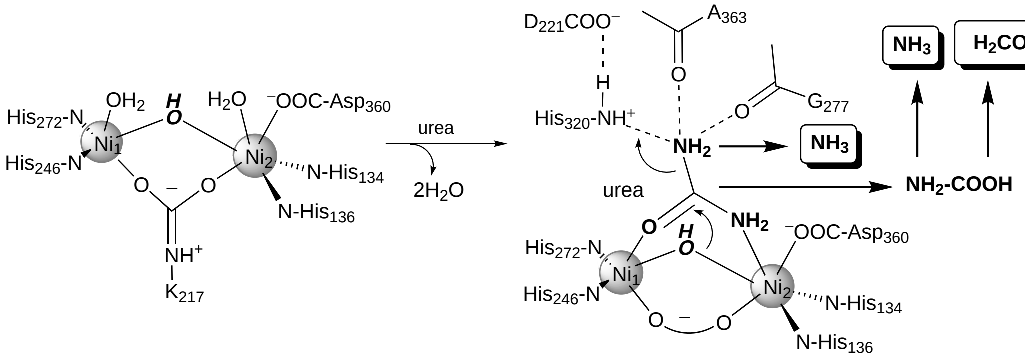

Figure 2 Mechanism of urease. This proposed mechanism features binding of urea through its carbonyl group to one of the Ni ions, making the carbon subject to nucleophilic attack by the bridging hydroxide leading to liberation of NH_2, which is protonated by $H^{32}0$ to form ammonia, and carbamate, which hydrolyzes to another mole of ammonia and carbonic acid. The same mechanism with proton transfer from water (instead of histidine) to ammonia is another possibility. Another possibility would be urea binding in a monodentate manner with a terminal hydroxide on Ni2 as the nucleophile

3 NiFe HYDROGENASES (EC 1.12.1.2, 1.2.2.1, OR 1.18.99.1)

Marjory Stephenson and Leonard Stickland proposed the name in 1931 for the enzyme that catalyzes equation (1), the oxidation of H_2 gas (Reaction 2, Table 1).[30] Hydrogenases are essential and versatile components of microbial metabolism that can catalyze the consumption as well as the production of H_2 gas.[31] Hydrogenases have been recently reviewed.[32,33] Uptake hydrogenases generate energy by coupling H_2 oxidation to the reduction of terminal electron acceptors like oxygen, nitrate, sulfate, CO_2, and fumarate. Hydrogenotrophic organisms catalyzing H_2 oxidation are important in the global carbon cycle because elevated H_2 levels inhibit the anaerobic biodegradation of biomass. On the other hand, evolving hydrogenases siphon off excess reducing equivalents by transferring electrons to protons. Hydrogenases also are key to the processes of interspecies H_2 transport and H_2 cycling, which have been studied in sulfate reducers that generate a proton gradient during growth on organic substrates in the presence of SO_4.[34] Efficient utilization of H_2 is accomplished by growth of microbes growing syntrophically, for example, by fatty- and aromatic acid-degrading fermentative bacteria growing in syntrophic association with a hydrogen-using microbes.[35] This association is important because fatty/aromatic acid degradation is thermodynamically unfavorable only at very low H_2 concentrations (equation (1)).

$$2H^+ + 2e^- \longleftrightarrow H_2 \quad \Delta E^{\circ\prime} = -414\,\text{mV} \tag{1}$$

Hydrogenases are classified into four categories: the NiFeSe, NiFe, Fe-only, and one represented by N^5,N^{10}-methylenetetrahydromethanopterin dehydrogenase that was previously thought to lack metals[36] but now has been shown to contain a metallic cofactor.[37] The immediate electron donors/acceptors are metalloproteins like ferredoxin or cytochromes or an organic cofactor, like NAD. When the natural electron acceptors are limiting, some metalloenzymes in their reduced states, like pyruvate:ferredoxin oxidoreductase and carbon monoxide dehydrogenase, can reduce protons to H_2.[38] Nitrogenase also generates H_2 with each cycle of N_2 reduction. This review will focus on the Ni enzymes.

All [NiFe]-hydrogenases contain at least two subunits (‘large’ and ‘small’) of approximately 60 and 30 kDa, containing a nickel center and at least one [4Fe−4S] cluster. The active site of H_2 oxidation/reduction by the Ni hydrogenases, located in the large subunit, is shown in Figure 1(b). This binuclear NiFe center is coupled to a ‘wire’ within the small subunit which is usually composed of three Fe–S clusters. The enzyme from *Desulfomicrobium baculatum*, shown in Figure 1(b), contains 3[4Fe−4S] clusters, although 2[4Fe−4S] and one [3Fe−4S] clusters are frequently observed. The hydrogenase shown here is a member of the subclass of the nickel-hydrogenases that contain a selenocysteine ligand.

Besides the reactions described above, hydrogenases also catalyze hydrogen isotope exchange, for example, between $^1H_2$ gas and deuterium oxide (equation (2)) and interconversion of *ortho*- and *para*-hydrogen.[39] These reactions are expected to proceed through a metal-hydride intermediate, as first proposed in 1959 based on studies of the H-D exchange reaction using D_2 and H_2O.[40] It is now generally accepted that hydrogenase catalyzes heterolytic cleavage of H_2 (equation (3)) followed by electron transfer to an external acceptor (equation (4)).[41] Electron transfer from the bound hydride to an external electron carrier protein is believed to be the function of the FeS clusters, which form an intramolecular ‘wire’.

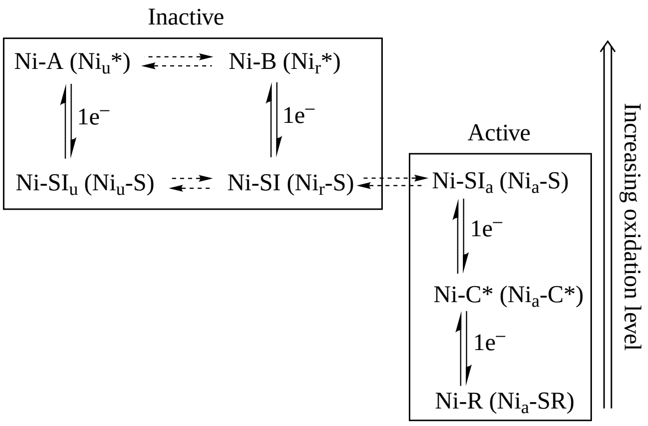
$$D_2O + H_2 \longleftrightarrow HDO + HD \tag{2}$$

$$E\text{–}Ni + H_2 \longleftrightarrow E\text{–}Ni\text{–}H^- + H^+ \tag{3}$$

$$E\text{–}Ni\text{–}H^- + \text{Acceptor}_{ox} \longleftrightarrow E\text{–}Ni + H^+ + \text{Acceptor}_{red} \tag{4}$$

The structure of the catalytic center of the NiFe hydrogenase is shown in Figure 1(b). X-ray crystallographic studies showed that the Fe site of the binuclear NiFe center contains three nonexchangeable diatomic ligands[42] that were identified as one CO and two cyanide ligands by FTIR spectroscopy,[43] and assigned in the structure by their interaction with the protein (hydrogen bonds in the case of CN, a hydrophobic pocket in the case of CO).[42,43]

EPR spectroscopic studies have uncovered various redox states of the Ni hydrogenases (Scheme 1). The oxidized state of the [Ni]-hydrogenases exhibit EPR signals (called Ni-A and Ni-B) that disappear on reduction and have been attributed to the Ni^{3+} oxidation state, with a $(d_{z}^{2})^1$ ground state (*see Splitting, Crystal Field & Molecular Orbital*).[44] The states of the enzyme that elicit these signals are called Form A and Form B. Neither Form A (an already oxidatively inactivated form) nor Form B is catalytically active, and neither is sensitive to inactivation by O_2, indicating that both are oxidized forms.



Scheme 1 The states of hydrogenase described here. Only the Ni–C* and Ni–R states appear to be in equilibrium with H_2. This scheme is revised from Ref. 49

Form A has been called the unready state (Ni_u) because it requires prolonged treatment with a reductant (like H_2) to undergo conversion to an EPR-silent state called SI_r (where the 'r' designates 'ready'), which is in redox equilibrium with Form B. Apparently this is a self-activation that occurs by electron transfer from the small amount of active enzyme present in the solution. An oxidizing agent is required to oxidize SI_r to Form B, indicating that Form B contains a Ni^{3+} state and SI_r contains a Ni^{2+} state. Form A and B are not in equilibrium; Form A must be reduced and reoxidized to convert it to Form B. SI_r is in equilibrium with SI_a, which is an active form that can be reduced to Form C, another EPR-detectable state, called Ni-C.

In the Ni-A state, the binuclear center appears to contain a hydroxide ligand that points toward a gas channel.[45] H_2 treatment generates an EPR-detectable species (Ni-C) that appears to contain a bound state of hydrogen, based on ENDOR and ESEEM spectroscopy.[46] ENDOR studies demonstrate that an OH^- ligand bridges the Ni and Fe sites in the Ni-A and Ni-B states and is lost upon reduction to the Ni-C state.[47] This is consistent with XAS[48] and electrochemical[49] studies indicating that a hydroxo ligand present in Form A, Form B and SI_u, is removed during activation at the SI_r level. Photolysis of the Ni-C state at low temperatures alters its EPR signal to form the Ni-L state at a rate that is six-fold slower when $^2H_2$ is used.[50] Ni-C forms and decays to an EPR-silent state at rates consistent with its involvement in catalysis.[51] The properties just described indicate that Ni-C is an intermediate state in the catalytic cycle. Although whether or not Ni-C contains a hydride species remains controversial, single-crystal EPR studies were interpreted to indicate that Ni-C can be described as a Ni(III) species with a bridging hydride between the Ni and the Fe atoms and that the photolysis product, Ni-L, is a Ni(I) species with a proton removed from the bridging position[52] or from one of the Cys ligands. If Ni-C does contain a hydride, perhaps it can be described in one of the following formulations: $Ni^{I}\cdot 2H^+$, or $Ni^{III}\cdot H_2$, or $Ni^{III}\cdot H^-$, although a Ni(I) state appears to be ruled out by XAS experiments.[48]

One of the shocking discoveries in the hydrogenase field was that the active site contains diatomic ligands, which were identified by IR spectroscopy.[53] The IR bands from the diatomic ligands are sensitive indicators of the state of the enzyme. In the Ni-A state of the *D. fructosovorans* [NiFe] hydrogenase, the CO stretching mode appears at 1947 cm^{-1}, while the CN bands appear at 2096 and 2084 cm^{-1}.[54] These bands appear at 1938, 2060, and 2074 cm^{-1} in the Ni-R state and at 1951, 2074, and 2086 cm^{-1} in the Ni-C state. These strong-field ligands are thought to maintain the Fe atom in the binuclear site in its low-spin ferrous state as indicated by Mössbauer spectroscopy.[55] This type of coordination appears to favor the binding of molecular hydrogen or hydride to the active site.

Besides identifying the tightly bound intrinsic CO and CN ligands to the Fe site of the NiFe center, IR studies provide evidence that another CO can interact weakly with Ni in the reduced Ni-C state, which blocks both electron and proton transfer at the active site.[54]

The biosynthesis of all the [NiFe] hydrogenases, including the H_2-sensing regulatory protein,[56] requires the function of seven Hyp proteins (HypA, HypB, HypC, HypD, HypE, HypF, and HypX) to assemble the [NiFe] active site. Their functions and the assembly process has been reviewed.[1,57] Before Ni is incorporated, the $Fe(CO)(CN)_2$ site appears to be assembled by HypD, E, and F, the diatomic ligands apparently derived from carbamoyl phosphate.[58] The other Hyp proteins, two of which are similar to UreE and UreG and a protease (HyaC, D, and I) are involved in Ni incorporation and maturation of hydrogenase to its active state.

H_2 accesses the active site through a tunnel in the protein,[59] where it forms a complex with the NiFe catalytic center buried 30 Å beneath the surface and then catalyzes heterolytic cleavage to form a Ni-hydride and a proton. Isotope effect studies indicate that electron transfer is rate limiting in H_2 oxidation and proton transfer is rate limiting in proton reduction.[60] When the NiFe hydrogenase is absorbed to a pyrolytic graphite edge-plane (PGE) electrode and studied by voltammetric methods, the rate of H_2 oxidation is diffusion-controlled (k_{cat}/K_m of 10^8–10^9 M^{-1} s^{-1}), with a turnover number reaching 9000 s^{-1} at 30 °C; thus the NiFe center has a similar catalytic activity to platinum.[61]

After binding and heterolytically cleaving H_2, the Ni-C state apparently is formed, which contains the bound hydride. One of the terminal cysteine ligands of the active-site nickel atom (the Se–Cys residue in Figure 1(b)) is considered to be the general base in the heterolytic cleavage reaction by binding the released proton. This conclusion is based on X-ray diffraction data, X-ray absorption spectroscopic studies, EPR, model complex studies, and theoretical calculations. A conserved glutamic residue (E25 in *D. fructosovorans* or E18 or *D. gigas*) that forms a hydrogen bond with this cysteine/selenocysteine residue[62] appears to be the first step in a proton transfer chain that couples the base catalyst to eventual proton release to the solvent.

A fifth type of hydrogenase is in the NiFe class, but is oxygen insensitive and has very low catalytic activity, functioning not as an enzyme, but as a hydrogen sensor.[63] Like the catalytic hydrogenases, this class of proteins contains two subunits encoded by *hupUV* in *Rhodobacter capsulatus* or *hoxBC* in *R. eutropha*). Remarkably, this protein has spectroscopic properties similar to the standard NiFe hydrogenase with 2 CN and 1 CO bound to the low-spin Fe site, indicating high structural homology between the two enzyme classes.[64] Why isn't this enzyme active? It apparently is blocked in the Ni-C state. Further reduction to the Ni-R is apparently required for catalytic turnover (above).[64] The regulatory mechanism involves interaction between the NiFe protein with histidine kinase and response regulator proteins, which modulate transcription of the hydrogenase-related genes.[65]

4 CARBON MONOXIDE OXIDOREDUCTASES (CODH, EC 1.2.99.2)

CODH is at the heart of the ability of microbes to use CO as a sole carbon and electron source. CODH rapidly and efficiently oxidizes CO at rates between 4000 and 40 000 s^{-1}, depending on the source, and reduces CO_2 ($\sim$11 s^{-1}) with virtually no overpotential and under mild conditions. CO biochemistry and bioinorganic chemistry has been most thoroughly studied in enzymes from the anaerobic microbes, *Moorella thermoacetica. Rhodospirillum rubrum, Carboxydothermus hydrogenoformans*, and the aerobic carboxydobacterium, *Oligotropha carboxidovorans*. Only the anaerobic CODHs will be discussed here since the aerobic CODHs lack Ni and have a Mo-pterin active site (*see* ***Molybdenum: MPT-containing Enzymes***). CODH and ACS have been the subjects of several reviews.[66–68]

There are two types of Ni-CODHs: one class is a homodimer and catalyzes only CO oxidation, while the other also contains acetyl-CoA synthase activity on a separate subunit. The *R. rubrum* CODH is encoded by *cooS*, which is part of the *coo* regulon consisting of at least two operons whose expression is induced at least 1000-fold when the microbe senses the presence of CO. CO is sensed and the *coo* gene cluster is regulated by the heme protein, CooA, which is a member of a large family of transcriptional activators that includes the cAMP regulatory protein (CRP) and fumarate nitrate regulatory protein (FNR).[69] The first operon in the *coo* gene cluster includes a NiFe hydrogenase and proteins just described that are involved in generating the mature enzyme, while the second operon consists of CODH (*cooS*), a membrane-associated electron transfer FeS protein (*cooF*), and genes involved in generating the NiFeS active site of CODH. Metal center assembly proteins include CooC, a Ni insertase similar to UreG, and CooJ, which is similar to UreE.[70] The proteins involved in Ni incorporation into CODH and their functions have been reviewed.[71]

The CODHs from *R. rubrum, C. hydrogenoformans*, and *M. thermoacetica* have been most extensively studied and structures are known for each of these proteins. All ligands at the active site, as well as some residues proposed to facilitate acid-base chemistry at the active site, are conserved among these proteins, even those that associated with ACS. The X-ray crystal structure of CODH reveals a mushroom-shaped homodimeric enzyme containing 5 metal clusters (Clusters B, C, and D).[6–8,72] Electrons generated during CO oxidation at the C-Cluster are transferred to a 'wire' consisting of the B-, a typical [4Fe–4S] cluster, and the D-Cluster, a [4Fe–4S] cluster with two cysteine ligands contributed by each subunit. As shown in Figure 1(e), the C-Cluster is a $NiFe_4S_{4-5}$ cluster that can be viewed as a [3Fe–4S] cluster bridged to a binuclear NiFe center. Controversy remains about whether the Ni and Fe are bridged by a sulfide or by a cysteine sulfide (C526 in *C. hydrogenoformans*). Adopting a distorted five-coordinate geometry with 4S and another unidentified ligand, the Ni site is part of the cube. In the *C. hydrogenoformans* structure, all 4Fe atoms are bridged to Ni through inorganic sulfide ligands, with Ni–Fe distances distributed over 1 Å (2.8, 2.9, 3.3, and 3.7 Å),[7] while in the 2.8 Å resolution structure of CO-treated Rr-CODH,[8] all four Ni–Fe distances are clustered within a much tighter range between 2.6 and 2.8 Å and the external Fe is bridged to the Ni by a cysteine S ligand. Ni EXAFS studies of 'as-isolated' and CO-treated *C. hydrogenoformans* CODH indicate that CO treatment and/or reduction induces a major structural rearrangement of the C-Cluster to adopt a conformation similar to that observed in the *R. rubrum* structure.[73]

Like the NiFe center of hydrogenase, the C-Cluster exists in several redox states, including C_{ox}, C_{red1}, C_{int}, and C_{red2}. C_{red1} and C_{red2} can be observed by EPR spectroscopy. The [3Fe4S] component is proposed to remain in the 1- redox state ($2Fe^{2+}/1Fe^{3+}/4S^{-2}$) throughout most of the catalytic mechanism, except in the C_{red2} and C_{int} states where it undergoes 1 electron reduction to the 2- state ($3Fe^{2+}$), with most of the redox changes occurring at the NiFe center (Figure 3).

The *C. hydrogenoformans* CODH can catalyze CO oxidation with a turnover number of 39 000 s^{-1} and a k_{cat}/K_m of over 10^9 M^{-1} s^{-1}.[78] The first step in the CODH reaction is binding of substrates, CO and H_2O or CO_2 and protons to Cluster C. Dobbek *et al*. described a hydrophobic CO channel in the COOH-terminal domain of ACS and a hydrophilic positively charged water channel that connects the surface and the C-Cluster in the *C. hydrogenoformans* CODH II.[7]

Then, after CO and water bind, it is proposed that the water molecule binds to a metal center, presumably Fe and perhaps in a bridging position. The active metal-hydroxide is then proposed to attack the M-CO complex to form M-COOH. Elimination of CO_2 and a proton would leave the C-Cluster two-electrons more reduced, presumably in the Cred2 state. Conversion of Cred1 to Cred2 occurs very rapidly, as studied by rapid quench EPR.[75] Several basic residues near the C-Cluster, including Lys563, His93, and His261 and several other histidine residues, described as a histidine tunnel, were proposed to participate in these acid-base reactions. The His tunnel leading from the active site to the surface is proposed to deliver protons that are liberated during the reaction to the solvent. Cred2 then transfers its electrons to the B and D clusters, which in turn reduce the external electron carriers. The scheme shown in Figure 3 indicates the existence of a diamagnetic form of the C-Cluster (Cint)[77] as an intermediate in the reduction of the B and D clusters.

5 ACETYL-CoA SYNTHASE (ACS) (EC 2.3.1)

ACS catalyzes the synthesis of acetyl-CoA from CO, CoA, and a methyl group donated by a methylated corrinoid iron–sulfur protein (Reaction 4, Table 1). In the CODH-only enzymes like CODHI and II from *C. hydrogenoformans* and *R. rubrum*, there is evidence for a channel between the surface and the C-cluster (above). On the other hand, in CODH/ACS,

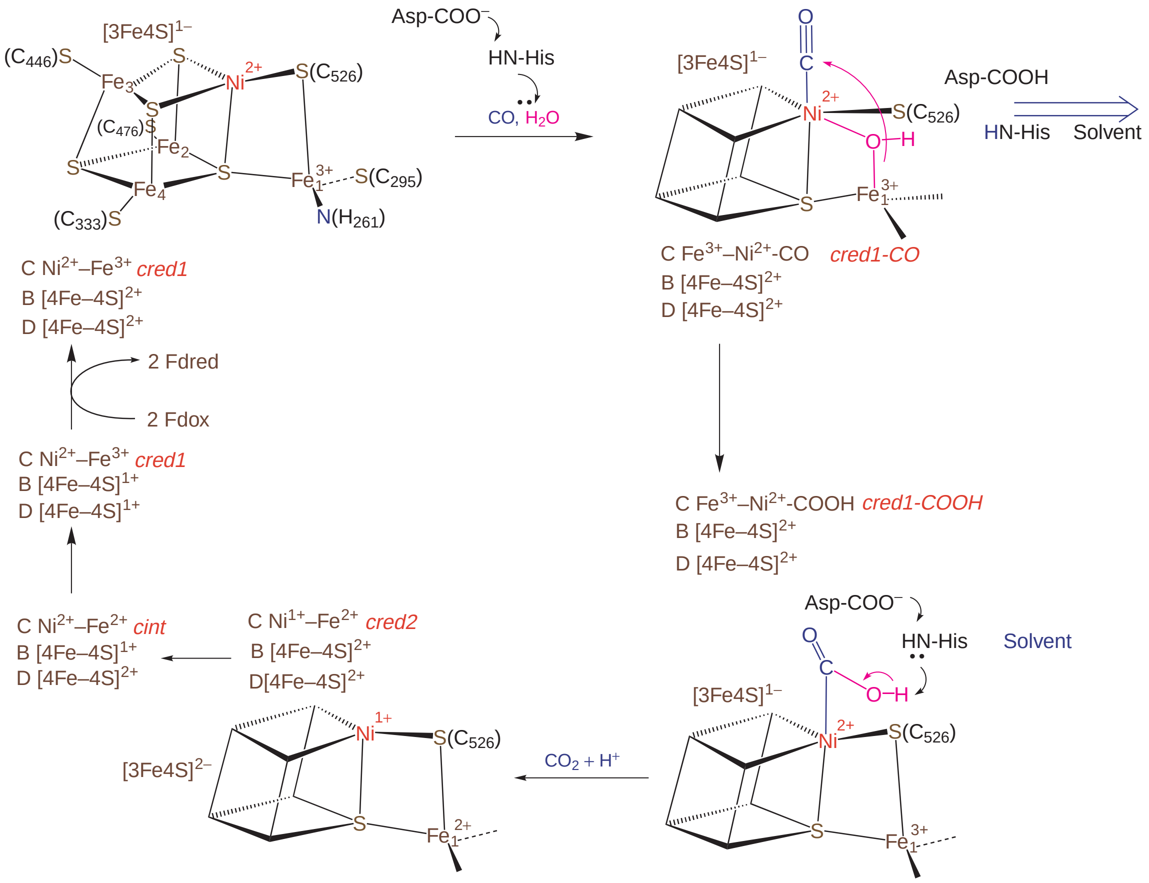


Figure 3 Proposed CODH mechanism. This mechanism proposes that the active state is Cred1, consistent with recent electrochemical studies,[74] which contains a bridging hydroxide at the binuclear NiFe center that serves as the nucleophile to attack a Ni-bound carbonyl forming a Ni-carboxylate. This OH, which is formed by acid-base catalysis by indicated acid-base residues, is in the position of the bridging sulfide in the *C. hydrogenoformans* structure.[7] The enzyme is proposed to remain in the Cred1 redox state until formation of CO_2 when it becomes two-electrons reduced to the Cred2 state. Conversion of Cred1 to Cred2 occurs faster than electron transfer from Cred2 to the FeS clusters,[75,76] which in turn reduce external electron acceptors. The electron transfer reactions are proposed to occur through a diamagnetic Cint state.[77]

such a channel would be detrimental, since the purpose of these proteins is to generate CO from CO_2 and utilize the CO in acetyl-CoA synthesis. Accordingly, there is both biochemical[79,80] and structural[6,72] evidence for a CO channel or tunnel between the C-Cluster in the CODH subunit and the A-Cluster in the ACS subunit. Such a channel would couple CO production to its utilization, explain why only very low levels of CO escape during growth of acetogenic bacteria, and protect host organisms that harbor the microbes from being exposed to potentially toxic CO levels.

The X-ray crystal structures of ACS both free[81] and bound to CODH[6,72] are available. The active site, called the A-Cluster, is present in a domain that is most distant from the interface with the CODH subunit separating the A- and C-Clusters by over 75 Å. The A-Cluster (Figure 1(d)) consists of a [4Fe−4S] cluster bridged to a Ni site (Ni_p) that is bridged by a cysteine thiolate to another Ni ion in a square-planar thiolato- and carboxamido-type N_2S_2 coordination environment. The distal site resembles the mononuclear Fe site of nitrile hydratase in which two Cys side chains and two backbone N atoms coordinate the Fe with a Cys-X-Cys motif.[82] Thus, one can describe the A-Cluster as a binuclear NiNi center bridged to a [4Fe−4S] cluster, similar to the Fe-only hydrogenases in which a Cys residue bridges a [4Fe−4S] cluster and a binuclear Fe site. The distal Ni atom is coordinated by the side chains of two Cys residues and by two backbone N atoms. When CO binds to CODH/ACS, an EPR signal, called the NiFeC signal is elicited, which appears to reflect the active state of the enzyme.

There has been controversy about the metal occupying the proximal metal center. In one structure, Cu was in high occupancy,[6] while, in another structure, Ni was in one molecule and Zn in the other.[72] There was evidence that the CuNi enzyme is active;[6,83] however, several papers insisted that only the NiNi form is active.[72,81,84–86] Recent spectroscopic, enzymatic, and computational studies provide further evidence that the NiNi enzyme is active and that the CuNi and ZnNi forms are not.[87]

A longstanding problem in studies of ACS are the heterogeneous composition of the protein, with only 20–30% activity, reflected in the intensity of the NiFeC EPR signal, described above. After recognition that the vulnerability of the proximal metal site in the A-Cluster to substitution with different metals underlies this heterogeneity, a protocol was developed in which a Cu^{+1}-specific chelator is used to remove the Cu and Ni is added to reconstitute the di-Ni center, resulting in nearly homogeneous preparations of ACS with a NiFeC signal intensity of ~0.8 spins per mol.[87] Recent DFT calculations[88] indicate that the NiFeC signal derives from a $[4Fe{-}4S]^{2+}$ (net $S = 0$) cluster bridged to a Ni(I)($S = 1/2$) at M_p that is bridged to square-planar Ni(II) ($S = 0$) at M_d, with the spin predominantly on the Ni(I).

Figure 4 summarizes two proposed catalytic cycles for ACS. In a mechanistically related reaction sequence, called

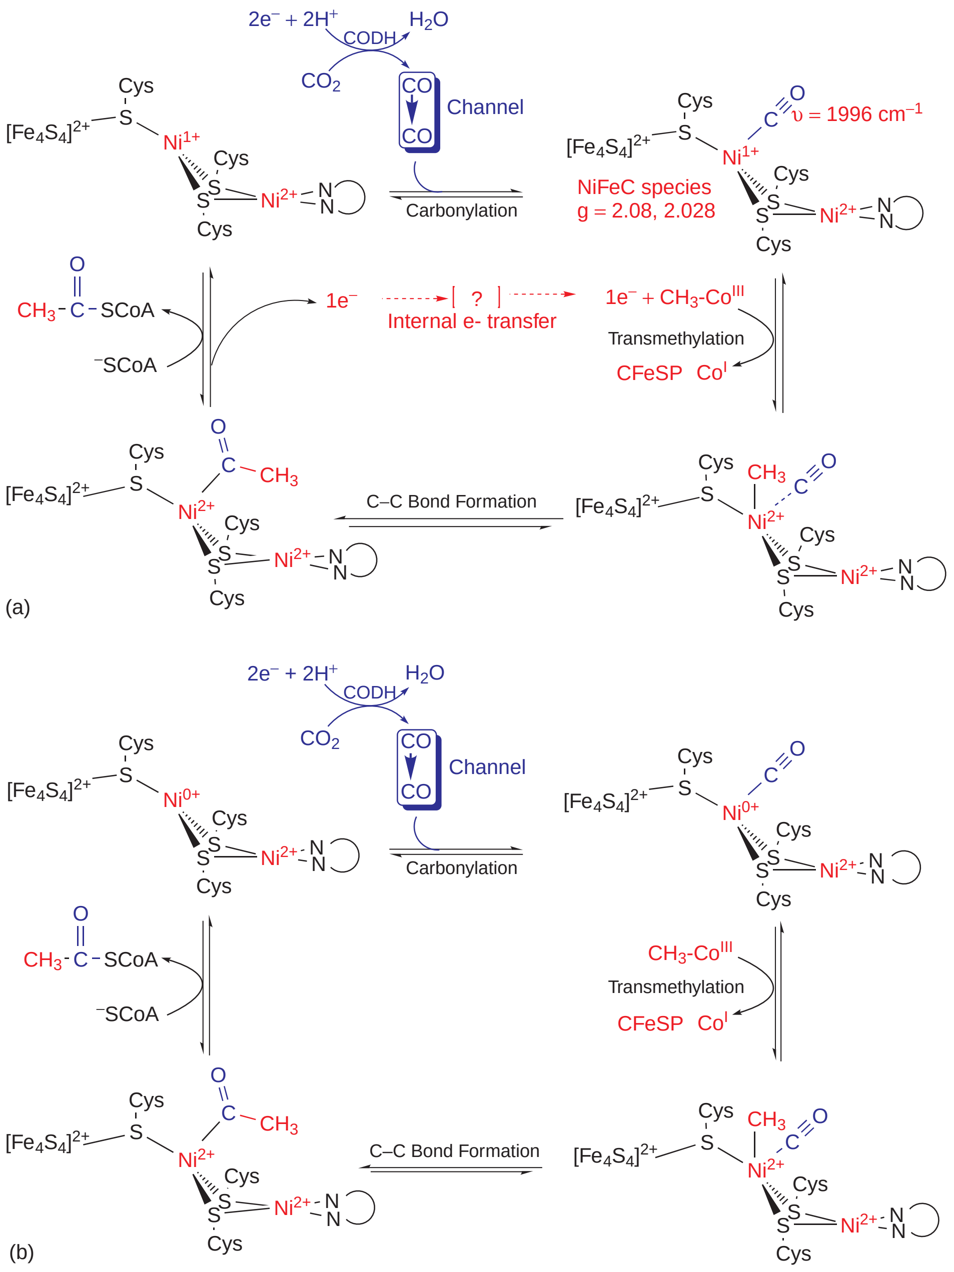

Figure 4 Proposed ACS mechanisms. The major difference between the two mechanisms is the oxidation state of the proximal Ni. In both cases, CO emerges from the channel and binds to the proximal metal of the A-Cluster to form a Ni–CO intermediate. Then, the Ni center performs nucleophilic attack on the methyl group of methylated CFeSP to form a $(CH_3)(CO)$ intermediate state of the A-Cluster. Then, carbon–carbon bond formation occurs by condensation of the methyl and carbonyl groups to form an acetyl-metal species. Finally, CoA binds to cleave the acetyl group as acetyl-CoA. See text for more details

the Monsanto or Reppe process, a rhodium complex catalyzes acetate formation from methanol and CO in the presence of HI through methyl-Rh, Rh-CO, and acetyl-Rh organometallic intermediates. ACS catalyzes the final steps of a biological process called the Wood–Ljungdahl pathway in which a methyl group, CO, and CoA are condensed to form acetyl-CoA at the A-Cluster of ACS. Although it also has been proposed that the methylation precedes carbonylation,[89] the first step in both reaction sequences proposed here is the binding of CO, emerging from the protein channel, to the A-Cluster to form a Ni–CO intermediate. In the top mechanism, the carbonylated enzyme is a Ni^{1+}-CO intermediate, the NiFeC species, which has been characterized by IR[90,91] and EPR[92] spectroscopy and has been shown to be catalytically competent in the pathway.[93] In the bottom mechanism, a diamagnetic Ni^0 active enzyme has also been proposed.[72] The next step is nucleophilic attack of the A-Cluster on the methyl group of methylated CFeSP to form a methylated state of the A-Cluster.[93] This reaction generates a diamagnetic product, which is easily accommodated into the bottom mechanism; however, this would require a one-electron reduction to accompany methylation if a diamagnetic CH_3–Ni^{+2} species is the product. This is proposed to occur through an internal electron transfer reaction, which could involve the FeS cluster. Then, carbon–carbon bond formation occurs by condensation of the methyl and carbonyl groups to form an acetyl-metal species. Finally, CoA would bind and cleave the acetyl group as acetyl-CoA. This would liberate two electrons, which would regenerate the Ni^0 state in the bottom mechanism. In the top mechanism, the electron transferred during the methylation would be returned and the other electron would be used to regenerate the Ni^{1+} active site. The overall reaction sequence is strongly inhibited by CO[94] and it appears that it is the methylation step that is inhibited.[93]

Based on the crystal structures, it is clear that the ACS subunit assumes two conformations: one in which the A-Cluster is inaccessible and the channel accessible to solvent and another in which the A-Cluster is accessible and the CO channel is inaccessible to solvent. Recent biochemical evidence indicates that major conformational changes occur during the catalytic cycle of acetyl-CoA synthesis.[95]

6 METHYL-COENZYME M REDUCTASE (MCR) (EC 2.8.4.1)

MCR catalyzes the final step in the biological synthesis of methane. Methanogenesis occurs in a unique group of microbes, called methanogens, which are members of the so-called third kingdom of life, the archaea. These organisms use very simple substrates as a source of carbon and energy, including H_2/CO_2, methanol, CO, methylamines, acetic acid, and methyl mercaptans. All biologically produced methane is the result of MCR activity and has reached a global emission rate of 560 million metric tons per year and a 2002 level of 1.75 ppm.

MCR catalyzes the conversion of methyl-coenzyme M (methyl-SCoM) and N-7-mercaptoheptanoylthreonine phosphate (CoBSH) to methane and the mixed disulfide CoBS-SCoM (Reaction 5, Table 1). Methanogenesis and MCR have both been reviewed fairly recently.[96,97] At the active site of MCR is Coenzyme F_{430} (Figure 1(c)), which is a nickel tetrapyrrole (specifically, a tetrahydrocorphin), exhibiting a maximum absorption at ∼430 nm in its Ni^{2+} state, making it bright yellow. F_{430}, like porphyrin, chlorophyll, and vitamin B_{12}, is derived from 5-aminolevulinic acid. The structure of free F_{430} was elucidated by X-ray crystallographic and NMR methods. It is the most reduced tetrapyrrole in nature, containing four conjugated double bonds linking Rings B, C, and D and one isolated double bond in Ring A. Based on X-ray crystallographic studies of the protein, F_{430} forms the base of a narrow well that accommodates the two substrates and shields the reaction from solvent.[5] The Ni site is ligated by the four tetrapyrrole N atoms, a side chain oxygen of a glutamine residue, and a sixth ligand that differs with the state of the enzyme. The structures of the inactive nickel (II) enzyme in complex with CoM and CoB ($MCR_{ox1-silent}$) and in complex with the heterodisulfide CoM-S-S-CoB product (MCR_{silent}) have been resolved at 1.16 Å and 1.8 Å resolution, respectively.[98]

Several states of MCR exhibit EPR signals. This includes MCR_{red1}, which is accepted to contain Ni^{1+} and is the active state of the enzyme. This assignment is well accepted based on the similarity of its UV-visible and EPR spectra with isolated Ni^IF_{430} and on DFT computations.[99,100] Several spectroscopic characteristics led to the hypothesis that red1 may also have undergone tetrapyrrole ring reduction; however, electrochemical,[101] and MCD and computational studies[100] demonstrate that this is incorrect – red1 retains the five double bonds present in the Ni^{2+} states. Another important form is MCR_{ox1}, which retains the basic symmetry of the red1 EPR signal and similar nitrogen hyperfine splitting constants. Recent computational studies indicate that the ox1 state should be described as a Ni^{2+} state coupled to a thiyl radical (formally equivalent to a Ni^{3+} state).[100]

EPR spectroscopic studies with ^{33}S-labeled coenzyme M demonstrate that, when CoBSH and CoMSH are both present, the thiol group of CoMSH interacts with the Ni(I) of F_{430}.[102] Apparently, CoBSH is required for MCR to exhibit this interaction.

Steady-state kinetic and crystallographic studies support an ordered ternary complex mechanism in which first methyl-SCoM and then CoBSH must bind before methane is formed. Presteady-state kinetic studies indicate that CoBSH is required for even a single turnover of methane formation, suggesting that CoBSH is integrally involved in the steps leading up to cleavage of the C–S bond of methyl-SCoM.[103] This may indicate that CoBSH forms an adduct with methyl-SCoM (a methylsulfuranyl species) before the methyl group is cleaved or that CoBSH is an obligate proton donor for the reaction. In many proposed mechanisms, a methyl-Ni intermediate is

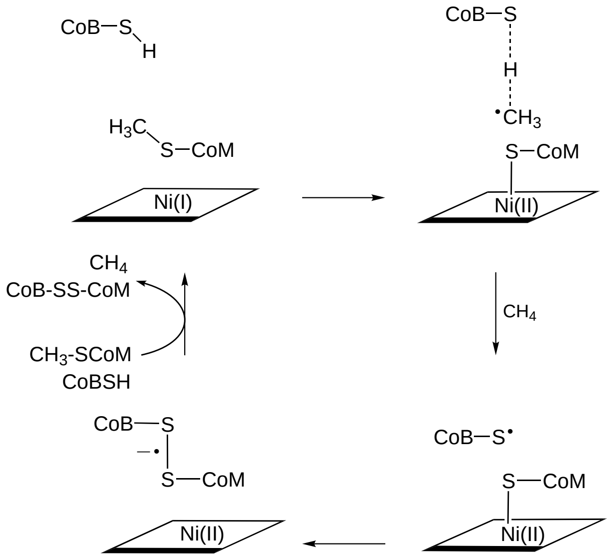

Figure 5 Proposed MCR mechanism. See text for details

included based on studies demonstrating that the Ni(I) form of the pentamethyl ester of F_{430} reacts with activated methyl donors (e.g. methyl sulfonium ions and methyl iodide) to yield methane through protonation of a methylnickel intermediate (*see* ***Nickel: Organometallic Chemistry***).

Density functional calculations indicate that a methyl-Ni species could not be part of the catalytic cycle of methane formation; instead methane formation occurs through a radical mechanism (Figure 5) in which a methyl radical abstracts a hydrogen atom from CoBSH to form methane.[104] *Step 1* involves homolytic cleavage of the C-S bond of methyl-CoM to generate a methyl radical and a thiyl radical on CoM. The thiyl radical is then proposed to accept an electron from Ni(I) to generate Ni(II) and the CoM-S^- thiolate. Negative charge on the thiolate is proposed to be stabilized by H bonding interactions from two active site tyrosine residues. In *Step 2*, the methyl radical is proposed to abstract a H-atom from CoBSH to form methane and a thiyl radical on CoB. This step should lead to inversion of stereochemistry at carbon. If so, the H-atom transfer to the methyl radical must occur before the methyl group has a chance to rotate in the active site. *Step 3* involves formation of a S–S bond between CoBS and $CoMS^-$, to generate a disulfide anion radical, while *Step 4* involves reduction of Ni(II) to regenerate active Ni(I) F430, release of products, and binding of substrates.

7 SUPEROXIDE DISMUTASE (SOD) (EC 1.15.1.1)

SOD protects cells against the detrimental effects of superoxide, a reactive oxygen species, by catalyzing the conversion of superoxide to hydrogen peroxide and oxygen (Reaction 6, Table 1).[105] The dismutation reaction catalyzed

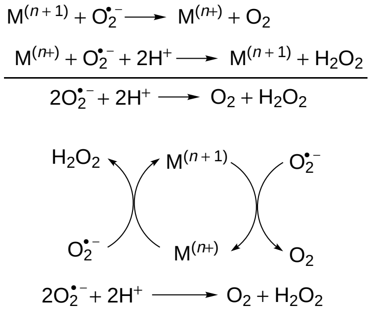

Figure 6 SODs catalyze the formation of hydrogen peroxide and oxygen from superoxide in a two-step reaction in which the metal is first reduced and then reoxidized by superoxide

by SODs proceeds via a mechanism wherein the metal is first reduced and then reoxidized by superoxide (Figure 6). Since the potentials involved in the oxidation and reduction of superoxide at pH = 7 are −0.33 and 0.87 V, respectively,[106] the metal center must have a redox potential between these extremes. Four types of SODs are known and are typically classed by their active-site metal composition: MnSOD, FeSOD, CuZnSOD, and NiSOD. The NiSOD, which has been identified in some Streptomyces[107] and cyanobacteria, has approximately the same catalytic rate constant as the CuZn enzyme, about $10^9\ M^{-1}\ s^{-1}$.[108]

Like the NiFe hydrogenase, NiSOD is translated as a pro-protein that requires processing to become an active enzyme. While the large subunit of hydrogenase requires processing of the C-terminal, 14 residues must be cleaved from the N-terminal of Ni SOD to generate an N-terminal histidine residue. Because active NiSOD could not be obtained without correct N-terminal processing, Maroney developed a strategy for heterologous expression of the SOD as a C-terminal fusion with a leader sequence containing a cleavable his tag sequence.[109]

Based on the XAS and EPR spectral changes associated with the reduction of NiSOD, it appears that it is the $Ni^{3+/2+}$ couple that is involved in superoxide disproportionation.[110] Spectroscopic studies indicated that the SOD active site could be either a mononuclear or a binuclear Ni site;[110,111] however, the X-ray crystallographic studies indicate a mononuclear Ni center (Figure 1(g)) that is coordinated by the N-terminal amino group of His1 and the amide nitrogen of Cys2, and the side-chain thiolate sulfurs of Cys2 and Cys6.[112,113] EPR and XAS studies indicate that the reduced 2+ state consists of a square-planar Ni ion that becomes square pyramidal in the 3+ state, as the side-chain ring nitrogen of His1 becomes a fifth ligand.[111] The existence of an axial nitrogen ligand in the five-coordinate Ni(III) state appears to be responsible for the nitrogen hyperfine splittings observed by EPR,[110] however, it is puzzling that the H1Q mutant still exhibited nitrogen hyperfine splittings. The sulfur ligands have been proposed to play a major role in poising the $Ni^{3+/2+}$ redox couple in the appropriate range for catalyzing both the reduction and

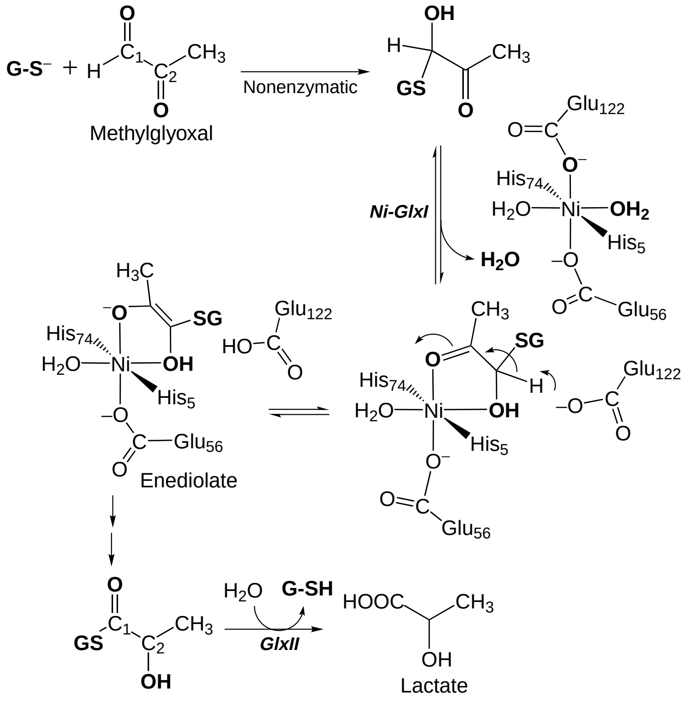

Figure 7 Mechanism of gloxylase I in methylglyoxal degradation. See text for details

the oxidation of superoxide,[110] and may also play a role as a source of protons in catalysis.[111]

8 GLYOXALASE-I (EC 4.4.1.5)

Methylglyoxal, which is a toxic species produced by several cellular reactions including the misfiring of triosephosphate isomerase during glycolysis, is hydrolyzed by the two-component glyoxalase system (GlxI and GlxII). As shown in Figure 7, after glutathione (GSH) reacts nonenzymatically with methylglyoxal to form a hemithioacetal, GlxI, the Ni component, catalyzes an isomerization reaction forming S-D-lactoylglutathione, which is hydrolyzed to lactate and GSH by GlxII. Glyoxal is harmful because it forms covalent adducts with DNA and proteins.

Although the yeast and human glyoxalases are Zn-dependent enzymes, the *E. coli* enzyme is specific for Ni.[114] The Ni site exhibits octahedral Ni coordination (Figure 1(f)), which is similar to the Zn coordination environment in the human enzyme.[115] *Yersinia pestis*, among other pathogens, are predicted to contain a Ni-dependent glyoxalase-I species.[116]

A suggested mechanism (Figure 7) for the *E. coli* GlxI[115] based on the X-ray structure (Figure 1(f)) includes binding of substrate to displace one of the water molecules and Glu122, which would allow Glu122 to act as a general base to abstract a proton from the substrate, which would lead to formation of the enediolate intermediate still coordinated to the Ni ion. For the Zn enzyme, it was pointed out that displacement of the Glu122 from coordination with the metal would increase the pK_a of the carboxyl group, while coordination of the substrate should decrease the pK_a of C1-H and that these combined effects would promote catalysis.[117] Reprotonation at C2 would form the product, which will then dissociate from the metal and leave the active site to serve as substrate for Glx2.

9 ACI-REDUCTONE DIOXYGENASE

During polyamine and ethylene biosynthesis, *S*-adenosylmethionine (AdoMet) is converted to methylthioadenosine.

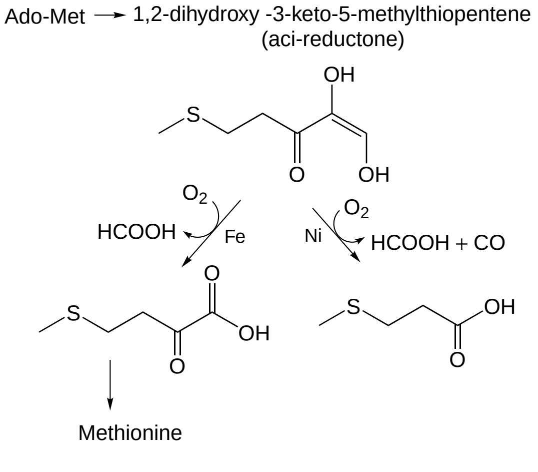

Figure 8 Role of aci-reductone dioxygenase in methionine salvage

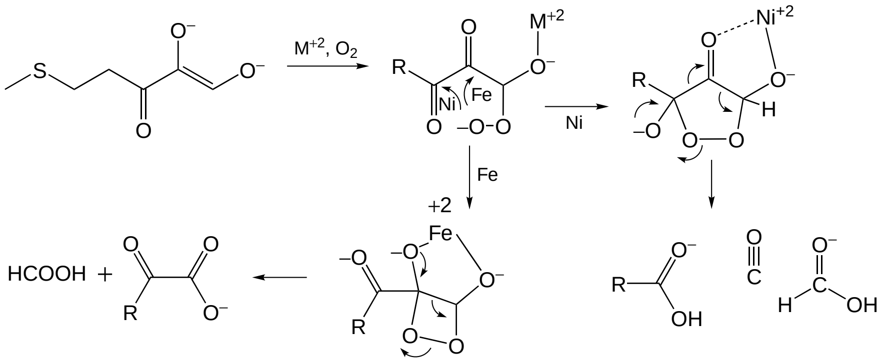

Figure 9 Proposed mechanism of aci-reductone dioxygenase. See text for details[9]

Regeneration of AdoMet is accomplished by the methionine salvage pathway, which converts methylthioadenosine to methionine. Besides regenerating methionine, this pathway functions to control the concentration of methylthioadenosine, which is a powerful inhibitor of polyamine biosynthesis and transmethylation reactions.[118] A key intermediate in the methionine salvage pathway is 1,2-dihydroxy-3-keto-5-methylthiopentene (aci-reductone), which is oxidized to the α-ketoacid precursor of methionine by aci-reductone dioxygenase (Figure 8). This dioxygenase catalyzes competing reactions, depending on its metal composition. The Fe-enzyme forms the methionine precursor, while the Ni enzyme generates methylthiopropionate, which is cytotoxic.

Aci-reductone dioxygenase folds into a beta-sandwich or jellyroll structure. The Ni active site (Figure 1(h)) is located at the loops connecting several of the beta sheets in a pseudo-octahedral environment consisting of oxygen and nitrogen ligands donated by the nitrogen atoms of three histidine residues, the oxygens from one glutamate residue, and the oxygens of two water molecules.

Figure 9 describes a proposed mechanism for the dioxygenase reaction based on enzymatic and structural studies.[9,118] It is proposed that the substrate binds as a dianion, which ligates the metal ion. Oxygen would then react to form an organic peroxide anion, which would then form a cyclic peroxide intermediate. The different reaction specificity is proposed to result from attack of the peroxide oxygen on alternative carbons. For example, the Ni-ARD would direct attack of the peroxide anion at the C3 carbonyl to form a five-membered peroxide intermediate, while the Fe-ARD would attack at carbon 2 to form a four-membered cyclic peroxide.

1 INTRODUCTION

Ni has the atomic number 28, atomic weight 58.69, and electron configuration [Ar]$3d^8 4s^2$, and has five naturally occurring isotopes, ^{58}Ni 68.27%, ^{60}Ni 26.10%, ^{61}Ni 1.13%, ^{62}Ni 3.59%, and ^{64}Ni 0.91%. Ni is the 22nd most common element in the Earth's crust, with an estimated abundance of 99 ppm. The element was isolated in 1751 by A. F. Cronsted and named after the ore '*Kupfernickel*'. Ni is widely distributed in silicate, sulfide, oxide, and arsenide ores; commercially important ores include garnierite, $(Ni,Mg)_6Si_4O_{10}(OH)_8$, limonite, $(Fe,Ni)O(OH)\cdot xH_2O$, and pentlandite, $(Ni,Fe)_9S_8$. The element is ferromagnetic and has a face-centered cubic structure.

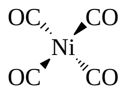
2 GENERAL FEATURES

The literature on the coordination chemistry of Ni is immense, and this article can only summarize general features and properties. Comprehensive reviews of the literature up to 1984 and up to 2002 have appeared,[1,2] while general summaries of Ni chemistry are given in inorganic textbooks[3] (*see also* ***Nickel: Organometallic Chemistry*** for descriptions of the organometallic and cluster chemistry of Ni).

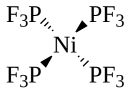
The coordination chemistry of Ni features a very wide variety of mono- and polydentate ligands, with metal oxidation states ranging from 0 to +IV, although organometallic Ni^{-I} and Ni^{-II} species have been reported. The most common oxidation state by far is Ni^{II}, although Ni^0 complexes are also well known. Ni^I and Ni^{III} species are less common, while Ni^{IV} complexes are established only for certain ligand types. Table 1 summarizes typical data on the oxidation states and stereochemistries of Ni complexes. The basic electronic and spectral features of Ni complexes have been reviewed.[4]

2.1 Nickel(0)

Ni^0 complexes have a d^{10} electron configuration and are typically stabilized by π-acceptor ligands such as PR_3, CO, alkenes, N_2, and CN^-. Thus, bonding in Ni^0 species is usually highly covalent, with strong π-backdonation from the electron-rich metal center to the π-acceptor ligand orbitals. Many Ni^0 complexes are organometallic species (*see* ***Nickel: Organometallic Chemistry***) and often have four-coordinate, tetrahedral geometries with an overall closed-shell 18-electron configuration, for example, $[Ni(CO)_4]$ (**1**) and $[Ni(PF_3)_4]$ (**2**). With more bulky tertiary phosphine ligands, three-co-ordinate Ni^0 complexes can be prepared, for example, $[Ni(PPh_3)_3]$ and $[Ni(PCy_3)_3]$. Square-planar adducts with O_2, CO_2, CS_2, and SO_2 have also been reported; this stereochemistry maximizes orbital overlap between the metal center and the adduct molecule(s) and may also reflect a degree of oxidative addition at Ni^0 to afford a formal Ni^{II} species. Ni^0 complexes are diamagnetic and generally highly reactive via oxidative-addition reactions to give octahedral Ni^{II} products (*see Catalysis*).



(**1**)



(**2**)

2.2 Nickel(I)

Ni^I complexes are relatively rare and are often stabilized by specialized ligands such as N-donor macrocycles and P-donor tripodal systems. Ni^I has a d^9 electron configuration and its complexes are therefore paramagnetic with one unpaired electron. They show a variety of stereochemistries depending upon the ligands present, although four or five

Table 1 Nickel complexes

Metal oxidation state	Complex
0	$[Ni(PR_3)_3]$, $[Ni(PR_3)_4]$, $[Ni(CO)_4]$, $[Ni(CN)_4]^{4-}$, $[Ni(N_3P)](N_3P = \text{tripod})$
+1	$[Ni(PR_3)_3Br]$, $[Ni(L)]^+$ (L = tetraaza macrocycle), $[Ni(PR_3)_2\{N(SiMe_3)_2\}]$, $[Ni_2(CN)_6]^{4-}$
+2	$[Ni(NPh_2)_3]^-$, $[Ni_2(NR_2)_4]$, $[Ni(CN)_4]^{2-}$, $[NiCl_4]^{2-}$, $[NiX_2(PR_3)_2]$, $[Ni(CN)_5]^{3-}$, $[Ni(H_2O)_6]^{2+}$, $[Ni(bipy)_3]^{2+}$
+3	$[NiCl_2([14]aneN_4)]^+$, $[NiX_3(PR_3)_2]$, $[Ni([9]aneX_3)_2]^{3+}$ (X = N, S)
+4	$[NiF_6]^{2-}$

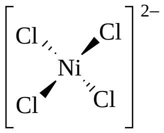
coordination is most common. Their general reactivity is based upon disproportionation to Ni^0 and Ni^{II}, electron-transfer reactions, and dimerization to give diamagnetic metal–metal bonded products.

2.3 Nickel(II)

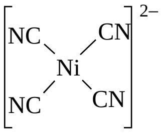
By far the most common oxidation state for Ni is the +II state with a d^8 electron configuration. Four, five, and particularly six coordination are all common geometries for Ni^{II} and depend upon the ligands present. Scheme 1 shows the d-orbital splitting pattern for tetrahedral, square-planar, tetragonal, and octahedral Ni^{II}.

2.3.1 Four Coordination

Four coordination for Ni^{II} is relatively common, with tetrahedral and square-planar geometries representing the two extreme possibilities. Good π-donor ligands such as halides tend to stabilize tetrahedral geometries, for example, $[NiCl_4]^{2-}$ (**3**), while π-acceptor ligands such as PR_3 and CN^- afford square-planar geometries, for example, $[Ni(CN)_4]^{2-}$ (**4**).

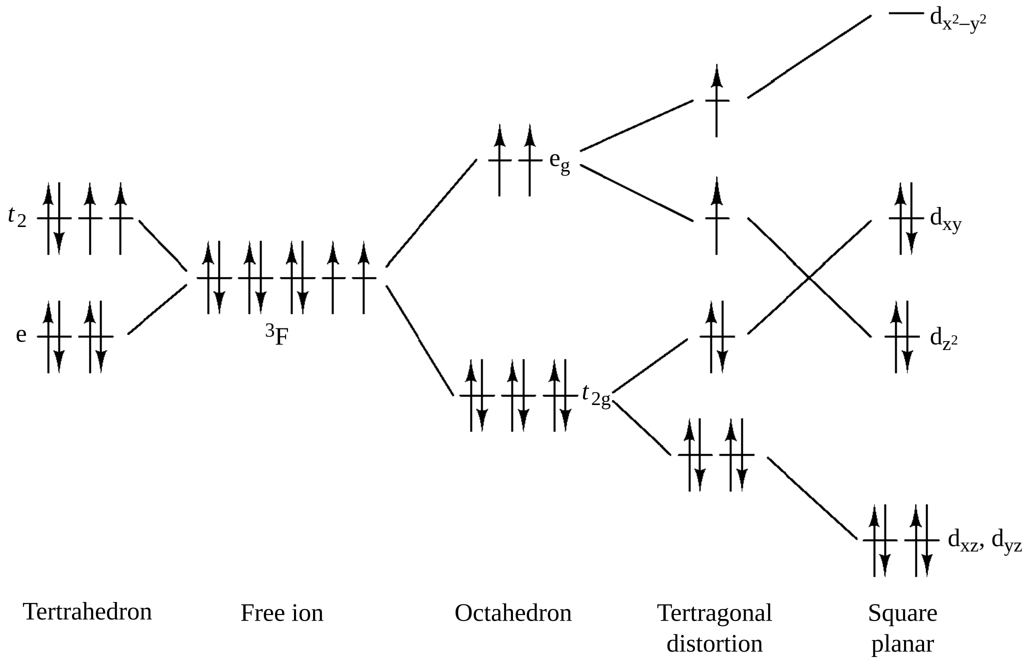


(**3**)

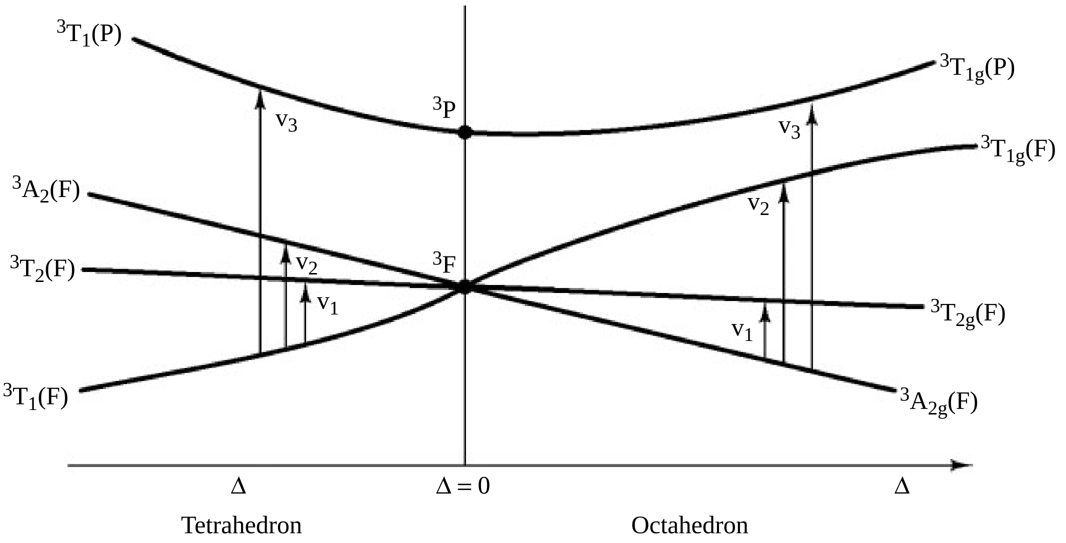


(**4**)

Tetrahedral complexes are usually highly colored (blue or green) with three expected d–d transitions, ${}^3T_1(F) \rightarrow {}^3T_2(F)$ (ν_1), ${}^3T_1(F) \rightarrow {}^3A_2(F)$ (ν_2), and ${}^3T_1(F) \rightarrow {}^3T_1(P)$ (ν_3), although the observed spectra tend to be complicated by spin–orbit coupling effects. Scheme 2 shows a simplified Orgel diagram (*see Tanabe–Sugano Diagram*) for tetrahedral and octahedral Ni^{II} complexes. The ligand field splitting parameter (*see Ligand Field Theory*) $10Dq$ for the complexes $[NiX_4]^{2-}$ varies from 4090, to 3790, to 3820 cm^{-1} for X = Cl, Br, I, respectively. Tetrahedral Ni^{II} would be expected to have two unpaired electrons, and such complexes do indeed show experimentally temperature-dependent magnetic behavior with μ_{eff} in the range 3.2 to 4.2 BM, consistent with a T ground-state for a $e_g^4t_{2g}^4$



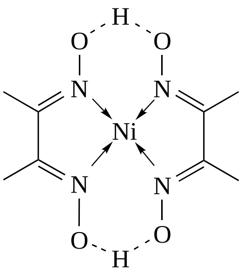
Scheme 1



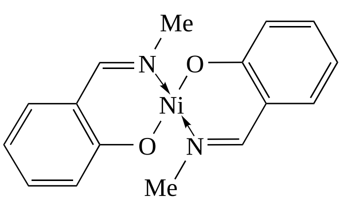
Scheme 2

configuration. The observed values of μ_{eff} for these complexes are related to the degree of distortion from pure tetrahedral coordination.

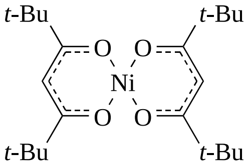
Square-planar Ni^{II} complexes are typically yellow, red, or brown in color, and are invariably diamagnetic with a spin-paired configuration, although there is one report of paramagnetic planar Ni^{II} species.[5] Planar coordination for Ni^{II} is common and is linked to the stabilization of this geometry for d^8 metal ions (*see* ***Palladium: Inorganic & Coordination Chemistry*** and ***Platinum: Inorganic & Coordination Chemistry***). Typical examples of square-planar Ni^{II} complexes include $[Ni(CN)_4]^{2-}$ (**4**), $[Ni(dmgH)_2]$ (**5**), $[Ni(Me\text{-}salen)_2]$ (**6**) and $[Ni(t\text{-}Bu_2acac)_2]$ (**7**).



(**5**)



(**6**)

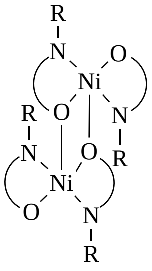


(**7**)

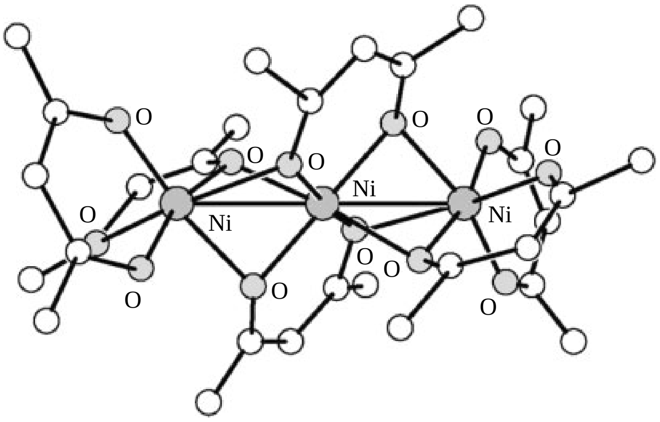
An interesting feature in four-coordinate Ni^{II} chemistry is the interconversion of paramagnetic, tetrahedral, and diamagnetic square-planar geometries.[6] Thus, complexes of the type $[NiX_2(PR_3)_2]$ can be tuned towards one stereochemistry rather than another by variation of X (halide) and PR_3 ligands. For example, $[NiCl_2(PPh_3)_2]$ is tetrahedral, while $[NiBr_2(PEt_3)_2]$ is square-planar. Temperature-dependent equilibria between tetrahedral (blue or green) and square-planar (yellow or red) geometries are also seen for related complexes incorporating PCy_3 and PPh_2Bu ligands. Moreover, in the solid-state structure of $[NiBr_2(PPh_2Bz)_2]$ both tetrahedral and square-planar forms are observed. These changes from tetrahedral to square-planar geometries are influenced by the steric bulk of the ligands, with tetrahedral coordination favored in general by highly bulky ligands.

Another common feature of square-planar Ni^{II} complexes is their ability to coordinate extra ligands in solution to set up equilibria between four-, five-, and six-coordinate complexes (equation 1). Thus, diamagnetic square-planar complexes can be transformed in coordinating solvents, or in the presence of extra ligands, to paramagnetic, octahedral Ni^{II} species. These transformations can be monitored by electronic spectroscopy. Aggregation of planar units can also occur in both solid state and solution, to form paramagnetic polymers. Thus, $[Ni(Me\text{-}salen)_2]$ forms dimeric and polymeric oligomers via bridging of the O-donor across planar units (**8**).[7] Another example is the structure of $[Ni(acac)_2]$ (**9**), which is actually trimeric with bridging acac ligands between octahedral, paramagnetic Ni^{II} centers.[8] Thus, in addition to tetrahedral $\longleftrightarrow$ square-planar $\longleftrightarrow$ five-coordinate $\longleftrightarrow$ octahedral equilibria, monomer $\longleftrightarrow$ oligomer/polymer equilibria may also exist for Ni^{II} complexes.

$$[Ni(L)_4] \rightleftharpoons [Ni(L)_4X] \rightleftharpoons [Ni(L)_4X_2] \quad (1)$$



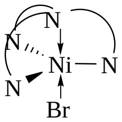
(**8**)



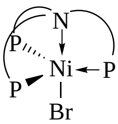
(**9**)

2.3.2 *Five Coordination*

Five-coordinate complexes usually incorporate polychelate or tripodal N-, P-, and As-donor ligands,[9] but are also observed in simpler systems such as $[Ni(CN)_5]^{3-}$ and $[Ni(PPhMe_2)_3(CN)_2]$. Interestingly, $[Ni(CN)_5]^{3-}$ has been crystallized and characterized as a square-based pyramidal and a trigonal bipyramidal species; this is consistent with facile Berry rotation (*see Berry Pseudorotation*) interconverting square-based pyramidal and trigonal bipyramidal geometries in five-coordinate transition metal complexes.[10] Five-coordinate complexes can be paramagnetic (high spin, $\mu_{eff} = 3.2–3.5$ BM), for example, $[NiBr(tren)]^+$ (**10**), or diamagnetic (low spin), for example, $[NiBr(NP_3)]^+$ (**11**).



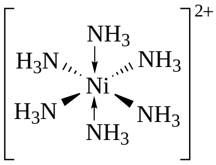
(**10**)



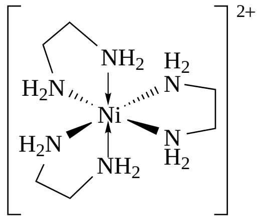
(**11**)

2.3.3 *Six Coordination*

Octahedral coordination is the most common geometry for Ni^{II} and is observed in a host of complexes with an extremely wide range of mono- and polydentate ligands, for example, $[Ni(L)_6]^{2+}$ (L = H_2O, py, NH_3 (**12**)), $[Ni(LL)_3]^{2+}$ (LL = en (**13**), bipy, phen), and $[Ni(terpy)_2]^{2+}$. Three d–d transitions, $^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)$ (ν_1, 10*Dq*), $^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$ (ν_2), and $^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$ (ν_3) (see Scheme 2), are expected for Ni^{II} in an octahedral field and these are usually observed. The value of 10*Dq* varies as a function of ligand donor set, with values of 7730 for $[Ni(DMSO)_6]^{2+}$, 8500 for $[Ni(H_2O)_6]^{2+}$, 10 750 for $[Ni(NH_3)_6]^{2+}$, 11 200 for $[Ni(en)_3]^{2+}$, and 12 500 cm^{-1} for $[Ni([9]aneN_3)_2]^{2+}$. The magnetic susceptibility of octahedral Ni^{II} is typically in the region $\mu_{eff} = 2.9–3.3$ BM. Octahedral Ni^{II} ($S = 1$) has a large zero-field splitting and so these complexes do not generally show EPR spectra, although paramagnetically shifted Nuclear magnetic resonance (NMR) spectra are observed in many cases.



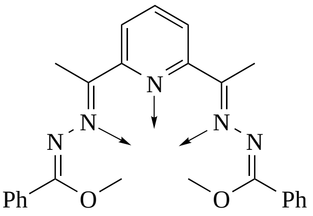
(**12**)



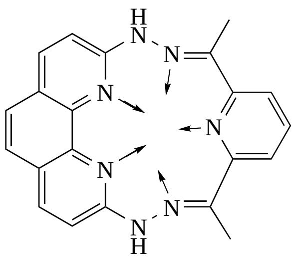
(**13**)

2.3.4 *Other Coordination*

Three coordination is very rare and has been observed in sterically hindered phosphine and amide complexes of type $[Ni(PPh_3)_3]$, $[Ni(NPh_2)_3]^-$, and $[(R_2N)Ni(\mu^2\text{-}NR_2)_2Ni(NR_2)]$.[11] Seven coordination, although rare, is observed in pentagonal bipyramidal complexes incorporating pentadentate chelate and macrocyclic complexes, for example, $[Ni(\mathbf{14})(L)_2]$[12] and $[Ni(\mathbf{15})(L)_2]^{2+}$.[13]



(**14**)

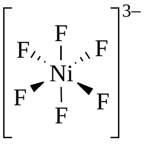


(**15**)

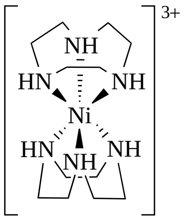
2.4 Nickel(III)

Ni^{III} complexes have a d^7 electron configuration [cf. Co^{II}] and are usually five-coordinate or Jahn–Teller distorted octahedral species (*see Jahn–Teller Effect*) with characteristic EPR spectra. Ni^{III} is stabilized by halides, as in $[NiF_6]^{3-}$ (**16**), and by strong σ-donor N- or P-ligands, as in $[Ni([9]aneN_3)_2]^{3+}$ (**17**) and $[NiBr_3(PR_3)_2]$ (**18**), and

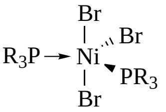
is usually prepared by chemical or electrochemical oxidation of the Ni^{II} precursors. Ni^{III} is still a relatively rare oxidation state, although increasingly more examples are being reported, particularly with polyaza macrocyclic ligands.[14] More recently, Ni^{III} centres have been implicated in the activity of [NiFe]hydrogenase enzymes (see Section 8).



(**16**)



(**17**)



(**18**)

2.5 Nickel(IV)

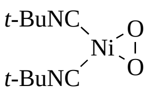
Ni^{IV} complexes have a d^6 electron configuration and are invariably octahedral and diamagnetic. They are stabilized by strong σ- and π-donors such as halide, O- and N-donor oxime, amino acid, and amido ligands. Ni^{IV} species are very highly oxidizing and often transient species. Several complexes assigned originally as Ni^{IV} species have been reformulated as ligand-oxidized products.

3 NICKEL(0)

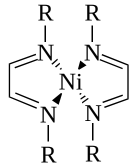
Ni^0 complexes are frequently highly reactive, air- and temperature-sensitive species, which undergo facile oxidative-addition reactions with a range of external substrates.

3.1 C-donor Complexes

The majority of Ni^0 complexes are organometallic species incorporating CO and related π-acceptor ligands, the best known being the tetracarbonyl species $[Ni(CO)_4]$ (**1**). Related isocyanide and cyanide complexes such as [Ni(CN-*t*-Bu)$_4$] and $[Ni(CN)_4]^{4-}$ have also been prepared. Both of these complexes are highly reactive and undergo substitution reactions with alkenes, alkynes, tertiary phosphines, CO, NO, and O_2.[15] [Ni(CN-*t*-Bu)$_2$(O_2)] (**19**) is a highly reactive complex and shows a square-planar stereochemistry at Ni with the O_2 ligand bound side-on (*see Side-on Coordination*).[16] The first stable complex of CO_2, $[Ni(\eta^2\text{-}CO_2)(PCy_3)_2]$, has been structurally characterized. Such electron-rich Ni^0 complexes undergo a host of oxidative coupling reactions with unsaturated organic molecules.[17] For an account of organometallic complexes and clusters of Ni, *see* ***Nickel: Organometallic Chemistry***.



(**19**)



(**20**)

3.2 N-, P-, As-, and Sb-donor Complexes

In general, N-donors are not sufficiently strong π-acceptors to stabilize low-valent states such as Ni^0. However, the diimine ligand dad can form stable tetrahedral Ni^0 complexes $[Ni(dad)_2]$ (**20**).[18]

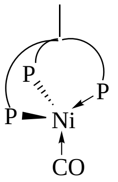
A wide range of Ni^0 phosphine and arsine complexes, $[Ni(L)_3]$, $[Ni(L)_4]$ ($L = PR_3$, AsR_3, SbR_3), and $[Ni(LL)_2]$ (LL = chelate ligand), can be prepared by reduction of Ni^{II} precursors in the presence of excess phosphine and arsine ligands. Alternatively, ligand replacement on $[Ni(cod)_2]$ or directly on to nickel sponge affords the same products (equations 2–4).[19]

$$NiX_2 \xrightarrow{2\,L} [Ni(L)_2X_2] \xrightarrow[\text{[H]}]{2\,L} [Ni(L)_4] \rightleftharpoons [Ni(L)_3] + L$$
$$\updownarrow \qquad (2)$$
$$NiX_2 \xrightarrow{LL} [Ni(LL)X_2] \xrightarrow[\text{[H]}]{LL} [Ni(LL)_2] \qquad [Ni(L)_2] + L$$

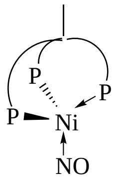
$$[Ni(cod)_2] + 4L \longrightarrow [Ni(L)_4] + 2\,cod \qquad (3)$$

$$[Ni] + 4L \longrightarrow [Ni(L)_4] \qquad (4)$$

With bulky PR_3 ligands, dissociation of ligand occurs to give the highly reactive $[Ni(PR_3)_3]$ and even $[Ni(PR_3)_2]$.[20] A range of mixed PR_3 and CO complexes $[Ni(CO)_{4-x}(PR_3)_x]$ ($x = 1-4$) and alkene complexes $[Ni(PR_3)_2(alkene)]$ have been reported. The complex [Ni(triphos)(CO)] (**21**) and related tripodal complexes can be readily isolated by reduction of Ni^{II} precursors in the presence of CO and triphos;[21] the analogous nitrosyl complex $[Ni(triphos)(NO)]^+$ (**22**) (NO is coordinated as NO^+ in this complex) can be prepared by a similar route.[22] A wide range of related tetrahedral nitrosyl complexes of Ni^0 incorporating bent NO, NO^-, and/or linear NO^+ ligands have been synthesized (*see Nitrosyl Complexes*).[23]



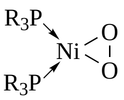
(**21**)



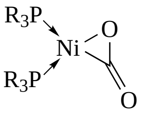
(**22**)

Reaction of [Ni(PR_3)$_4$] or [Ni(PR_3)$_2$(C_2H_4)] with O_2 affords the highly reactive species [Ni(PR_3)$_2$$O_2$] (**23**) which is related to the isocyanide complex (**19**). Ni^0–phosphine adducts of CO_2 (**24**),[24] CS_2 (**25**),[25] and SO_2 (**26**)[26] can also be prepared,[17] while the formation of mononuclear N_2 adducts has been proposed (equation 5).[27] The binuclear complex [Ni(PCy_3)$_2$]$_2$$N_2$ (**27**) has been structurally characterized and shows a μ^2-bridging N_2 ligand, N–N = 1.12 Å, with the sterically bulky cyclohexyl groups stabilizing the general structure.[28]

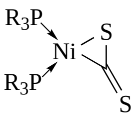
$$[Ni(PR_3)_3] \underset{}{\overset{N_2}{\rightleftharpoons}} [Ni(PR_3)_3N_2] \rightleftharpoons [Ni(PR_3)_3]_2N_2 \qquad (5)$$



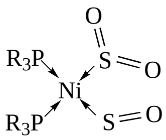
(**23**)



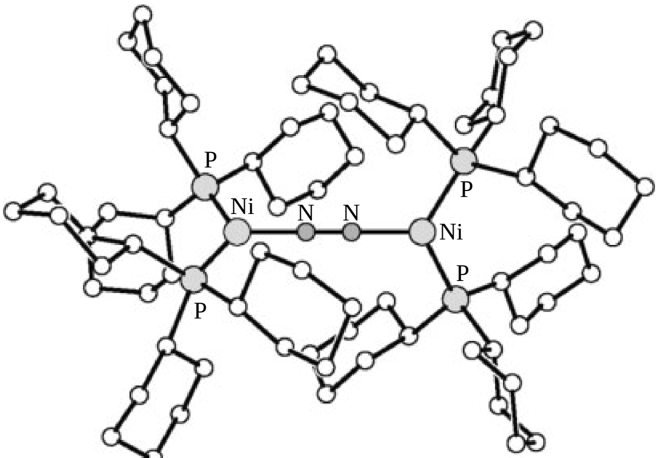
(**24**)



(**25**)

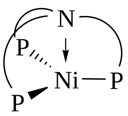


(**26**)

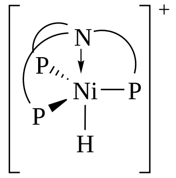


(**27**)

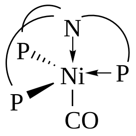
The tripodal Ni^0 complex [Ni(NP_3)] (**28**) can be prepared by reaction of Ni^{II} salts with NP_3 in the presence of reducing agents such as BH_4^-.[29] A series of related tripodal Ni^0 have been reported. The complex (**28**) and related tripodal species are highly reactive and add H^+ to form complexes of the type [Ni^{II}H(NP_3)]$^+$ (**29**), add CO to form [Ni(NP_3)CO] (**30**), and add P_4 to form [Ni(NP_3)(η^1-P_4)] (**31**).[30] Related P_3- and As_3-bridged dimers [Ni_2(triphos)$_2$(P_3)]$^{2+}$ (**32**), [Ni_2(triphos)$_2$(As_3)]$^{2+}$, and related mixed-metal complexes can be prepared by reaction of Ni^{II} salts with triphos in the presence of white phosphorus P_4 or yellow arsenic As_4.[31] The same reaction with P_4S_3 and As_4S_3 in place of P_4 and As_4, respectively, affords the mononuclear species [Ni(triphos)(P_3)]$^+$ (**33**) and [Ni(triphos)(As_3)]$^+$.[32] A fascinating complex [Ni(P-*t*-Bu)$_6$] (**34**) containing a planar P_6 ring has been reported from the reaction of $NiCl_2$ with (P-*t*-Bu)$_3$. By considering intramolecular P–P interactions, [Ni(P-*t*-Bu)$_6$] can be regarded as an 18-electron species.[33]



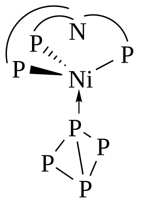
(**28**)



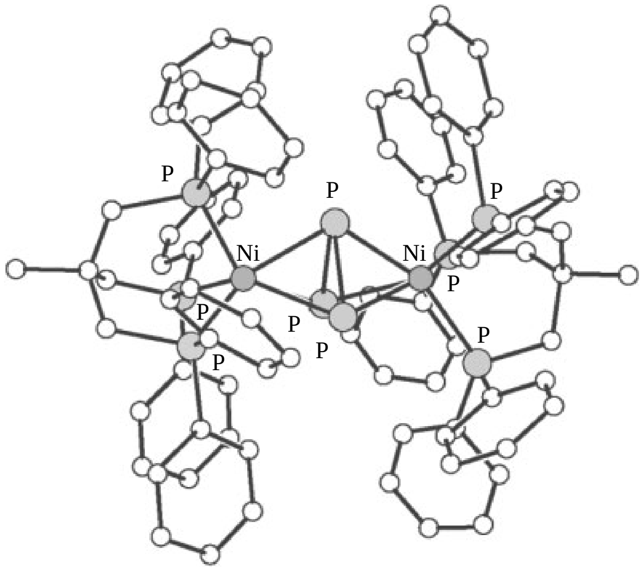
(**29**)



(**30**)



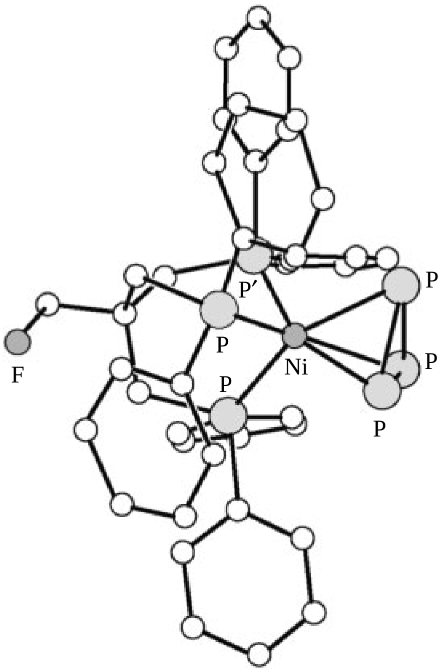
(**31**)



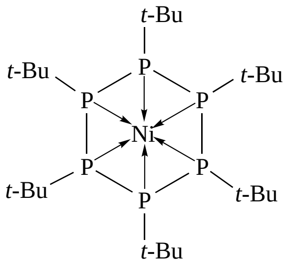
(**32**)

4 NICKEL(I)

In comparison with the relatively large number of Ni^0 complexes that have been reported, relatively few Ni^I compounds



(**33**)

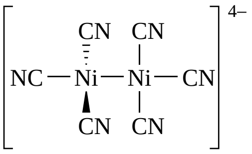


(**34**)

have been well characterized. Ni^{I} species are generally prepared via chemical or electrochemical reduction of Ni^{II} precursors, and are almost invariably highly reducing and air sensitive. They are often postulated as radical intermediates in electron-transfer reactions of Ni^{0} and Ni^{II} and have been implicated in the Ni-L form of [NiFe]hydrogenase. Mononuclear Ni^{I} species formally have a d^9 electron configuration and have magnetic susceptibilities corresponding to one unpaired electron, $\mu_{eff} = 1.7$ to 2.3 BM. Mononuclear Ni^{I} complexes are EPR active and often show $g_{\parallel} > g_{\perp} > 2.0023$ for a $(d_{x^2-y^2})^1$ ground-state configuration. The stereochemistries of Ni^{I} species vary from sterically hindered three-co-ordinate species, to four- and five-coordinate complexes. The chemistry of Ni^{I} complexes has been reviewed.[14]

4.1 C-donor Complexes

Reduction of $K_2[Ni(CN)_4]$ with K/NH_3 or Na/Hg affords $K_2[Ni(CN)_3]$, which has been shown to be a Ni^{I}–Ni^{I} bonded dimer $[Ni_2(CN)_6]^{4-}$ (**35**). The complex is diamagnetic with a Ni–Ni distance of 2.32 Å and the $Ni(CN)_3$ units twisted by 82° to one another.[34]



(**35**)

4.2 N-donor Complexes

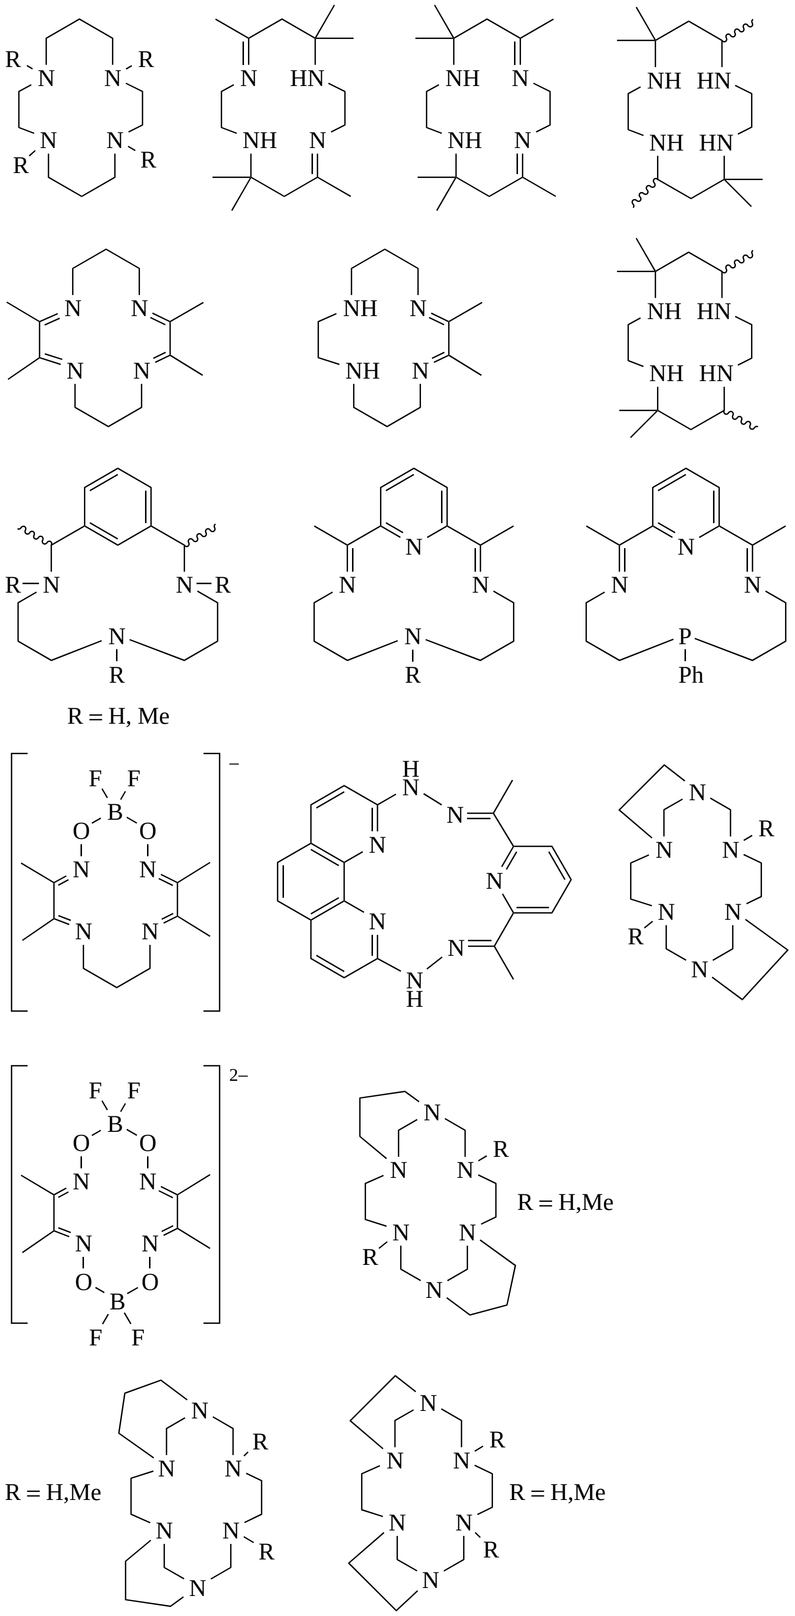
Electrochemical reduction of $[Ni(bipy)_3]^{2+}$ affords $[Ni(bipy)_3]^{+}$ and $[Ni(bipy)_3]$, which are formulated as Ni^{I} and Ni^{I}-$bipy^{-}$ radical anion complexes, respectively.[35] These species are highly reactive and illustrate the problems of assigning redox products as genuine metal-based or ligand-based radicals.

A very wide range of tetraaza macrocyclic complexes of Ni^{II} have been prepared and studied. An important feature of many Ni^{II} macrocycles is their high stability and inertness. Macrocyclic ligands can therefore be regarded as protecting groups for the metal center, and this has led to the study of metal redox properties and the electrochemical generation of Ni^{I} products.[36] Some of the ligands that have been studied for Ni^{I} complexation are listed in Scheme 3.

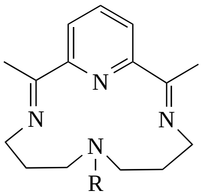
The redox properties of the complexes (the reversibility and potential of the $Ni^{II/I}$ couple) are related to the ring size, the donor atoms, the unsaturation, and the degree of functionalization of the macrocyclic ring. EPR spectroscopy has been particularly useful in differentiating between metal- and ligand-based radical species. Interestingly, the degree of alkylation at the N-donor ligands enhances the stabilization of Ni^{I} species by shifting the $Ni^{II/I}$ couple to more anodic potentials; this effect has been ascribed to solvation and stereochemical effects.[37] Interestingly, Ni^{I} species can also be generated from pentagonal bipyramidal Ni^{II} precursors.[13] Reduction of the $[Ni(\mathbf{36})]^{2+}$ by one electron affords a ligand-based radical species; addition of CO to these reduced solutions gives a metal-based Ni^{I} product $[Ni(\mathbf{36})CO]^{+}$, which has been assigned by EPR spectroscopy. This is an example of intramolecular electron transfer within a macrocyclic complex (equation 6).[38]

$$[Ni^{II}(36^{\bullet-})]^{+} \underset{-CO}{\overset{+CO}{\rightleftharpoons}} [Ni^{I}(36)(CO)]^{+} \qquad (6)$$

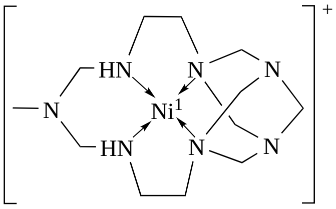
The single-crystal X-ray structures of macrocyclic Ni^{I} species showing square-planar coordination at the metal center have been reported. The complexes (**37**)[39] and (**38**)[40] both show Ni^{I} bound to four aza N-donors of a saturated macrocycle to give square-planar coordination at the metal center. The electrochemistry of a wide range of Ni^{II}–porphyrin complexes



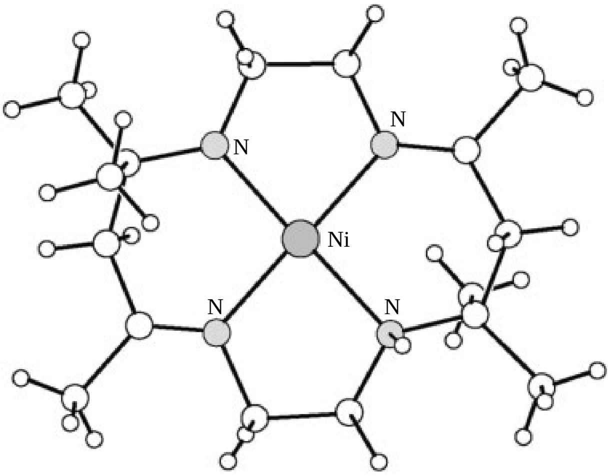
Scheme 3



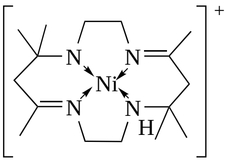
(**36**)



(**37**)

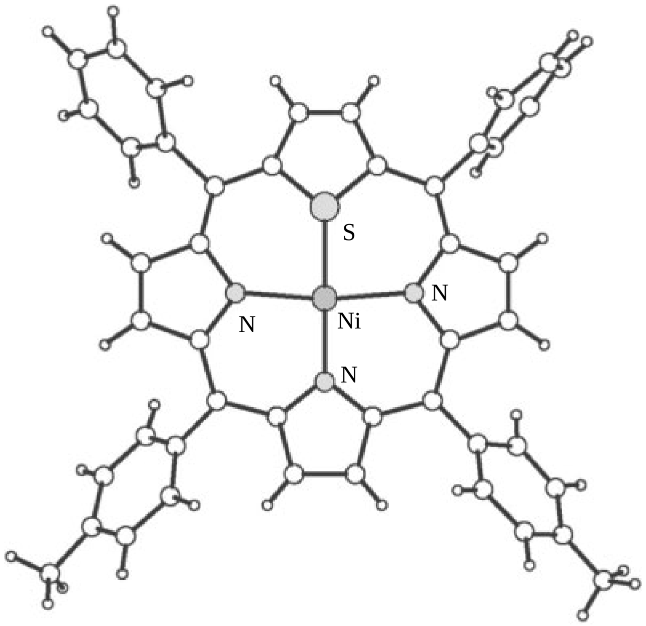


(a)

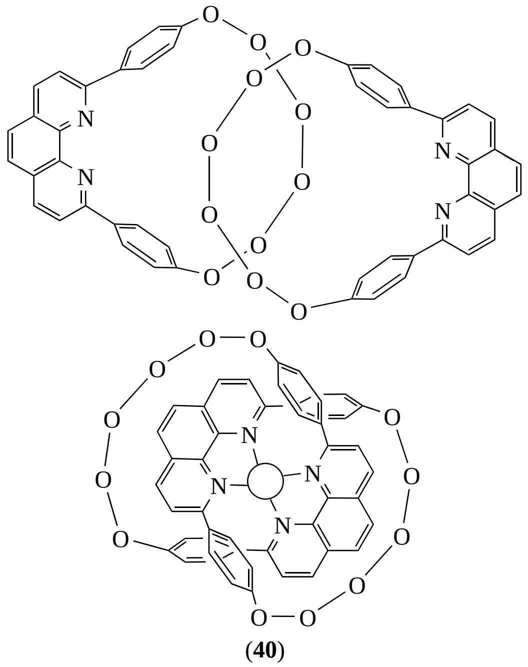


(b)

(**38**)



(**39**)



(**40**)

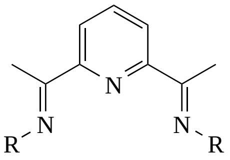
has been investigated, particularly with regard to the formation of Ni^{I} and ligand-based ligand-radical anions.[41] The structure of a Ni^{I} complex of a modified porphyrin has been reported; in (**39**), one of the N-donors of the porphyrin has been replaced by an S-donor, with the resultant SN_3-donor ligand binding to Ni^{I} in a square plane. Interestingly, the S-donor acts as a long-range bridging ligand to another [Ni(L)] unit to give an overall binuclear structure.[42]

A highly unusual air-stable Ni^{I} species has been produced using an interlocking catenane ligand (**40**). The Ni^{II} precursor has an enforced tetrahedral geometry and shows a particularly anodic $Ni^{II/I}$ couple. The resultant Ni^{I} species, which is assumed to be tetrahedral, is stable in air for extended periods.[43] The electrochemical generation and stabilization of Ni^{I} centres by 2,6-diiminopyridyl ligands (**41**) in $[Ni(\mathbf{41})_2]^{2+/+}$ has been reported.[44]

The mechanisms and kinetics of CO_2 reduction by Ni^{I} macrocycles have been investigated.[45]

An electrochemical study of Ni^{II} meso-tetraphenylhomoporhyrins, -secochlorins, and -chlorophin has shown that

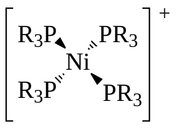
the rigid homoporphyrin complexes are reduced at the ligand sites. In contrast, the more flexible chlorin and secochlorin complexes form Ni^{I} complexes upon reduction as the increased flexibility can better accommodate the larger Ni^{I} ion.[46]



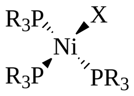
(**41**)

4.3 P- and As-donor Complexes

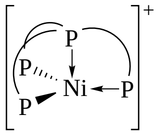
A series of air-sensitive trigonal bipyramidal and trigonal pyramidal Ni^{I} complexes, $[Ni(PR_3)_4]^+$, $[NiX(PR_3)_3]$, $[NiX(AsR_3)_3]$ (X = halide), and $[Ni(tripod)]^+$ and [NiX(tripod)] (tripod = face-capping tripodal P, As ligand), have been reported.[47] The methods of synthesis of these species are varied, but essentially are based on the reduction of Ni^{II} or oxidation of Ni^{0} precursors. A range of four- and five-coordinate Ni^{I} complexes have been structurally characterized and some of these are illustrated in (**42**)–(**46**).



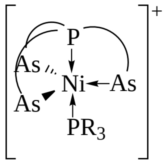
(**42**)



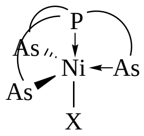
(**43**)



(**44**)

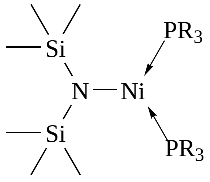


(**45**)

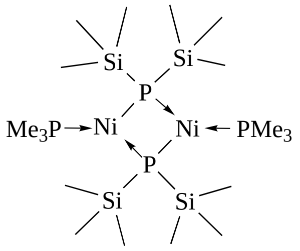


(**46**)

The magnetic moments of these complexes are consistent with the presence of one unpaired electron. Unusual three-coordinate Ni^{I} species (**47**) and (**48**) have been isolated using sterically hindered amido ligands.[48]



(**47**)



(**48**)

4.4 S-donor Complexes

The reductive electrochemistry of several Ni^{II} complexes of unsaturated dithiolate ligands has been examined.[49] On the basis of the electrochemical redox potentials, EPR spectral evidence, and SCF calculations, these reduction products are best formulated as Ni^{I} complexes for dithiocarbamate and 1,2-dithiolene ligands, and as Ni^{II} stabilized ligand-radical anions for dithiodiketonate species. It is often difficult to assign electron-density distributions within a molecule, particularly with delocalized ligands such as dithiolenes.

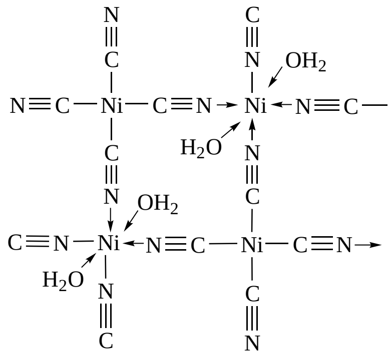
5 NICKEL(II)

The literature on the coordination chemistry of Ni^{II} is vast, and this brief review can only cover aspects of this chemistry. Essentially, all types of ligands that have been used for metal coordination chemistry have been investigated with Ni^{II}.

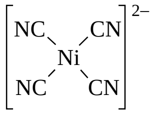
5.1 Cyanide Complexes

$[Ni(CN)_2]$ is a polymeric material with the CN^- ligand bridging between Ni^{II} ions (**49**). $[Ni(CN)_4]^{2-}$ (**50**) is a particularly stable, yellow Ni^{II} species with a formation constant of some 10^{30}. The complex is diamagnetic and square-planar at Ni^{II} with Ni–C = 1.86 Å.[50] The solid-state structure also shows stacking of these planar layers to give a Ni^{II}–Ni^{II} interaction with a 3.30 Å separation. This type of stacking interaction is relatively common for square-planar Ni^{II} complexes. Addition of another CN^- ligand to $[Ni(CN)_4]^{2-}$ affords $[Ni(CN)_5]^{3-}$, which shows square pyramidal (**51**) or trigonal bipyramidal (**52**) structures depending upon the counterion (equation 7, $K_{eq} = 0.28$ at 298 K).[51]

$$[Ni(CN)_4]^{2-} \rightleftharpoons [Ni(CN)_5]^{3-} \qquad (7)$$

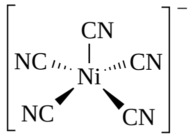


(**49**)

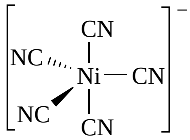


(**50**)

Recent work has indicated that Ni^{II} complexes can interact with buckminsterfullerene, C_{60}, and related fullerenes[50] (*see* ***Carbon: Fullerenes*** and Section 5.2).



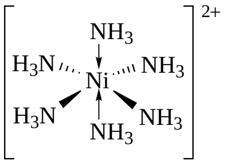
(**51**)



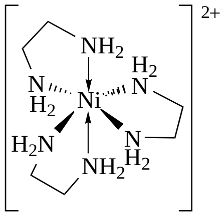
(**52**)

5.2 N-donor Complexes

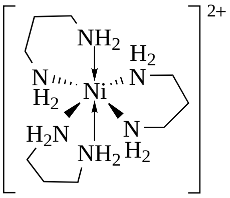
Ni^{II} amine chemistry was investigated by Werner as part of his classic experiments on metal coordination chemistry.[52] This work led to an understanding of ligand field and the chelate effects, and pioneered the modern era of coordination, organometallic, and bioinorganic chemistry.[53] The chelate effect is illustrated by comparison of the stepwise stability constants for $[Ni(NH_3)_6]^{2+}$ (**53**) ($\log K_1 - \log K_6 = 2.36, 1.90, 1.55, 1.23, 0.85, 0.42$, respectively) and $[Ni(en)_3]^{2+}$ (**54**) ($\log K_1 - \log K_3 = 7.66, 6.40, 4.55$, respectively), which shows greater stability for the latter bidentate five-membered chelate system. Further, replacement of en by pn leads to the formation of $[Ni(pn)_3]^{2+}$ (**55**), which is less stable owing to the larger six-membered chelate ring. A wide variety of substituted amine complexes of the type $[Ni(en)_2X_2]^{x+}$ have been reported.



(**53**)

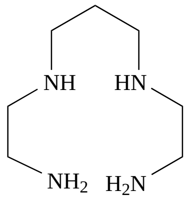


(**54**)

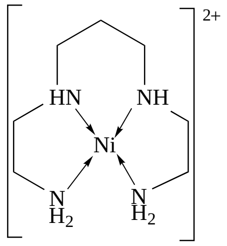


(**55**)

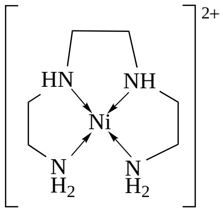
Polychelate triamine and tetraamine ligands can form even more stable complexes with Ni^{II}. For example, 2,3,2-tet (**56**) forms a particularly stable, yellow, square-planar Ni^{II} complex, $[Ni(2,3,2\text{-tet})]^{2+}$ (**57**), which is some 10^2 times more stable than the corresponding $[Ni(2,2,2\text{-tet})]^{2+}$ (**58**). This illustrates the variation of stability constant with ligand size. Interestingly, $[Ni(2,2,2\text{-tet})]^{2+}$ can be regarded as somewhat strained owing to the presence of three, five-membered ring chelates within an equatorial plane. This strain can be released by formation of the *cis* octahedral



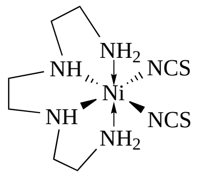
(**56**)



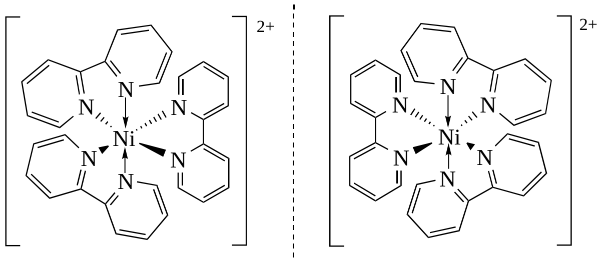
(**57**)



(**58**)



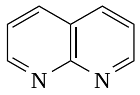
(**59**)



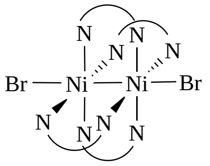
(**60**)

species $[Ni(2,2,2\text{-tet})(NCS)_2]$ (**59**), which is formed readily on addition of ^{-}NCS to a solution of $[Ni(2,2,2\text{-tet})]^{2+}$.[54]

Many examples of Ni^{II} complexes containing pyridyl, substituted pyridyl, imidazoles, pyrazoles, and related heterocyclic N-donor ligands have been reported, for example, $[Ni(L)_4X_2]$ (X = halide, L = monodentate N-donor), $[Ni(LL)_3]$, $[Ni(LL)_2X_2]$ (LL = chelate N-donor, for example, bipy, phen).[55] These compounds can be very readily prepared by reaction of NiX_2 and related Ni^{II} starting materials with L and LL. The complexes $[Ni(LL)_3]^{2+}$ (LL = bipy (**60**), phen) are normally isolated as racemic mixtures of (+) and (−) enantiomers, which can be resolved by crystallization with chiral counter anions.[56] Sterically hindered heterocyclic chelates or chelates with a small bite angle tend to form binuclear and polynuclear structures. For example, reaction of Ni^{II} salts with 1,8-naphthyridine (**61**) affords an unusual species in which the tight chelate bite of the ligand leads to the formation of a Ni^{I}–Ni^{II}-bonded dimer $[Ni_2(\mathbf{61})_4Br_2]^+$ (**62**). The Ni–Ni distance in (**62**) is 2.41 Å with Ni–N(av) = 2.11 Å.[57] Magnetic and EPR data on this complex suggest that it is a spin-delocalized system with an average oxidation state of +1.5 on each Ni. Second-sphere coordination of $[Ni(H_2O)_5py]^{2+}$ in a calixarene host has been reported.[58]

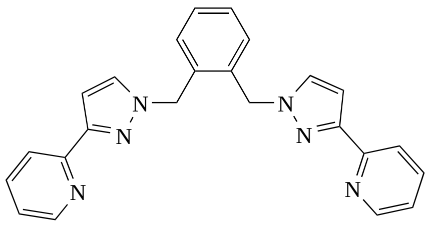


(**61**)



(**62**)

The tetradentate amine ligand (**63**) (L) displays an unusual binding to Ni^{II} ions to form the complex $[Ni_2L_3]^{4+}$. This species does not show the expected helical structure but incorporates two ligands each bound to a Ni^{II} ion in a tetradentate manner with the third ligand L in a bis-bidentate bridging mode.[59] Such a structure has been previously observed for the binding of siderophore alcilagin to Fe^{III}.

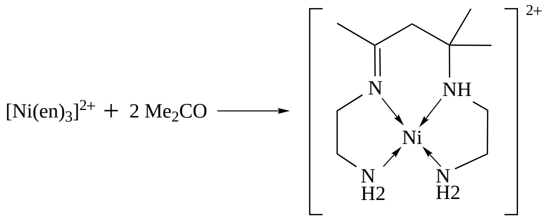


(**63**)

The structural trends and magnetic behavior of polynuclear Ni(II) and Mn(II) azido bridged complexes have been assessed.[60]

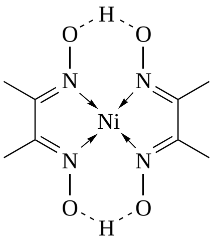
A very wide range of Schiff-base polychelate ligand complexes of Ni^{II} have been reported. These complexes can be prepared by reaction of Ni^{II} with the preformed ligand. More frequently, however, the complex is prepared in one step by Schiff-base condensation of the free aldehyde or ketone with the corresponding amine in the presence of Ni^{II}. The Ni^{II} ion thereby acts as a template, bringing together and stabilizing the intermediates and final product of the reaction.[61] Scheme 4 illustrates some of the ligands that have been prepared and complexed to Ni^{II}.

The report by Curtis[62] of the condensation of $[Ni(en)_3]^{2+}$ with acetone to give the open-chain condensation product and subsequently the macrocyclic complex (equation 8) was the first example of the synthesis of N-donor macrocycles by a metal template, and predates work on the oxycrown ligands such as 18-crown-6 ($[18]aneO_6$).

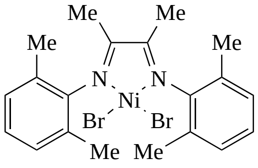


(8)

An enormous, wide-ranging literature on Ni^{II} macrocyclic chemistry is now available (see Section 5.7). The H-bonded dimethylglyoxime complex $[Ni(dmgH)_2]$ (**64**) is one of the more important, since this species is used for the gravimetric determination of Ni. Like many square-planar Ni^{II} complexes it stacks in the solid state with a Ni–Ni separation of 3.24 Å.[63] Related Ni^{II} complexes of functionalized dmg ligands frequently show this type of stacking interactions.



(**64**)

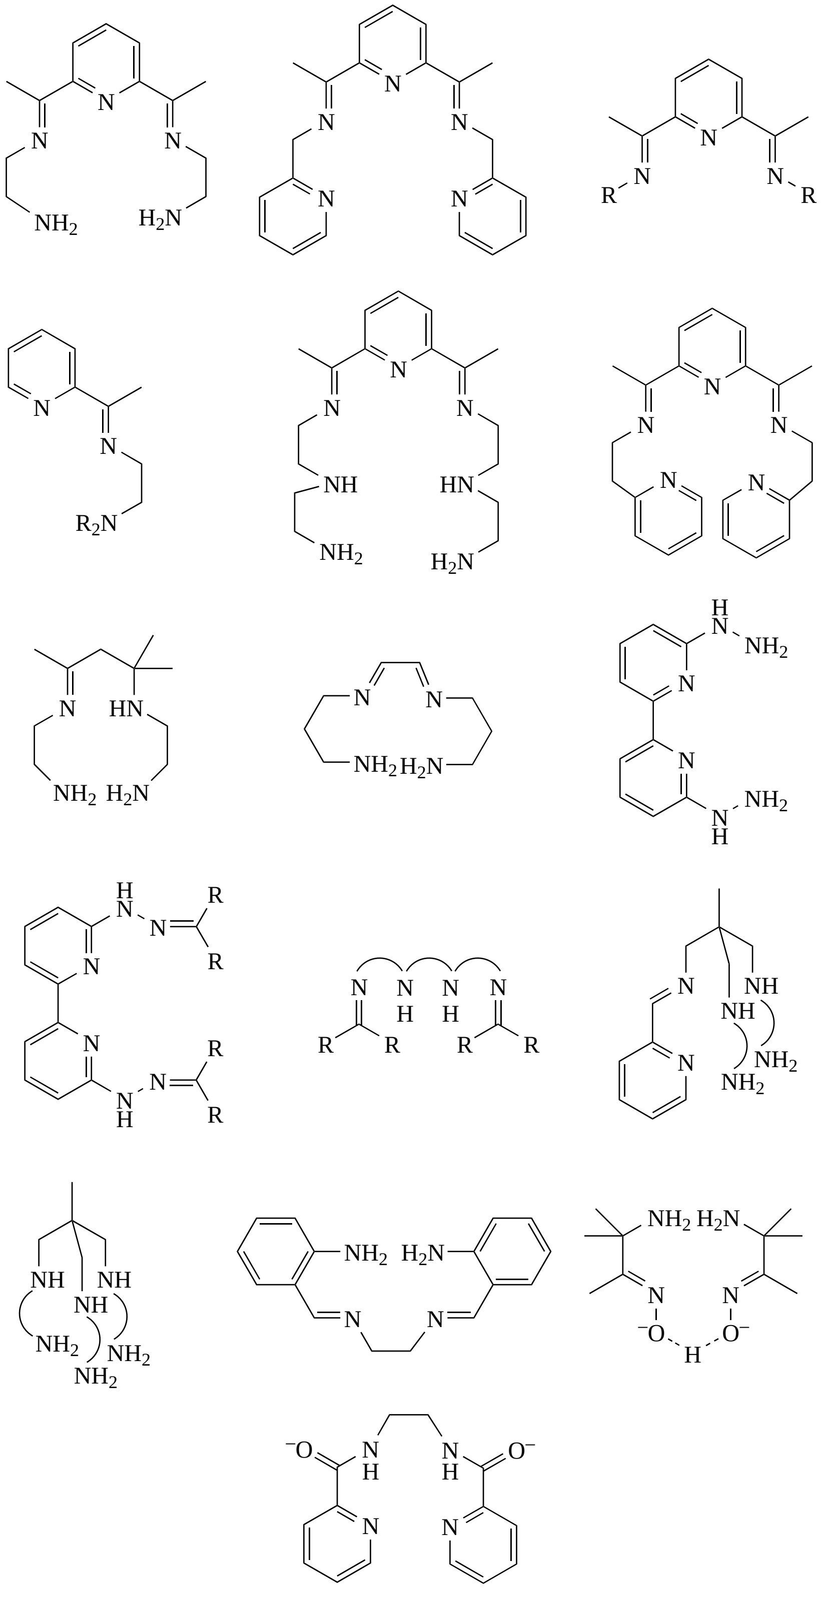


(**65**)

There has been an explosion in interest in diimine Ni^{II} complexes such as (**65**) since the report of Brookhart and coworkers detailing[64] their activity in the polymerization of alkenes with toleration of functional groups such as ethers, esters, and carboxylic acids. The incorporation of steric bulk within the ligand framework,that is, alkyl groups on the aromatic rings, is crucial for efficient polymerization rather than oligomerization.[64]

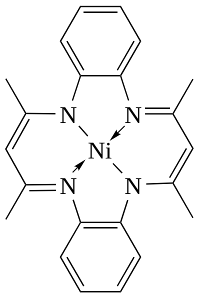
Ni^{II} octaethylporphyrin has been cocrystallized with C_{70}, in which the eight ethyl groups are arranged so that they encircle the C_{70}. This allows the close face–face contact of two flat Ni^{II} porphyrins.[65] This contrasts with the structure of Ni^{II} octakis(dimethylamino)porphyrazinato with C_{60} in which the porphyrazinato ligand is warped to a significant degree with each C_{60} lying in a cleft formed by two steeply inclined Ni^{II} porphyrazinates; there is additional π-stacking between the C_{60} molecules to produce a zig-zag chain. By contrast the analogous copper octakis(dimethylamino)porphyrazinato complex remains flat when cocrystallized with C_{60}.[66]

The tetraazamacrocyclic complex (**66**) adopts a saddle shape about Ni^{II} and allows the formation of a 1:1 supramolecular complex with C_{60} and a 2:1 complex with other



Scheme 4

globular molecules for example, 1,2-dicarbadodecaborane and the phosphorus chalcogenide P_4S_3.[67]

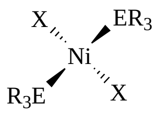


(**66**)

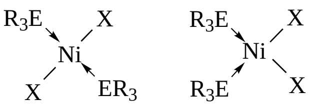
A range of complexes incorporating organic nitriles, nitrosyls, cyanates, thiocyanates, pyrazolyl borates, and azides have been reported.[1,2]

5.3 P-, As-, and Sb-donor Complexes

A very large number of phosphine, phosphite, stibine, and arsine complexes of type four-coordinate $[NiX_2(ER_3)_2]$ and five-coordinate $[NiX_2(ER_3)_3]$ (X = halide) have been reported, although this area is dominated by complexes of tertiary phosphines. The complexes $[NiX_2(ER_3)_2]$ can be either tetrahedral (**67**) or square-planar (**68**), depending upon the electronic and steric effect of the coordinated phosphine, arsine, and stibine ligands (see Section 2).[68]



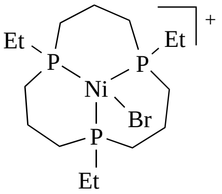
(**67**)



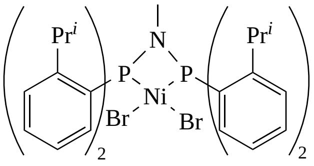
(**68**)

1,5,9,-Triethyl-1,5-9-triphospacyclododecane reacts with $NiBr_2$ to form an unusually distorted four-coordinate complex (**69**) as a result of constraints imposed by the macrocyclic ligand.[69] Indeed, the coordination geometry at Ni can best be described as a trigonal bipyramidal with a vacant vertex. Surprisingly, this apparent vacancy only leads to low activity in the polymerization of ethane.[69]

The square-planar complex (**70**) incorporating a C_2 symmetric diphosphine catalyzes the polymerization of ethene,[70] which is somewhat surprising as diphosphine



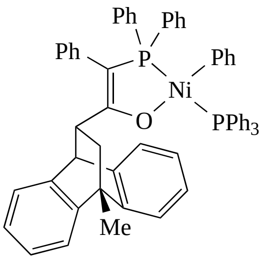
(**69**)



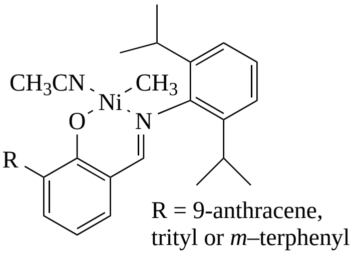
(**70**)

complexes tend to be much less active than related diimine complexes (see Section 5.2).

The Ni^{II} complex incorporating mixed-donor P/O-ligands find industrial application in the Shell Higher Olefin Process (SHOP) to yield α-alkenes, while the complex (**71**) has been shown to be active in the polymerization of olefins and will also tolerate functionalized monomers such as methyl methacrylate.[71] Grubbs and coworkers have adapted the standard SHOP catalyst to yield a highly active family of catalysts (e.g. **72**) for the polymerization of low-branched polyethylene.[72] This is in contrast to the diimine catalysts (Section 5.2) which lead to a more highly branched polyethylene.

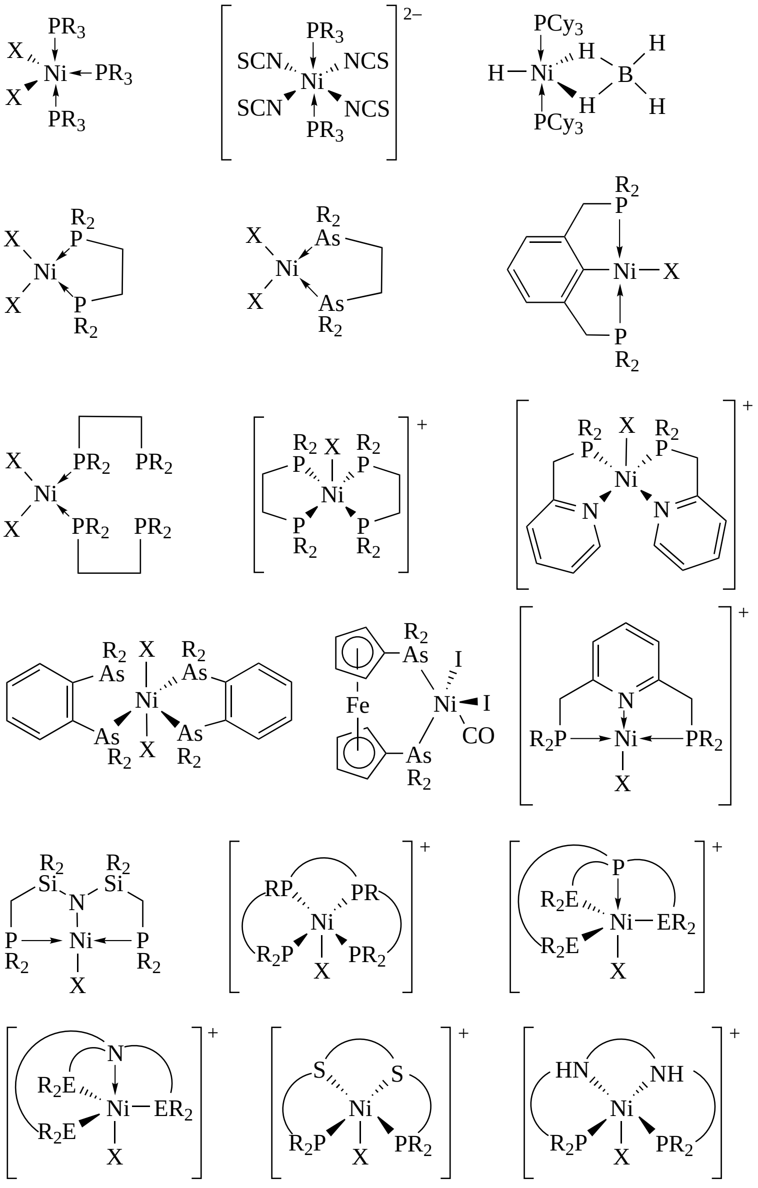


(**71**)



(**72**)

An extensive range of polychelate P-donor and mixed P/N-, P/S-, P/O-, and P/C-donor ligand complexes have been

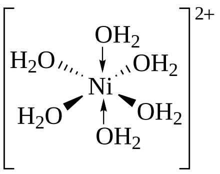


Scheme 5

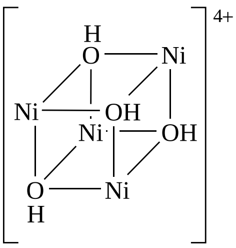
prepared.[1,2] Their complexation to Ni^{II} is based, in general, on four-coordinate Ni^{II} species in equilibrium, in the presence of other ligands, with five- and six-coordinate products. Some of the complexes that have been prepared are illustrated in Scheme 5.

5.4 O-donor Complexes

$[Ni(H_2O)_6]^{2+}$ (**73**) is the main cation formed when Ni^{II} is dissolved in aqueous solution in the absence of other coordinating ligands; a second hydration sphere of some 15 water molecules has been proposed.[73] In addition, most simple salts written as $NiX_2{\cdot}xH_2O$ actually contain the hexaaqua ion $[Ni(H_2O)_6]^{2+}$. Under alkaline conditions, Ni^{II}–hydroxy species are formed, including $[Ni(OH)_6]^{4-}$, $[Ni(OH)_4]^{2-}$, and $[Ni_4(OH)_4]^{4+}$ (**74**), which presumably has a cubane structure.[74]

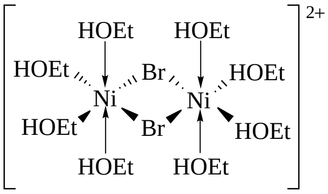


(**73**)



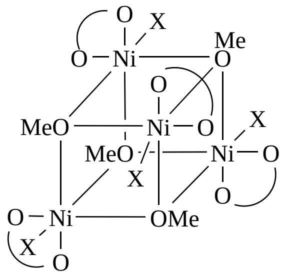
(**74**)

Complexes such as $[Ni(ROH)_6]^{2+}$ and $[NiX_2(ROH)_4]$ can be generated under anhydrous conditions, although they tend to be water sensitive and can be readily hydrolyzed.[75] O-Donor ligands such as alcohols, ethers, and ketones are in general very poor donors to Ni^{II} and so their complexes are labile and often unstable. The structure of $[NiBr(EtOH)_4]^+$ (**75**) shows it to be a halo-bridged dimer.

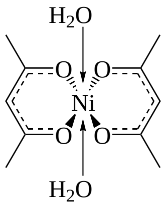


(**75**)

Alkoxide complexes of stoichiometry $[Ni(OR)_2]$ can be prepared by reaction of simple Ni^{II} salts NiX_2 with RO^-.[73] In general, the structures of these complexes are not known for certain, although the X-ray structure of $[Ni_4(OMe)_4(acac)_4(MeOH)_4]$ (**76**) confirms[76] it to be based on a $Ni_4(OMe)_4$ cube. Similar cubane structures have been proposed for a variety of other Ni^{II} alkoxide complexes.

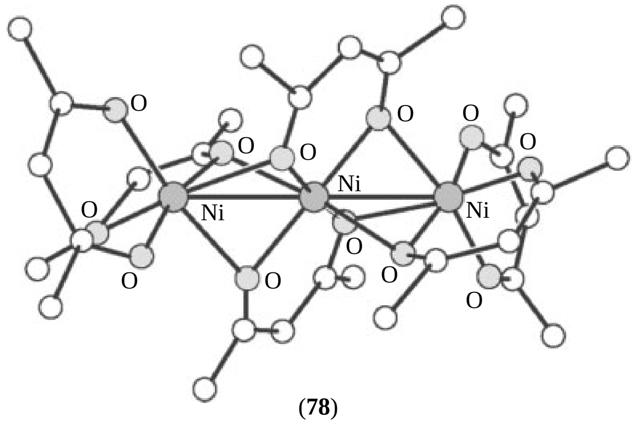


(**76**)



(**77**)

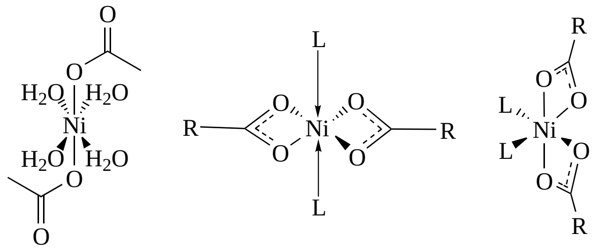
Reaction of Ni^{II} with acac affords *trans*-$[Ni(acac)_2(H_2O)_2]$ (**77**), which can be dehydrated to $[Ni(acac)_2]$ (**78**). $[Ni(acac)_2]$ is actually trimeric with bridging acac ligands.[77] The complexes $[Ni(acac)_2(L)_2]$ (L = py and related amine ligands) have been prepared, and some structurally characterized. Related tropolone, quinone, and catechol complexes have been reported.[1,2] Coupled electronic states in the complexes *trans*-$[MCl_2(H_2O)_4]^{n+}$ complexes (M = Ni^{2+}, Co^{2+}, V^{3+} and



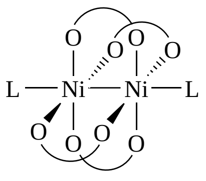
(**78**)

Cr^{3+}) have been probed by absorption and luminescence spectroscopy. The strongest interaction occurs for the Ni^{II} complex, where the lowest energy singlet state is very close in energy to a spin allowed crystal field band, giving rise to intense vibronic patterns.[78]

Treatment of Ni^{II} salts with acetic acid affords *trans*-$[Ni(O_2CMe)_2(H_2O)_4]$ (**79**) incorporating monodentate acetate ligands. By altering the reaction conditions and the carboxylic acid, complexes of type *trans* and *cis* $[Ni(O_2CR)_2(L)_2]$ (**80**) (L = N-, O-donor ligands) in which the carboxylate moiety is acting as a bidentate ligand can be prepared.[79] Binuclear species of the type $[Ni_2(O_2CR)_4(L)_2]$ (**81**) can also be synthesized,[80] and a cubane complex $[Ni_4(OMe)_4(O_2CMe)_2(L)_4]^{2+}$ (L = dinitrile ligand) (**82**) has been reported.[81]

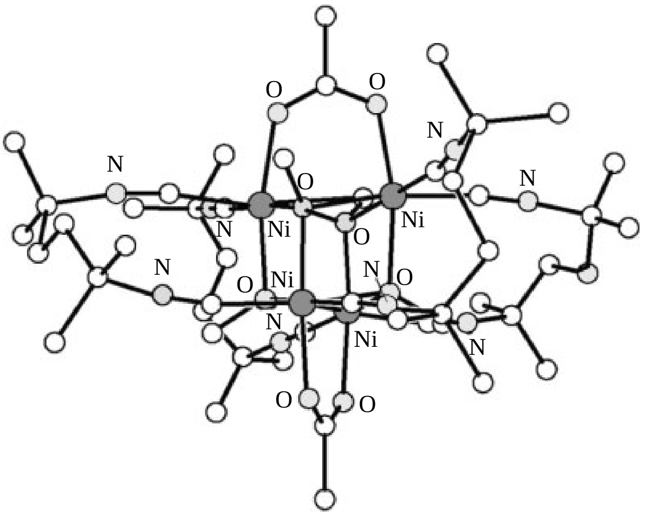


(**79**) (**80**)

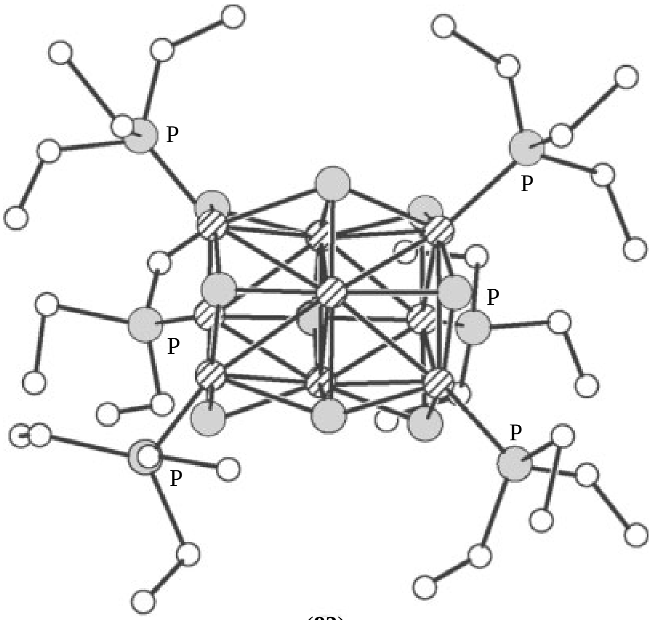


(**81**)

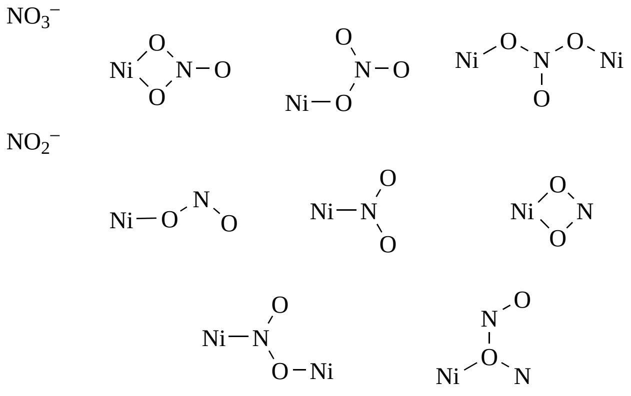
$[Ni(NO_3)_2]$ is a common starting material for Ni^{II} coordination chemistry, since the nitrato ion is not a very strong donor. However, many nitrato[82] and nitrito[83] complexes are known in which these ligands are bound directly to



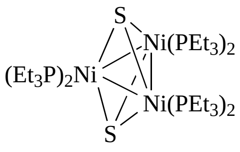
(**82**)



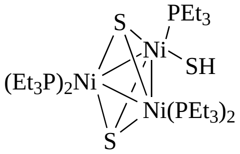
(**83**)



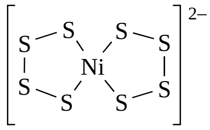
Scheme 6



(**84**)



(**85**)



(**86**)

Ni^{II} either as monodentate, bidentate, or bridging ligands. Differentiation between these modes of coordination can be difficult in the absence of good X-ray structural data, although IR spectroscopy has been used effectively. The different bonding modes of NO_3^- and NO_2^- ligands are summarized in Scheme 6.

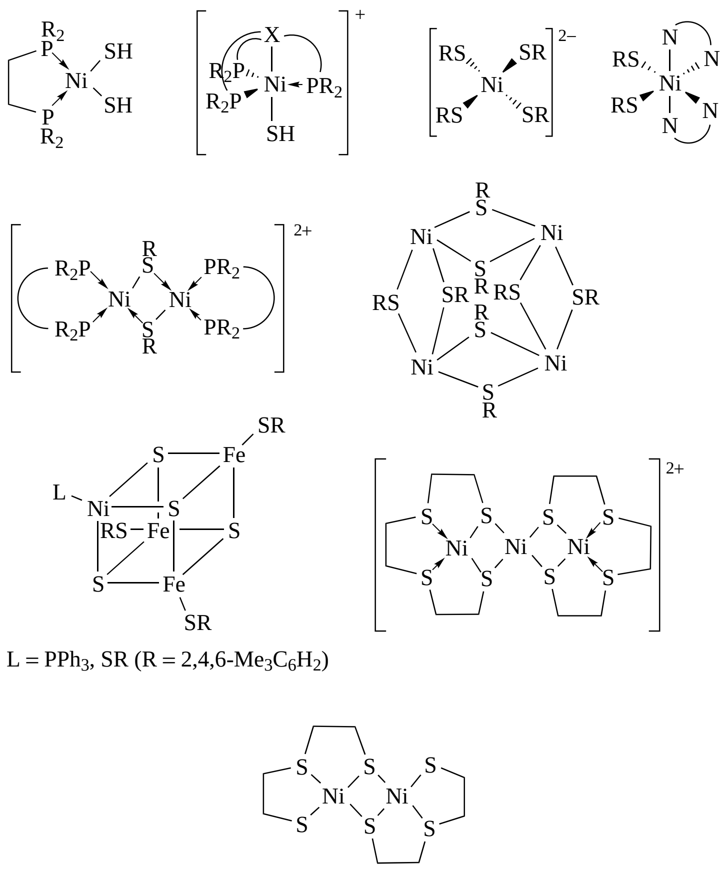
5.5 S-, Se-, and Te-donor Complexes

The chemistry of Ni^{II} with S-ligands is not as well-developed as for N- and O-donor ligands. This is partly due to the formation of insoluble Ni^{II} sulfide polymers. The ability of S^{2-} to act as a bridging and capping ligand has led to the formation of polynuclear cluster species such as $[Ni_9(\mu^4\text{-}S)_3(\mu^3\text{-}S)_6(PEt_3)_6]^{2+}$ (**83**),[84] $[Ni_3(\mu^3\text{-}S)_2(PEt_3)_6]^{2+}$ (**84**), and $[Ni_3(\mu^3\text{-}S)_2(SH)(PEt_3)_5]^{2+}$ (**85**).[85] Reaction of $[Ni(OAc)_2]$ with ammonium polysulfide affords $[Ni(S_4)_2]^{2-}$ (**86**) in good yield as a square-planar, diamagnetic product.[86]

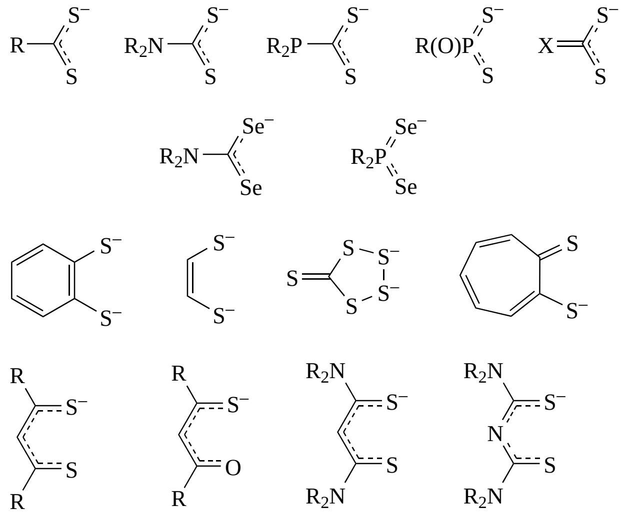
A range of dithiocarboxylate, dithiocarbamate, xanthate, dithioformate, thioformate, and sacsac complexes have been reported for Ni^{II}.[1,2] These ligands are illustrated in Scheme 7. Many of the complexes are square-planar of type $[Ni(L)_2]$ with the mono negatively charged ligand chelating to the Ni^{II} center, although there are examples where the complexes stack in the solid state. Dithiolene complexes of Ni^{II} are of particular interest since they are generally redox active at the metal and/or ligand centers.

Work on Ni-thiolate complexes has focused on the synthesis of mononuclear, S-bridged polynuclear, cluster, and cubane model complexes of relevance to active site in biological systems (see Section 8).[87,88] Scheme 8 illustrates some of the thiolate complexes that have been prepared.

The synthesis of homoleptic Ni-thiolate complexes $[Ni(L)_4]$ (L = hindered thiolate) has been reported by Armstrong and coworkers.[89] Preparations of Ni^{II} thiolates



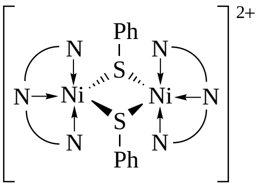
Scheme 8



Scheme 7

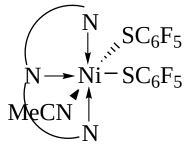
are very solvent dependent particularly when synthesizing coordinatively unsaturated metal complexes, and can be highly O_2 sensitive with the required synthetic procedure varying according to the thiolate used.

Recently, interest in Ni^{II} thiolate chemistry has increased owing to the recognition that certain enzymes incorporate mixed N/S coordination at Ni^{II}. Several mixed N/S-donor complexes have been prepared and characterized, including $[Ni(terpy)(SPh)_2]_2$ (**87**), $[Ni(terpy)(SC_6F_5)_2(NCMe)]$ (**88**), and $[Ni(terpy)(SR)_2]$ [$R = 2,4,6\text{-}i\text{-}Pr_3C_6H_2$ (**89**), 2,6-$Me_2C_6H_3$ (**90**)], and their chemical and redox properties related to the in vivo systems.[90] More recent examples of low molecular weight model complexes are described in Section 8.

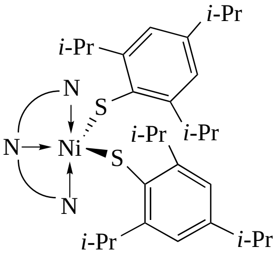


(**87**)

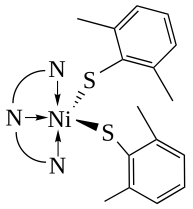
Oxidation of a series of Ni-bound thiolates (such as **91**) demonstrate the formation of sulfones and further oxidation to give sulfoxides.[91] The oxidation of thiolates was found not to occur for the analogous Fe or Zn



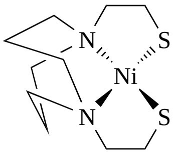
(**88**)



(**89**)



(**90**)

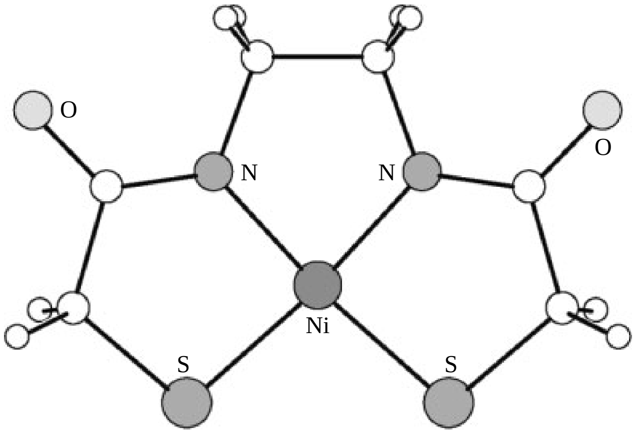


(**91**)

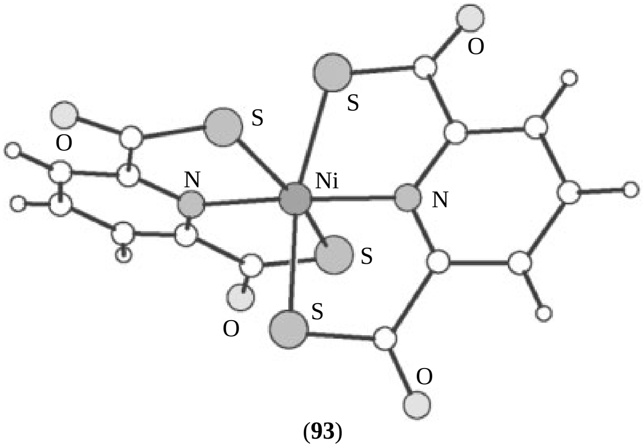
complexes. By cyclic voltammetry, the Ni complexes display a reversible Ni^{II}–Ni^{I} reductions and irreversible ligand-based oxidation presumably to give unstable thiyl radical intermediates. The bis(sulfone) complexes, however, show reversible Ni^{II}–Ni^{III} oxidative processes as do the analogous complexes where the S-centres have been alkylated.[91] The possibility for a two centred Ni-SR site to function in an oxidative-addition mode was suggested as an intriguing solution developed by Nature to achieve the desired reactivity.

Holm and coworkers have investigated the structural and redox properties of mixed N/S-donor and related oxime Ni^{II} complexes, for example, (**92**) and (**93**), and have generated and studied the corresponding Ni^{III} species.[92]

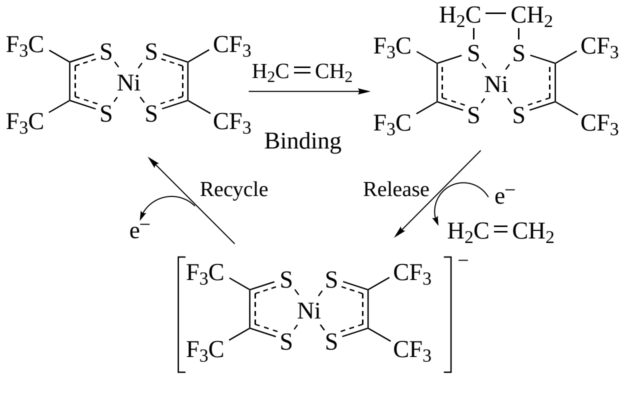
Significantly, Ni^{II} dithiolenes have been shown to be effective for the electrochemical separation of alkenes from complex streams. No poisoning was observed with common impurities including hydrogen, carbon monoxide, acetylene, or hydrogen sulfide. Reactivity of these complexes occurs via



(**92**)



(**93**)



Scheme 9

alkene binding to S-centres rather than at the Ni (Scheme 9) reflecting the radical nature of these ligands.[93]

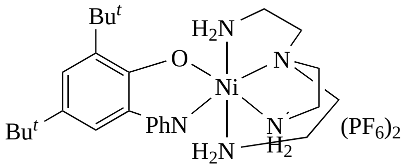
5.6 Halide Complexes

Anhydrous NiX_2 (X = F, Cl, Br, I) can be prepared by reaction of elemental Ni with the free halide.[94] These

species are polymeric and show octahedral coordination at Ni^{II}. The trihalo complexes $[NiX_3]^-$ also show octahedral coordination at Ni^{II} via bridging μ^2-Cl_3 units. The tetrahedral tetrahalo complexes $[NiX_4]^{2-}$ are readily prepared by reaction of NiX_2 with excess X^-. Substituted species $[NiX_3(L)]^-$ (L = py, substituted py, PPh_3) have been isolated as tetrahedral complexes.

5.7 Open-chain Mixed Donor and Macrocyclic Complexes

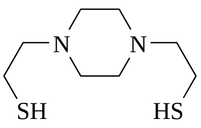
The redox noninnocence of the 2-mercapto-3,5-di-tert-butylaniline ligand has recently been investigated with Ni^{II} ions.[95] The spectroelectrochemistry of the complex displays a range of electron transfers where the monocation, the neutral species, and the mono- and dianions have been characterized. In a related manner, Wieghardt and coworkers have reported the first example of a stable N, O-coordinated *o*-iminobenzoquinone via air oxidation of the initial Ni^{II} complex with 2-anilino-4,6-di-tert-butylphenol (**94**).[96] The analogous *o*-iminobenzosemiquinonate π-radical complex was also isolated for this system and earlier for the bis-(*o*-iminobenzosemiquinonate)nickel(II) complex.[97]



(**94**)

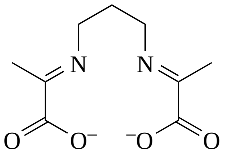
In recent years, the development of new concepts for the rational design of larger, more complex molecules has led to considerable progress in supramolecular chemistry to afford structures of a variety of symmetries, sizes, and stoichiometries. Ni^{II} complexes have provided versatile molecular tectons in a plethora of such structures.

The aggregation of Ni^{II} complexes using amine-thiolate ligands such as (**95**) has been observed to yield homo-hexanuclear complexes. Fascinating pinwheel motifs have been observed where two Ni centres bridge four Ni amino-thiolate complexes.[98] Here, both the bite angle of the S^-–Ni–S^- unit and the choice of bridging metal ion influence whether a simple trinuclear aggregate is favoured or a higher motif.[98]



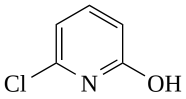
(**95**)

The imino-carboxylate ligand (**96**) coordinates to Ni^{II} in an equatorial manner to yield the monomer tecton $[Ni(L)(MeOH)_2]$. Subsequently, in the presence of templating lanthanide or group II metal ion these Ni^{II} complexes aggregate into an octahedral cage $\{M[Ni(L)]_6\}^{x+}$ (M = Sr^{II} or Ba^{II}, $x = 2$, M = La^{III}, Ce^{III}, Pr^{III} or Nd^{III}, $x = 3$).[99] However, in the presence of group I metal ions, aggregates of the alkaline metal-oxide cations template various cage compounds. For example, Na^+ forms the trigonal bipyramidal $[Na_5O]^{3+}$ core within a tricapped trigonal prismatic $[Ni(L)]_9$ aggregate to yield $\{(Na_5O) \subset [Ni(L)]_9(MeOH)_3\}(BF_4)_2 \cdot OH \cdot CH_3OH$, whilst Li^+ forms a tetrahedral $[Li_4O]^{2+}$ core within a hexanuclear open cage $[Ni(L)]_6$ in $\{(Li_4O) \subset [Ni(L)]_6(MeOH)_3\}(ClO_4)_2 \cdot 1.85\ CH_3OH$.[99]

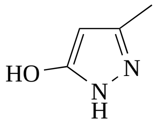


(**96**)

Complexes of $Ni(OAc)_2$ with 6-chloro-2-pyridonate (**97**) have been organized into an elegant Ni_{12} wheel, which has been investigated as a 'single-molecule magnet'.[100,101] With 3-methyl-3-pyrazol-5-one (**98**) the larger Ni_{24} wheel has been assembled.[102]



(**97**)



(**98**)

Bis(thiosemicarbazide)nickel(II) forms charge augmented double hydrogen-bonded chains with 1,4-terephthalate and trans-fumarate anions, which are further linked into sheets by hydrogen bonds between the N–H···O units. The methylation of the primary amine disrupts these interactions markedly so that hydrogen-bonded sheets result, involving now molecules of water.[103]

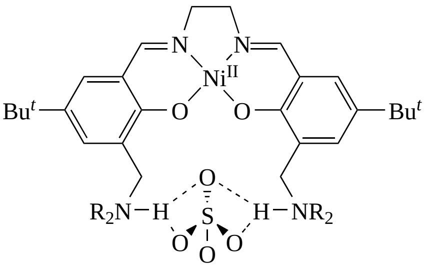
Crystals of $Ni(NO_3)_2$ with 4,4′-bipyridine produce a ladder type framework polymer, which can be desolvated to yield a stable porous solid.[104] The adsorption of methanol has then been studied and shown to cause a guest-driven solid-to-solid transformation. Fascinatingly, this material is able to accept

toluene into its pores, in spite of the pore window being lower than the cross-sectional area of toluene.[105] Molecular frameworks which grow as homochiral single crystals have been realized through the use of 1,3,5-benzenetricarboxylic acid, nickel(II) nitrate and 1,2-propanediol. The chiral 1,2-propanediol represents the first demonstration that chiral molecules can specifically template helix handedness in a chiral porous framework solid.[106]

Van Koten and coworkers have described the first example of a dendrimer employed as a catalyst support (Scheme 10).[107] This system is based upon diaminoarylnickel(II) complexes attached to the dendrimer surface and catalyze the Kharasch-type additions of polyhalogenoalkanes to alkenes. There is a clear advantage with regard to catalyst recovery, although in comparison to the analogous mononuclear catalyst the activity of the supported material was reduced.[107]

Supramolecular interactions have been exploited in the extraction of Ni^{II} salts using ditopic ligands (e.g. **99)** with specific binding sites for both the cation, in the salen $N_2O_2{}^{2-}$, and the anion being hydrogen-bonded to the external protonated amines.[108] The formation of metallomacrocycles and the supramolecular chemistry of salen type complexes for cation binding studies with alkaline-earth metal ions has been investigated.[109]

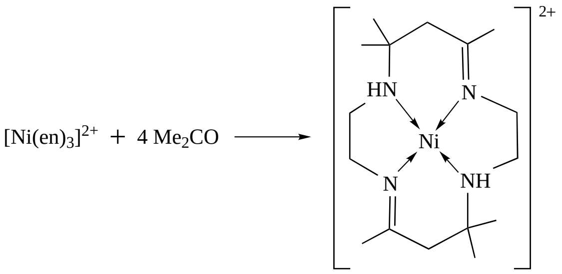
A very extensive and wide-ranging literature has built up around the coordination chemistry of Ni^{II} about N-donor Schiff-base ligands (see Section 5.2), open-chain mixed-donor ligands, and macrocyclic ligands. This burgeoning area is based on the ease of complexation of Ni^{II} by these types



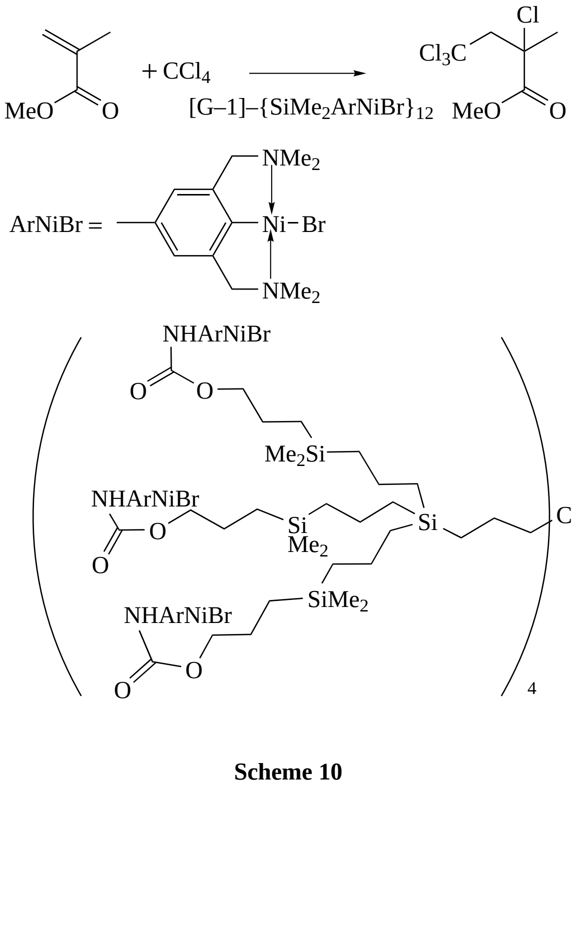
(**99**)

of ligands. Interest in these types of complexes derives from their potential and practical uses in metal extraction processes, metal ion transport and recognition, for the stabilization of unusual oxidation state and stereochemistries at the metal center, as models for biological systems, in host–guest chemistry, and for small molecule binding and catalysis. Several reviews and texts specifically dealing with polydentate and macrocyclic complexes, porphyrins, and phthalocyanins have been published.[110–112] Scheme 11 illustrates some of the open-chain mixed-donor ligands and metal complexes that have been investigated.

Much of the macrocyclic chemistry of Ni^{II} is based on Schiff-base template condensation reactions. The pioneering work of Curtis[62] showed that the condensation of en and acetone could be templated by Ni^{II} to afford the corresponding tetraaza macrocycle (equation 9). Related template condensation reactions are illustrated in Scheme 12.



(9)



Scheme 10

Subsequently, syntheses of tri-, tetra-, penta-, and hexaaza macrocycles, using methods developed by Richman and Atkins, have been published.[113] More recently, methods have been developed for the synthesis of polythioether macrocyclic ligands, some of which complex Ni^{II} very strongly.[114,115] This is particularly significant since monodentate thioether ligands are notoriously poor ligands for Ni^{II}.[116] Scheme 13 illustrates some of the macrocyclic ligands that have been coordinated to Ni^{II} and some of the complexes derived from them (see also Scheme 3). Of particular interest has been the determination of conformations of the coordinated rings, the stereochemistry and configuration at the metal center, and the assignment of configuration at the coordinated N-donors,that is, whether the side groups are ‘up’ or ‘down’ relative to one another. The coordination geometry and electronic environment at Ni^{II} can be specifically controlled by the protecting macrocyclic

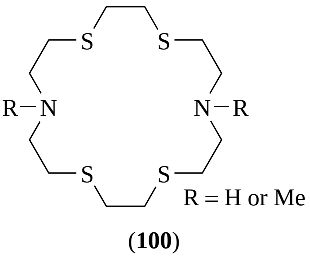
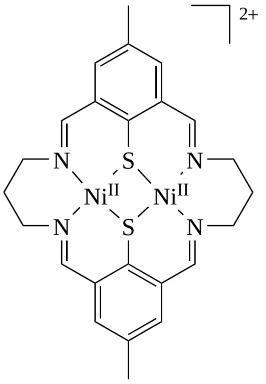
ligand, and this has led to the stabilization of a range of Ni^{I} and Ni^{III} centers (see Sections 4 and 6, respectively).[111,112]

For example, an electrochemical investigation on $[Ni[18]aneN_2S_4]^{2+}$ confirms a reversible Ni(II)–Ni(III) couple and an irreversible reduction. In contrast, $[Ni(Me_2[18]aneN_2S_4)]^{2+}$ shows an irreversible Ni(II)–Ni(III) couple but a reversible Ni(II)–Ni(I) process. This contrasting redox behavior can be rationalized by the different binding characteristics of the ligands (**100**).[117]



(**100**)



(**101**)

The binuclear nickel-thiolate macrocyclic complex (**101**) displays noteworthy redox behavior, in which one-electron oxidation yields a Ni^{III}. Ni^{II} product with significant delocalization of the unpaired electron density onto the bridging thiolate ligands and not onto the second nickel ion.[118] The charge delocalization consequently lies between the two redox extremes of nickel(III)-thiolate and nickel(II)-thiyl radical, thus mimicking the Ni-C state in [NiFe]hydrogenase (see Section 8).

Ni^{II} macrocyclic complexes have also been investigated as covalent attachments to photosensitizers such as $[Ru(bipy)_3]^{2+}$,[119] and as interchelating agents for the cleavage of DNA.[120]

6 NICKEL(III)

The coordination chemistry of Ni^{III} has been reviewed,[14] and electron-transfer reactions of Ni^{III} and Ni^{IV} complexes assessed.[121] Ni^{III} species are stabilized by σ-donor ligands and are excellent oxidizing agents. The complexes usually show tetragonally distorted octahedral geometries consistent with a d^7 electron configuration; the EPR spectra of Ni^{III} species show $g_{\perp} > g_{\parallel} \sim 2.0023$ assigned to a $d^1_{z^2}$ ground-state configuration for an axially elongated octahedron. Coordination of solvent molecules such as MeCN to apical sites leads to hyperfine coupling to N in the $g_{\parallel}$ component of the EPR spectrum.[122] Many Ni^{III} species have relatively short half-lives for decomposition and may be regarded as transient species.

The oxidation of a range of Ni^{II} complexes of open-chain mixed-donor ligands (Scheme 14) has generated Ni^{III} complexes that have been characterized by EPR spectroscopy.[123] Many of these complexes incorporate deprotonated amide and amino acid functionalities. The stabilization of Ni^{III} by diimino ligands has also been reported.[44,92]

A wide range of Ni^{III} complexes of aza macrocyclic[124] and porphyrin[125] ligands has been reported. The structures of $[Ni([9]aneN_3)_2]^{3+}$ (**102**), the thioether analogue $[Ni([9]aneS_3)_2]^{3+}$ (**103**), $[Ni([14]aneN_4)Cl_2]^{+}$ (**104**), $[Ni(R_3[9]aneN_3)]$ ($R = CH_2CO_2^{-}$) (**105**), and the Ni^{III} analogue of (**92**) confirm the stereochemical preference of Ni^{III} for distorted octahedral coordination.[92,126] The oxidation of organic substrates and biological materials by Ni^{III} macrocyclic species (generated by oxidation of Ni^{II} precursors) has been reported.[127] The generation of Ni^{III} species by pulse radiolysis has been a particularly useful technique for the study of kinetics and mechanism,[128] while the oxidative addition of R–X to Ni^{I} to form Ni^{III} species has been described (equation 10).[129]

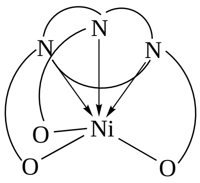
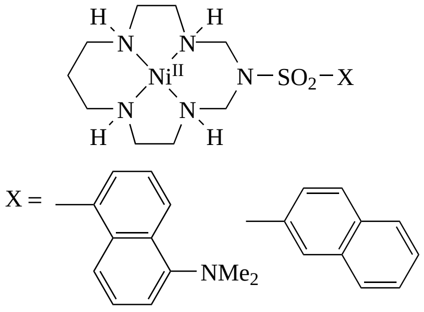
(**104**)



(**105**)

The ability of tetraazamacrocycles (**106**) to stabilize nickel ions in the +3 oxidation state has been employed to demonstrate redox switching of fluorescence. The wavelength of the emitted light is controlled through the choice of pendant group X.[130]

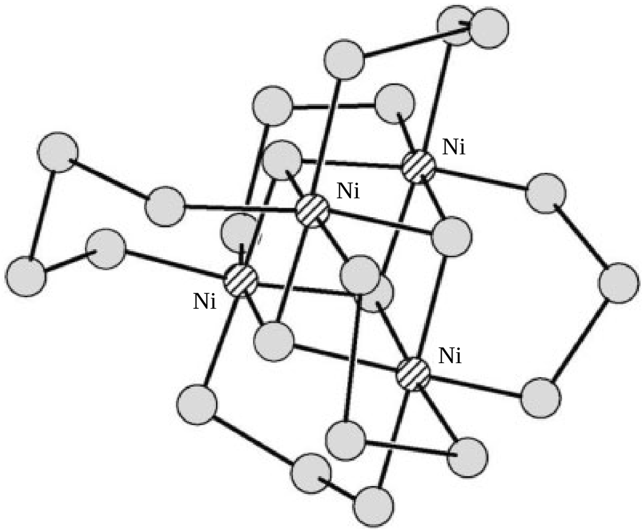
A limited series of phosphine and thiolene complexes of Ni^{III} have been generated. These include the species $[NiX_3(PR_3)_2]$ and $[M(L)_2]^-$ (L = dithiolene), although in the latter complexes the formation of Ni^{III}-stabilized ligand-radical cations has been observed. The synthesis of $[NiF_6]^{3-}$ has been reported.



(**106**)

7 NICKEL(IV)

Ni^{IV} complexes are relatively rare and very few have been characterized fully. The structure of $[NiF_6]^{2-}$ shows octhedral coordination with Ni–F = 1.72, 1.76 Å.[131] With Ni^{III} and Ni^{IV} centers deprotonation of coordinated amine occurs very readily, reflecting the requirement of these metal ions for electronegative ligands. Ni^{IV} has been stabilized by polydentate oxime, amide, and amino acid ligands (see Scheme 14). Examples of Ni^{IV} stabilized by dithiocarbamate and dithiolene ligands are now believed to be ligand-oxidized complexes. The stabilization of Ni^{IV} in molybdates and niobates is also known. A highly unusual Ni^{IV} cubane complex $[Ni_4Se_4(Se_3)_5(Se_4)]^{4-}$ (**107**) has been isolated and characterized.[132]



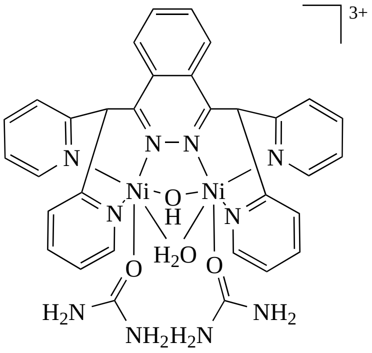
(**107**)

8 BIOLOGICAL CHEMISTRY

A major impetus for the study of Ni redox chemistry has been provided by the discovery of paramagnetic Ni centers

in several biological systems.[133,134] Several enzymes are now known to contain Ni and in a number of these the Ni is thought to take part in redox reactions.[135,136]

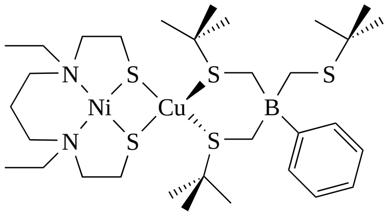
Urease catalyzes the hydrolysis of urea to NH_3 and CO_2 and incorporates Ni^{II} in an octahedral environment.[137] The function of the Ni center(s) in these enzymes is thought to be analogous to that of Zn^{II} in carbonic anhydrase, to activate the urea substrate electrostatically to nucleophilic attack.[138] The binuclear Ni^{II} complex (**108**) displays urease activity, firstly via conversion of urea to ammonia and cyanate, followed by a second step involving the hydrolysis of the cyanate.[139,140] In addition, a related asymmetric complex reacts with urea and allows the structural characterization of the isocyanate product.



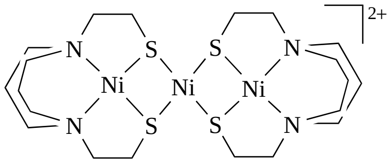
(**108**)

Methyl-coenzyme M reductase requires a Ni-containing prosthetic group for activity, Factor F_{430}. This is a Ni complex of a tetrahydroporphyrin which forms an octahedral Ni complex in the intact protein. The active ('reduced') form of this enzyme is EPR active ($g_{\perp} = 2.23$, $g_{\parallel} = 2.17$),[141] which is consistent with the formation of a d^9 Ni^I center. A recent X-ray structure of methyl-coenzyme M reductase shows the octahedral Ni^{II} ion bound in a tetrapyrrole hydrocorphin ring and the oxygen from a glutamine residue at the 5th site. The sixth site is occupied by either a thiol group of coenzyme M in the methyl-coenzyme M reductase$_{\text{ox1-silent}}$ structure or a sulfonate oxygen of coenzyme M in the methyl-coenzyme M reductase$_{\text{silent}}$ structure.[142,143]

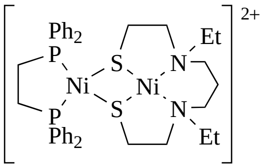
Carbon monoxide dehydrogenase is a bacterial enzyme that catalyzes the interconversion of CO and CO_2, the active site has been shown to contain an asymmetric [Ni-4Fe-5S] cluster.[144,145] There have been two recent independent reports of X-ray structures for the bifunctional enzyme carbon monoxide dehydrogenase/acetyl-coenzyme A synthase. In both structures Ni^{II} is present bound within a N_2S_2 polychelate, which via the thiolate donors bridges to either a Cu, Zn, or Ni ion, which in turn is bound to a 4Fe4S cluster.[146,147] Helix-loop-helix peptides have been designed as scaffolds for the stabilization of Ni^{II}-Fe_4S_4 bridged assemblies to model the active site of the A-cluster of carbon monoxide dehydrogenase. Herein, the Fe_4S_4 is incorporated in the flexible loop of the peptide and is bridged by a cysteine residue to the bound Ni^{II}; this Ni^{II} appears to be in equilibrium with a peptide free Ni^{II} species.[15,148] Low molecular weight models for the active site of acetyl-coenzyme A synthase have been prepared (**109**,[149] **110**,[150] **111**,[151]), and these are also able to form higher aggregates containing more metal ions in the centre of the complexes.



(**109**)



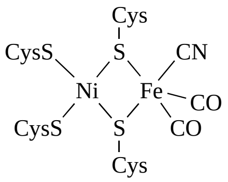
(**110**)



(**111**)

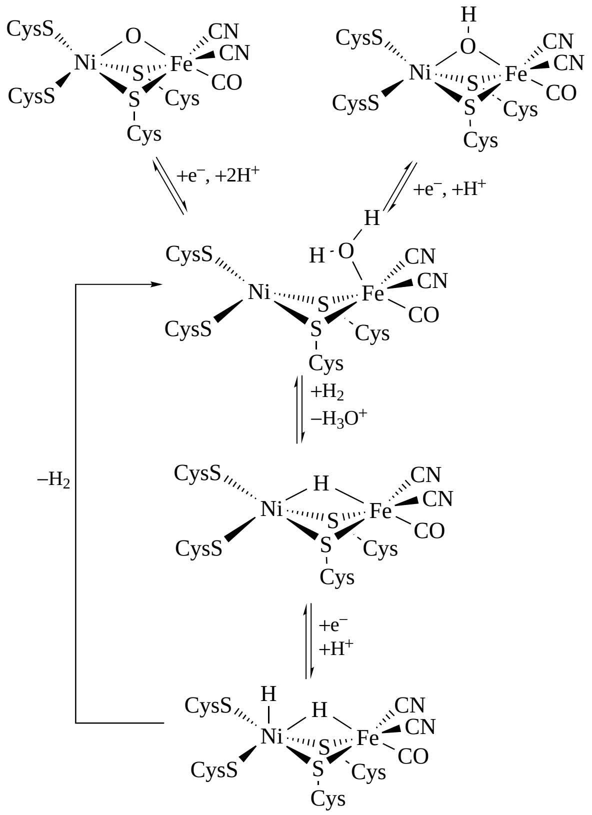
Hydrogenase enzyme catalytically interconvert H_2 and $2H^+$. The X-ray structure of [NiFe] hydrogenase has been solved for Desulfovibrio gigas to a resolution of 2.85 and 2.54 Å.[152,153] The active site comprises a heterobimetallic [NiFe] center, with the Ni ligated by four cysteines, two of which are terminal and two which bridge to iron (**112**). The Fe is ligated further by three nonprotein diatomics, namely, two cyanide and one carbonyl, a third bridging group completes the octahedral coordination sphere and is assigned as an oxo-oxygen more closely associated with the Ni than the Fe. Activation of the enzyme is believed to involve loss of the oxo-ligand and contraction of the nickel–iron separation to some 2.5–2.6 Å.[154]

The precise mechanistic detail of the enzymic reaction is not fully understood, although a Ni^{III}–(H_2) complex appears to be involved;[155,156] Crabtree and coworkers have published evidence for the first example of a Ni^{II} complex that interacts directly with H_2,[157] while Lubitz and coworkers have proposed using multi-frequency EPR analysis a reaction scheme for H_2 and H^+ interconversion at the biosite (see Scheme 15).[158]



(**112**)

The active site of [NiFe] hydrogenase



Scheme 15

The synthesis and study of low molecular weight model complexes that mimic the electronic structure and coordination chemistry of the hydrogenase active site is a timely area of research and has been reviewed.[159] Typical examples of mixed Ni-Fe complexes that have been prepared include complexes (**113**),[160] (**114**),[159] (**115**),[159] and (**116**).[161]

H_{2ase} = hydrogenase; Hbsms = 4-mercapto-3,3-methyl-1-phenyl-2-thiabutane; S_{cys} = cysteine thiolate; psnet = bis(5-(diphenylphosphino)-3-thiapentanyl)amine; bdptz = 1,4-bis (2,2′-dipyridylmethyl)phthalazine; OTs = *p*-toluenesulfonate; tmen = N,N,N',N'-tetramethylethylenediamine; AA = acetohydroxamate anion; [PhTt^{tBu}] = phenyltris((*tert*-butylthio)-methyl)borate; bipy = bipyridine.

1 INTRODUCTION

Recently, major progress has been made in solving the active-site structures of the nickel-containing metalloenzymes by single-crystal X-ray diffraction (the unsolved problem of bioinorganic chemistry as it exists in the 1980s–1990s) and in deducing the ways that nature activates/catalyzes reversible hydrogen oxidation (hydrogenases), hydrolysis of urea to ammonia and carbamate (ureases), reversible CO oxidation (carbon monoxide dehydrogenases), acetyl coenzyme assembly (acetyl coenzyme A synthase), and the formation of methane by the methanogens (methyl coenzyme M reductase). The high-resolution X-ray crystal structures of the active sites of the nickel-containing hydrogenases, carbon monoxide dehydrogenases (CODH/ACS), ureases, methyl coenzyme M reductase (MCR), as well as the role(s) of nickel in these enzymes have now been explored in detail. In such pursuit, extensive spectroscopic experiments and kinetic measurements on these enzymes have also been performed, as a background for the subsequent modeling studies. Since the mechanism(s) of catalytic reactions by the microorganisms remain elusive at the present time, modeling approaches have been adopted to correlate the spectral and reactivity parameters of model compounds with those of Ni-containing enzymes and to derive conclusions regarding mechanistic and functional characteristics of the biological nickel site.

2 HYDROGENASE

2.1 Background

Hydrogen metabolism (reversibly catalyzed oxidation of H_2 molecules) in the biological energy cycle is mostly mediated by two types of metal-containing enzymes, [NiFe] hydrogenases, and [Fe] hydrogenases.[1–5] [NiFe] hydrogenase containing a [Ni–Fe] center that is believed to be the catalytic site for hydrogen activation functions more effectively in the direction of H_2 oxidation. The recent X-ray crystallographic studies of the active-site structure of [NiFe] hydrogenases isolated from *Desulfovibrio gigas*, *Desulfovibrio vulgaris*, *Desulfovibrio fructosovorans*, and *Desulfovibrio desulfuricans* ATCC27774 in combination with infrared spectroscopy have revealed an active site comprised of a heterobimetallic $(S_{cys})_2Ni(\mu\text{-}S_{cys})_2(\mu\text{-}X)Fe(CO)(CN)_2$ (X = O, OH) cluster (Figure 1). The bridging ligand X was proposed to be an oxide or hydroxide in the oxidized state, and was found to be absent in the reduced state. Three nonprotein diatomic groups (two cyanide and one carbonyl ligands) ligate the iron center.[4–21]

The nickel site has been proposed to be redox active and changes between Ni(III) and Ni(II), while the iron site remains as Fe(II) in all spectrally defined redox states of the enzyme.[11–21,25–41] The EXAFS/EPR studies indicate that the formal oxidation state of the Ni center is paramagnetic Ni(III) in Ni–A, Ni–B and Ni–C states.[28–41] Actually, the active form Ni–C (the paramagnetic Ni–C intermediate) of [NiFe] H_{2ase} was proposed to exist as the $[(S_{cys}\text{-}H)Ni^{III}\text{-}H^{-}\text{-}Fe]$ intermediates after an active state Ni–SIa (silent-active $[(S_{cys}\text{-}H)Ni^{II}(S_{cys})_3]$) is passed. Ni–C is believed to be an intermediate in the catalytic cycle. Upon illumination,

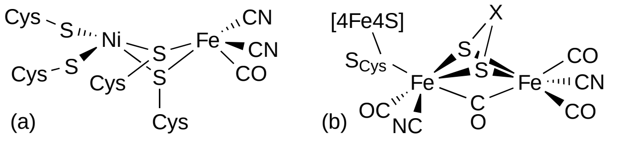

Figure 1 (a) A schematic drawing of the active site of [NiFe] hydrogenases as deduced from the crystallographic studies.[6–10] (b) A schematic drawing of the H-cluster of the CO-inhibited form of the *Clostridium pasteurianum* [Fe] hydrogenases as deduced from the recent X-ray crystallographic studies[22–24]

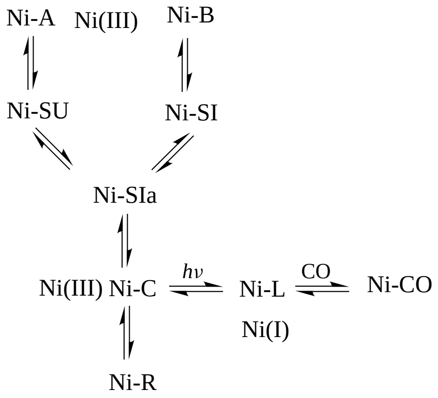

Scheme 1 The possible redox states of the active center of [NiFe] hydrogenases.[11–21,25–43]

the Ni–C state is transformed into a fourth paramagnetic Ni–L state. These conversions are considered to correspond to photodissociation of proton species from the [Ni–Fe] center.[28–41] Interestingly, the recent X-ray crystal structures of CO-inhibited forms and single-crystal EPR studies of the reduced active site of [NiFe] H_{2ase} isolated from *D. vulgaris Miyazaki F* implicate that the Ni–C intermediate is a formal Ni(III) oxidation state with a hydride (H^-) bridging between the Ni and the Fe atoms and the sulfur atom of Cys 546 hydrogenated for the catalytic reaction of the enzyme.[40,41] In addition, the active form Ni–C has also been shown to contain a solvent exchangeable proton, assigned as an in-plane hydride, as a S–H proton directly interacting with nickel, or as H_2 from ENDOR studies.[42,43] Interpretations of these results tend to favor the assignment of a Cys–SH proton directly interacting with nickel. The redox states of the active center of [NiFe] hydrogenases are shown in Scheme 1.

The recent report of high-quality X-ray crystal structures of [Fe]-only hydrogenases isolated from *D. desulfuricans* (DdH_{2ase})/*Clostridium pasteurianum* (CpH_{2ase}) revealed that the active sites are composed of a conventional [4Fe-4S] subcluster linked by a bridging cysteine to a dinuclear iron subcluster.[22–24,44,45] The crystal structures, in combination with FTIR data, suggest that the dinuclear iron subcluster is ligated by terminal CO and CN^- diatomic molecules with the two iron atoms linked by a di(thiomethyl)-amine ligand (DdHase)/two thiolate ligands (CpHase) and a carbonyl group. Upon reduction, FTIR spectra and crystal structure show that the previously bridging CO shifts toward the distal iron that most likely serves as the primary hydrogen binding site.[22–24,44,45] Mössbauer studies of the H-cluster in [Fe] hydrogenases isolated from *C. pasteurianum* (CpII) showed that the dinuclear Fe subcluster contains a low-spin $Fe^{II}-Fe^{II}$ site in the reduced state (H_{red}), while it is in the mixed-valence $Fe^{III}-Fe^{II}$ form in the oxidized state (H_{ox} and H_{ox}–CO).[46] It is generally believed that the dinuclear Fe subcluster of DdH_{2ase} and CpH_{2ase} may be assigned as [$Fe^{II}Fe^{II}$], [$Fe^{I}Fe^{II}$], and [$Fe^{I}Fe^{I}$] in the fully oxidized (inactive), the oxidized (active), and reduced states, respectively.[45,47–51]

2.2 Structural Models

Designing and synthesizing structural model complexes, in addition to serving as spectroscopic references, may provide an essential understanding about the active-site construction and function of [Fe] and [NiFe] hydrogenases, and the role/function of CO, CN^- ligands, and may elucidate the electronic structure of active centers of the binuclear subcluster.[52–54] Examples of structurally characterized, thiolate-bridged heterobimetallic NiFe complexes with iron coordinated by CO/NO ligands are few. [Ni{Fe(NS_3)(CO)–S,S′}$_2$] (NS_3=[N(CH_2CH_2S)$_3$]$^{3-}$) (**1**) is made up of two trigonal bipyramidal Fe(NS_3)(CO) units bridging to a central Ni(II) atom.[55] A review of the heterobimetallic NiFe compounds finds Ni–Fe distances ranging from 2.80 to 3.323 Å (Ni–Fe distance: **2**, 3.323(1) Å; **3**, 3.308(2) Å; **4**, 3.10 Å; **5**, 2.80 Å; **6**, 2.80 Å), far beyond the enzyme Ni–Fe distance. [($C_6H_4S_2$)Ni (μ-'S_3')Fe(CO)(PMe_3)$_2$] ('S_3'=bis(2-mercaptophenyl)sulfide (2−)) (**2**) nearly duplicates the donor atom set of [NiFe] hydrogenases centers with the ν(CO) frequency 1948 cm^{-1} (KBr) corresponding to the most reduced Ni–R state of hydrogenases.[56] The Ni of [Fe(CO)$_2${N(CH_2CH_2S)$_3$-S,S′}NiCl(dppe)] (**3**) is five-coordinate in a square pyramidal pattern and is displaced 0.307(2) Å from the base plane towards the chloride ligand in the apical site.[57] The unique NiFe heterotrimetallic (**4**) is formed by two {NiN_2S_2} fragments serving as a bidentate metallothiolate ligand bound to {Fe(CO)$_2$} motif.[58] Formation of [Ni^{II}(N_2S_2)Fe(NO)$_2$] (**5**) and [(NO)Ni^0(S_3)Fe(NO)$_2$] (**6**) may be rationalized according to the ability of the chalcogenolate (or metal-modified calcogenolate) ligand to stabilize the oxidized, {Fe(NO)$_2$}^{9}, or reduced, {Fe(NO)$_2$}^{10} forms.[59,60] The Ni^{II}-bound dichalcogenolate stabilizes the electron-rich or reduced form and the [Ni^0NO^+] unit effectively generates a monoanionic dithiolate ligand donor set that stabilizes the oxidized form.

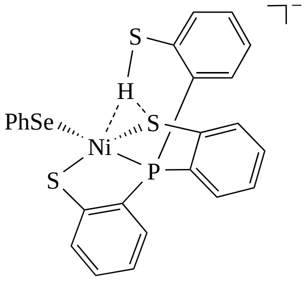
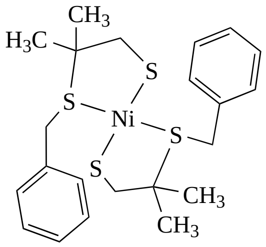
(**8**)

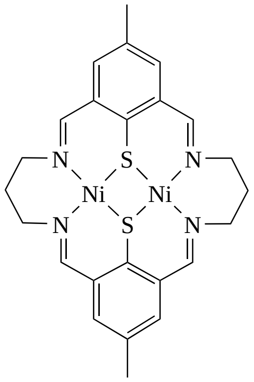


(**9**)

Mononuclear nickel-thiolate complexes may serve as precursors for synthetic goals of preparing Ni–Fe heterometallics in biological-type ligation settings. Structural models as $[Ni(CO)(SPh)_n(SePh)_{3-n}]^-$ ($n = 0, 1, 2$) (**7**), a distorted square-planar Ni^{II}–CO complex, may be appreciated as possibilities for intermediates in biological reaction pathways or as structures important to CO-inhibitory processes in the [NiFe] enzyme.[61,62] Interestingly, the mononuclear Ni^{III} $[Ni(SePh)(P(o\text{–}C_6H_4S)_3)]^-$ complex (**8**) with S-donor ligands has been structurally characterized recently.[63] Complex (**8**) is five-coordinate with three equatorial S-donors, one axial selenolate Se-donor and one axial P-donor. The distorted square-planar $[Ni(SePh)(P\text{–}(o\text{-}C_6H_4S)_2(o\text{-}C_6H_4SH))]^-$ (**9**) with the thiol proton interacting with both the nickel and sulfur sites was verified in the solid state by the observation of one $\nu_{S\text{–}H}$ stretching band (2274 cm^{-1}) in its IR spectrum and subsequently confirmed by an X-ray diffraction study.[63] The H/D exchange reaction between complex (**9**) and D_2O occurred in CH_3CN as indicated by IR and ^2H NMR. The facile conversion of complex (**9**) into complex (**8**) accompanied by by-product H_2O was observed upon exposure of complex (**9**) to O_2. In $[Ni(bsms)_2]$ (**10**), a promising complex for new structural models of [NiFe] hydrogenases, the two ligands are coordinated with the thiolates in trans positions to each other.[64] $[Ni_2(L)]^{3+}$, the one-electron oxidation product of $[Ni_2(L)]^{2+}$ (**11**), can be described with a proportion (ca. 30%) of the unpaired electron density delocalized onto the bridging thiolate ligands, that is, the charge delocalization lies between the $[Ni^{III}\text{-(–SR)}]$ and $[Ni^{II}\text{-}(\cdots SR)]$ redox extremes.[65]



(**10**)

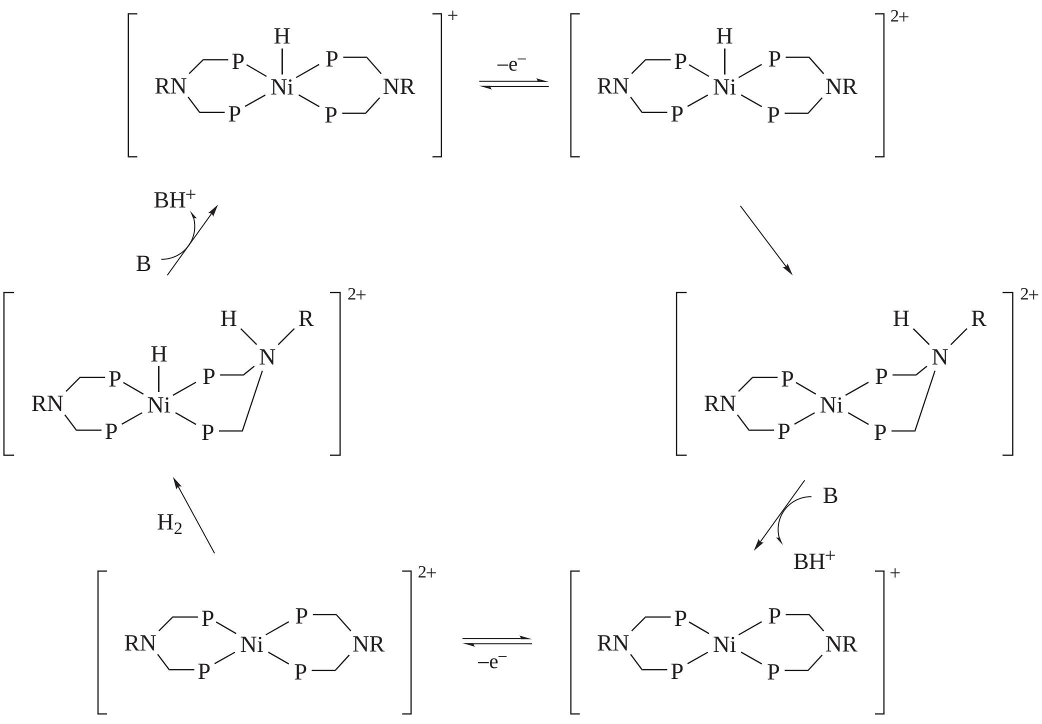


(**11**)

2.3 Models of Hydrogenase Catalysis

Hydrogenases catalyze the heterolytic cleavage of the hydrogen molecule. During catalysis, the Ni ion in [NiFe] hydrogenase has been proposed to serve as the catalytic site, heterolytically splitting the H_2 molecule into hydride and proton with the thiolate of Cys_{530} serving as a base. In model compounds, an electrochemical study provided evidence for such a Ni(III)-H species generated by one-electron reduction of a nickel(II) macrocyclic complex accompanied by protonation.[66] Recently, two elegant examples have been provided, $[Ni(diphosphine)_2]^{2+}$ containing ligand-appended nitrogen bases (**12**) and $[Ni(NHP\textit{n}Pr_3)(\text{'}S_3\text{'})]$ ($\text{'}S_3\text{'}^{2-}$=bis(2-sulfanylphenyl)sulfide(2−)) (**13**).

In one interesting model compound, complex $[Ni(PNP)_2]^{2+}$ (PNP = $Et_2PCH_2NMeCH_2PEt_2$) (**12**) is an electrocatalyst for the oxidation of hydrogen to protons, and stoichiometric reaction with hydrogen forms $[HNi(PNP)(PNHP)][(BF_4)_2]$ in which the hydride ligand is associated with nickel and the proton is bound by nitrogen.[67,68] Complex $[HNi(PNP)(PNHP)]^{2+}$ undergoes reversible deprotonation to yield $[HNi(PNP)_2]^+$. Meanwhile, the hydride ligand and the NH proton of $[HNi(PNP)(PNHP)]^{2+}$ undergo rapid intramolecular exchange with each other and intermolecular exchange with protons in solution. The proposed electrocatalytic reaction sequences are summarized in Scheme 2.[67,68] The one-electron oxidation of $[HNi^{II}(PNP)_2]^+$

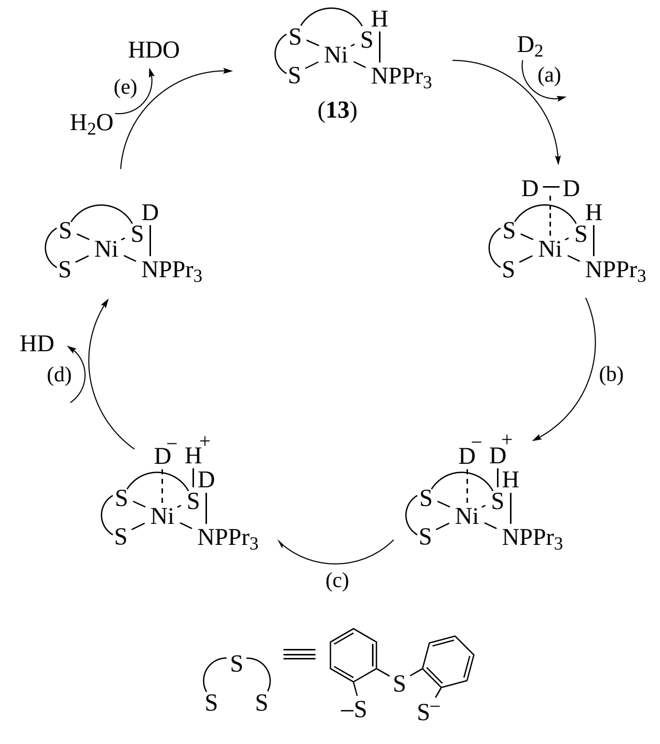


Scheme 2 A proposed mechanism for the oxidation of hydrogen. (Reprinted from *Inorg. Chem.*, 2003, **42**, 216–227. © 2003 American Chemical Society)

to $[HNi^{III}(PNP)_2]^{2+}$ is followed by rapid transfer of the proton bound to Ni in $[HNi^{III}(PNP)_2]^{2+}$ to the N atom of the chelating PNP ligand. A proton transfer occurs from the diphosphine ligand to give $[Ni^{I}(PNP)_2]^+$ and $HNEt_3^+$ in the presence of triethylamine. Oxidation of $[Ni^{I}(PNP)_2]^+$ to $[Ni^{II}(PNP)_2]^{2+}$ completes the two-electron oxidation process.

Model compound $[Ni(NHP\textit{n}Pr_3)$('S_3')] (**13**) was presumed to catalyze the heterolytic cleavage of H_2 (reaction of H_2 and D_2O yielding HD and HDO). Reactions of $[Ni(NHP\textit{n}Pr_3)$('S_3')] with D_2 and D_2O yielding $[Ni(NDP\textit{n}Pr_3)$('S_3')]/HD, and $[Ni(NDP\textit{n}Pr_3)$('S_3')]/HDO, individually, demonstrate that complex (**13**) is able to exchange NH protons with molecular D_2 and with H^+ or D^+.[69] The proposed mechanism of the catalyzed D_2/H^+ exchange is shown in Scheme 3.[69]

Recent kinetics studies on protonation of $[Ni(SEt)((Ph_2PCH_2CH_2)_2PPh)]^+$ (**14**) proposed that the proton interacts with both the nickel and sulfur sites,[70] consistent with the proposal of intramolecular proton transfer between cysteinate sulfur and Ni atom in the Ni-based hydrogenases. Additionally, the mononuclear complex $[Ni(psnet)]^+$ (**15**) of known structure and a mildly negative redox potential can stoichiometrically evolve H_2 from protic sources. On the basis of kinetics analysis, the reaction paths considered most probable involve steps of protic oxidative addition to Ni(I) to generate Ni^{III}-H^-, and electron transfer to Ni(III) followed



Scheme 3 A proposed mechanism for the oxidation of hydrogen. (Reprinted from *Angew. Chem. Int. Ed. Engl.*, 2000, **39**, 561–563. © 2000 John Wiley & Sons, Ltd)

by protonation of bound hydride or the bimolecular reaction $2Ni^{III}\text{-}H^- \rightarrow 2Ni^{II} + H_2$ to yield H_2.[71]

2.4 Models for the Iron Site of [NiFe] Hydrogenase

Examples of cyanide (CN^-) coordination to iron(II) and the spectroscopic signals of dicyanide iron(II) thiolate carbonyl complexes ($[(CN)_2(CO)Fe^{II}(SR)_2]^{n-}$) are of much interest, particularly in catalytically active-site construction of the $(CysS)_2Ni(\mu\text{-}Scys)_2Fe(CN)_2(CO)$ active site of [NiFe] hydrogenases. In the iron-site architecture of the [NiFe] hydrogenase active site, a vacant coordination site around iron, trans to the carbonyl ligand, may serve as a potential H_2-binding site and presumably plays an important role in biological hydrogen activation. By application of oxidative addition and stepwise ligand exchange route, *trans, cis*-$[(CN)_2(CO)_2Fe(S, S\text{–}C\text{–}R)]^-$ (R = OEt **16**, R = $N(Et)_2$ **17**) were isolated and characterized by X-ray crystallography and infrared spectroscopy.[72] Photolysis of THF solutions of complexes (**16**/**17**) led to the formation of coordinatively unsaturated iron(II) dicyanocarbonyl thiolate complexes $[(CN)_2(CO)Fe(S, S\text{–}C\text{–}R)]^-$ (R = OEt **18**, R = $N(Et)_2$ **19**, respectively), with two cyanides occupying cis positions and a vacant site preferably trans to the CO ligand. Complexes (**18**/**19**) and Ni–A/Ni–C states of [NiFe] hydrogenases from *D. gigas* exhibit a similar one-band pattern in the ν_{CO} region and two-band pattern in the ν_{CN} region, individually, but in different positions, which may be accounted for by the distinct electronic effects between $[S, S\text{–}C\text{–}R]^-$ and cysteine ligands.[72] Also, two particularly elegant model compounds $[Fe(CO)_2(CN)_2(SPh)_2]^{2-}$ (**20**) and $[Fe(CO)(CN)_2(S,S\text{–}C_6H_4)]^{2-}$ (**21**) have been characterized by IR and X-ray diffraction, recently.[73] Scrutiny of the coordination chemistry of iron(II)-thiolate species $[Fe^{II}(CO)_x(CN)_y(SR)_z]^{n-}$ reveals that certain combinations of thiolate and cyanide ligands ($3 \leq y + z \leq 4$) ligated to the Fe(II) center provide significant stabilization to the iron(II)-thiolate cyanocarbonyl species $[Fe^{II}(CO)_x(CN)_y(SR)_z]^{n-}$.[74,75]

3 UREASE

3.1 Background

The metalloenzyme urease catalyzes the hydrolysis of urea to ammonia and carbamate (equation 1).[76]

$$H_2NCONH_2 + H_2O \longrightarrow NH_3 + H_2NCOOH \quad (1)$$

The X-ray crystallographic studies of the enzyme isolated from *Klebsiella aerogenes* reveals an active site composed of a dinickel center with 3.5-Å Ni···Ni separation. A schematic view of the active site of urease isolated from *K. aerogenes* is

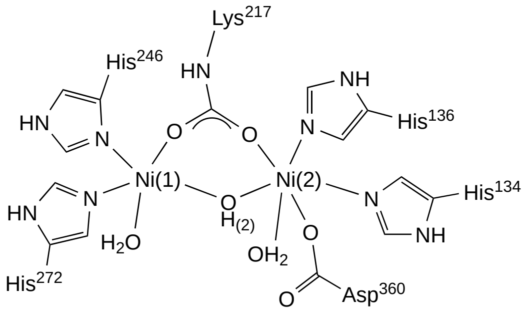


Figure 2 A schematic drawing of the active site of urease isolated from *K. aerogenes*[77–79]

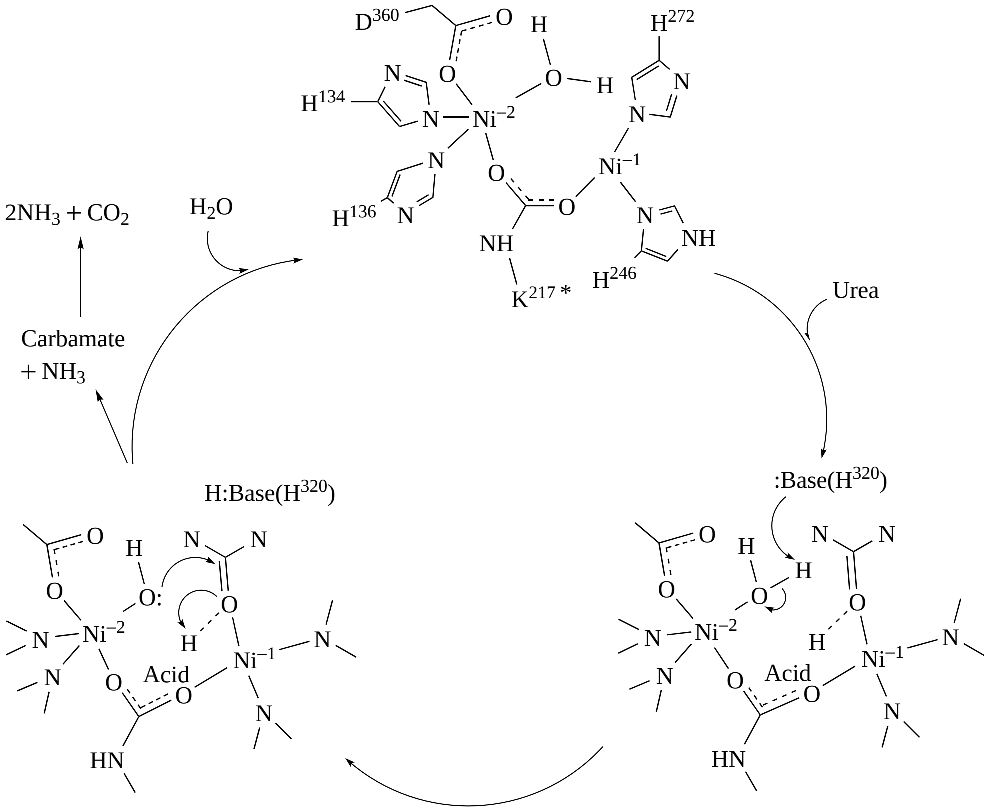
shown in Figure 2.[77,78] The two nickel ions are bridged by a carboxylate group of a carbamylated lysine residue (*see* ***Metal-mediated Protein Modification***) and one water molecule or hydroxide ion.[77–81] The geometry around one nickel ion (Ni(1)) is best described as a distorted square pyramidal with further coordination of two histidine residues from the protein and one terminally coordinated water molecule; the position is only partially occupied by a water molecule and considered to be a likely candidate for binding urea in the catalysis. One terminally coordinated water molecule, one additionally ligated aspartate residue, and two histidine residues complete the coordination spheres of the second nickel ion (Ni(2)), resulting in a pseudooctahedral geometry for Ni(2). The nickel centers are in the stable diamagnetic Ni(II) state; thus the role of Ni in urease may be essentially catalytic without necessarily redox chemistry.

Urease catalyzes hydrolysis of urea to ammonia and carbamate at a rate at least 10^{14} times faster than the spontaneous hydrolysis rate of urea in aqueous solution between pH 2 to 12.[82,83] The stability of urea is attributed to its resonance energy, which has been estimated at 30–40 kcal mol^{-1}.[84] The zwitterionic resonance forms of urea donate electrons to the carbonyl carbon, causing it to be less reactive toward nucleophiles.

It is considered that urease employs such an unsymmetric dinuclear core to promote the concerted binding of the substrate at one nickel center and a hydroxide nucleophile at the other nickel center.[80] There are many studies of urease[77–85] and model dinickel complexes to elucidate the relationship between the structure and function of the dinickel active site.[86–91] The generally accepted mechanism has suggested that both nickel ions are involved in the hydrolysis of urea. Several key features of the molecular geometry at the active site are essential for the function of the enzyme: (i) an open coordination site at each nickel center, (ii) the generation of a Ni-bound hydroxyl group resulting from removal of a proton from coordinated water by the assistance of a basic histidine residue located in proximity to the dinickel core, and (iii) polarization of the urea substrate through oxygen binding



Scheme 4 A mechanism for the hydrolysis of urea by urease

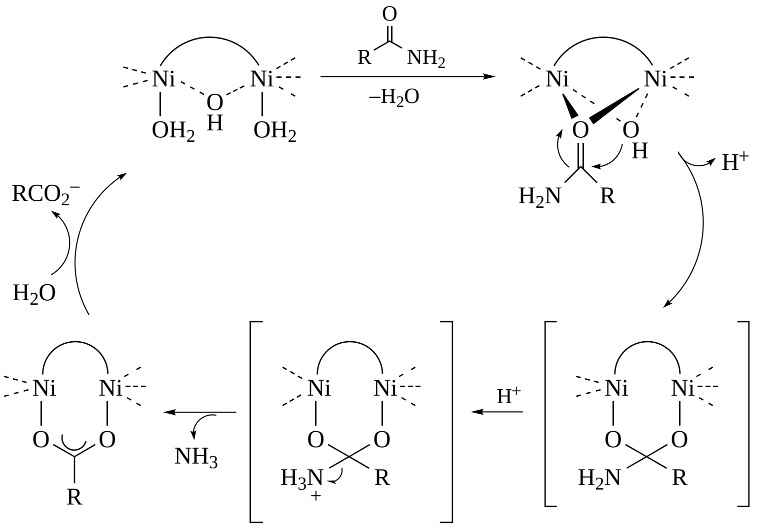
to one Ni center followed by nucleophilic attack by a Ni-bound hydroxyl group.[77–92] The choice of Ni for this catalytic hydrolysis reaction may be attributed to the high affinity of the urea-Ni binding and the stability of the urease Ni-containing active site. The proposed catalytic cycle of ureases is shown in Scheme 4.[80]

3.2 Structural and Functional Models

Numerous dinickel complexes have been reported as models for urease. As depicted in Scheme 5, a dinickel complex $[Ni_2(\mu\text{-OH})(\mu\text{-}H_2O)(bdptz)(H_2O)_2][OTs]_3$ is capable of hydrolyzing a bound amide substrate by intramolecular nucleophilic attack of a coordinated hydroxide ion, either from a bridging position or from a transient terminally bound form.[86] This amide hydrolysis mimics the hydrolysis of urea by urease in that a hydroxide nucleophile is generated by the dinickel center, and the coordination of the substrate to the dinickel center as well as a nickel-bound hydroxide ion serving as the nucleophile are crucial to hydrolysis. Protonation of the amine group by an acidic residue in the active-site results in loss of ammonia.

A number of dinickel urease models with urea bound to the dinickel center implicate preferential binding of urea via the carbonyl oxygen atom;[87–91] this coordination mode is believed to be a species formed for the urea substrate binding to Ni(1) by replacing the terminally bound water molecule in the catalytic cycle of urease.[77,79] In addition to these model complexes, catalytic ethanolysis of urea by a (μ-alkoxo)(μ-carboxylato)dinickel(II) complex, presumably taking place via nucleophilic attack of ethanol solvent on coordinated urea, was also reported.[88,90]

An alternative mechanism for the urease-catalyzed hydrolysis of urea is hydrolysis of urea to ammonia and carbon dioxide through formation of a cyanate intermediate.[92–95] This reaction proceeds via a pathway, which is distinct from the proposed enzymatic hydrolysis of urea shown in Schemes 4 and 5. Upon heating, a dinickel complex $[Ni_2(\mu\text{-OH})(\mu\text{-urea})(bdptz)(urea)(CH_3CN)][ClO_4]_3$ containing a bridging urea molecule promotes the hydrolysis of urea in a two-step reaction; a molecule of ammonia is eliminated from urea with concomitant formation of a cyanate intermediate and, subsequently, the cyanate-containing intermediate is hydrolyzed by an external water molecule upon further heating. In this catalytic reaction, it is proposed that the coordinated hydroxide ion is not sufficiently nucleophilic to hydrolyze the coordinated urea molecule. On the contrary, the coordinated hydroxide ion serves as a base aiding in the deprotonation of urea to favor elimination. These results establish the precedence for hydrolysis of urea via a cyanate



Scheme 5 A mechanism for the hydrolysis of urea. (Reprinted from *J. Am. Chem. Soc*, 1999, **121**, 11751–11757. © 1999 American Chemical Society)

intermediate for the urease-catalyzed hydrolysis of urea, as shown in Scheme 6.[92]

In addition, urease is inhibited by a variety of agents including fluoride[96] and disulfides,[97] as observed recently in the acetohydroxamate-inhibited C319A variants of *K. aerogenes* urease.[78] It is proposed that this mode of inhibition involves coordination of the inhibitor to only one nickel center, while another involves the inhibitor bridging the dinickel center. Urease is slowly inhibited by fluoride in both the presence and absence of substrate, and fluoride binding rates are directly proportional to inhibitor concentration. Fluoride inhibition is pH-dependent due to a protonation event linked to fluoride dissociation. That fluoride binding is pH-independent suggests that fluoride anion, not HF, is the actual inhibitor.[96] Reaction of the model complex $[Ni_2(OAc)_3(urea)(tmen)_2][OTf]$ ($OAc = CH_3COO^-$) with acetohydroxamic acid (AHA) gives the monobridged hydroxamate complex $[Ni_2(OAc)_2(AHA)(urea)(tmen)_2][OTf]$, a close model of the proposed mode of urease inhibition by hydroxamic acids.[78,89,98] In particular, only one bridging hydroxamate for the inhibited urease was suggested.[98]

4 CARBON MONOXIDE DEHYDROGENASE/ ACETYL COENZYME A SYNTHASE (CODH/ACS)

4.1 Background

Carbon monoxide dehydrogenase/acetyl coenzyme A synthase (CODH/ACS) describes two different classes of enzymes; carbon monoxide dehydrogenase (CODH) isolated from *Rhodospirillum rubrum* or *Carboxydothermus hydrogenoformans* reversibly oxidizes CO to CO_2 according to equation (2), and the bifunctional CODH/ACS enzyme from *Moorella thermoacetica* catalyzes the reversible reduction of CO_2 to CO (CODH) and acetyl coenzyme assembly/disassembly (ACS) (equation 3).[99–101]

$$CO + H_2O \rightleftharpoons CO_2 + 2H^+ + 2e^- \quad (2)$$

$$CO + HSCoA + CH_3\text{-Co(III)-CFeSP} \rightleftharpoons CH_3\text{-}\overset{\overset{\displaystyle O}{\|}}{C}\text{-SCoA} + \text{Co(I)-CFeSP} + H^+ \quad (3)$$

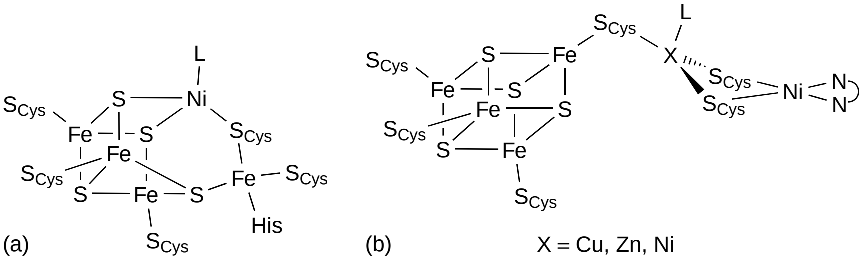

Figure 3 (a) A schematic drawing of the active-center C-cluster of CODH isolated from *R. rubrum* or *C. hydrogenoformans*.[102–104] (b) A schematic drawing of the active site of the ACS enzyme isolated from *C. thermoaceticum*[104–106]

Recent X-ray crystallographic studies indicated that the dimeric CODH isolated from *R. rubrum* or *C. hydrogenoformans* contains two [Fe-NiFe_3S_4] C-clusters, two conventional cysteine-ligated [Fe_4S_4] B-clusters, and a D-cluster that bridges the two subunits.[102–104] The B-cluster is involved in electron transfer and the *R. rubrum* enzyme catalyzes the biological oxidation of CO at the C-cluster. The active-center C-cluster is composed of the mononuclear Fe site and the four-metal cubane cluster [NiFe_3S_4] bridged by cysteine and one of the sulfides of the cube, as shown in Figure 3(a). Recently, the crystallographic characterization of the ACS enzyme isolated from *C. thermoaceticum* revealed an unprecedented hexametallic active site, a cuboidal [Fe_4S_4] unit linked via cysteine to a binuclear [CuNi] subcluster. The proximal copper atom is coordinated by three cysteine sulfur atoms and the unidentified fourth ligand. The distal Ni is in a square-planar environment with two amide nitrogens (deprotonated protein backbone) and two cysteine thiolates coordination (Figure 3(b)).[104–106]

The amount of Cu in CODH/ACS directly correlates with ACS activity. However, Cu is not the only metal that can occupy the Cu site. The negative correlation between Zn content and ACS activity suggests that Zn can replace Cu and inhibit the enzyme.[106] In contrast, the active-site structure from *M. thermoacetica* ACS enzyme (an $\alpha_2\beta_2$ tetramer) shows that the two α-subunits display different conformations (open and closed conformations). One α- subunit contains one Zn, located in the proximal site, and one Ni at its active-site metal cluster (α-closed form), while the A-cluster of the other α subunit contains two Ni ions at the corresponding positions (α-open form).[107,108] These investigations also demonstrate that Cu-containing ACS is inactive and only the A-cluster containing two Ni ions are responsible for the observed catalytic activity.[107,108] Such a Ni(μ-Cys)$_3$ low-coordinate site may be susceptible to demetalation by 1,10-phenanthroline, accounting for the observation that 1,10-phenanthroline removes some of the Ni in the protein resulting in loss of ACS activity and the correlated spectroscopic signals.[107,108]

The CODH from *R. rubrum* catalyzes both the oxidation of CO as well as the reduction of CO_2, and does not synthesize acetyl CoA. A mechanism for CO/CO_2 oxidation catalyzed by the C-center of CODH has been proposed in which the C-center can be stabilized in three states. The detailed electronic structures of the various [Fe-NiFe_3S_4] oxidation states remain ambiguous. As shown in Scheme 7, CO binding to the Fe site and subsequent nucleophilic attack of OH^- on the CO or CO insertion into the Ni–OH bond leads to the release of CO_2. In this catalytic cycle, it is proposed that CO is bound to a unique Fe site of the C-cluster and at least two sites of the C-cluster are essential for the catalytic interconversion of CO and CO_2. Meanwhile, the Ni ion is proposed to be redox active.[109–111] On the basis of recent studies, a model for the mechanism of CO_2 reduction was proposed. In this model, fully oxidized CODH ($[(CO_L)Fe^{2+}\text{-}Ni^{2+}]^{4+}$) and CODH at the C_{red1} state ($[(CO_L)Fe^{3+}\text{-}Ni^{2+}\text{-}H^-]^{4+}$) are unable to reduce CO_2 to CO. CO_2 reduction only occurs effectively when the putative [Fe-NiFe_3S_4] subcluster is fully reduced $[(CO_L)Fe^{2+}\text{-}Ni^{2+}\text{-}H^-]^{3+}$ (C_{unc} state).[111–114] The B-cluster mediates electron flow from the C-center to the external electron acceptors in *R. rubrum* CODH and to the A-cluster via the 13.8-Å-long hydrophobic channel in *M. thermoacetica* CODH.[115] Cyanate, thiocyanate, and azide have been shown to bind to the C-center and inhibit CO oxidation.[116]

In addition to the CO oxidation occurring at the C-center, the *M. thermoacetica* enzyme is also capable of catalyzing the synthesis of acetyl coenzyme A at the A-center located in the α subunit.[117] The bifunctional enzyme CODH/ACS plays a central role in the Wood–Ljungdahl pathway of autotrophic CO_2 fixation.[99] In the acetate-production pathway, one CO_2 molecule is reduced to a methyl group in a set of enzymatic reactions. CO generated from CO_2 reduction at the C-cluster travels through a 70-Å channel and binds to Cu to generate a paramagnetic species NiFeC observed by FTIR and EPR spectroscopy.[105,118–120] The proposed mechanism of acetyl CoA synthesis is shown in Scheme 8. Methylation of Ni by the methyl group of protein-bound methylcob(III)amide yields cob(I)amide and a diamagnetic state, a transient methyl-Ni(III) species.[121,122] Electron transfer from $[Fe_4S_4]^+$ to the transient methyl-Ni(III) species generates methyl-Ni(II). The reaction of CO and the methyl group could proceed through an alkyl migration yielding an acetyl-metal-bound intermediate, and then HSCoA is deprotonated and acetylated.[123]

4.2 Structural Models

There are several bimetallic systems bearing a stoichiometric and structural resemblance to the bimetallic site of ACS. Structures of the binuclear complexes (**22**) and (**23**) show that the adjacent thiolate donors of the $[N_2S_2]$Ni motif can serve as a chelate in coordinating to a single Cu metal. Reactivity studies confirm that the binuclear complexes (**22**) and (**23**) bind CO, and subsequently, generate the respective mononuclear species, $[N_2S_2]$Ni and $[PhTt^{tBu}]$Cu(CO) resulting from the rupture of the thiolate bridges,[124,125] as observed in the paramagnetic NiFeC species. The NiFeC species, produced from reductive carbonylation of the A-cluster, indicates Cu-CO and acetyl-Cu intermediates characterized by EPR, IR, and Mössbauer studies.[105,126–128] The dimeric 'staircase' structure $[Cu_2\{NiS_2N_2\}_2]^{2+}$ (**24**), structurally analogous to the ACS active site, was obtained by reaction of $[Cu(NCMe)_4]^+$ and the nickel hexamethylated diamino dithiolate ($[NiS_2N_2]$).[129] Treatment of complex (**24**) with PR_3 (R = *i*Pr, NMe_2) yielded the bimetallic derivative $[\{(R_3P)(MeCN)Cu\}\{NiS_2N_2\}]^+$ (**25**).

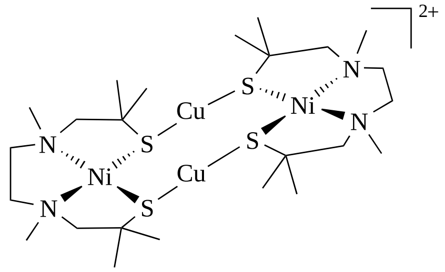
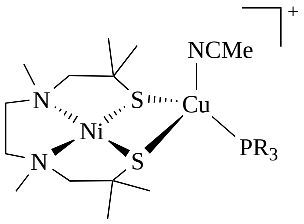
(23)

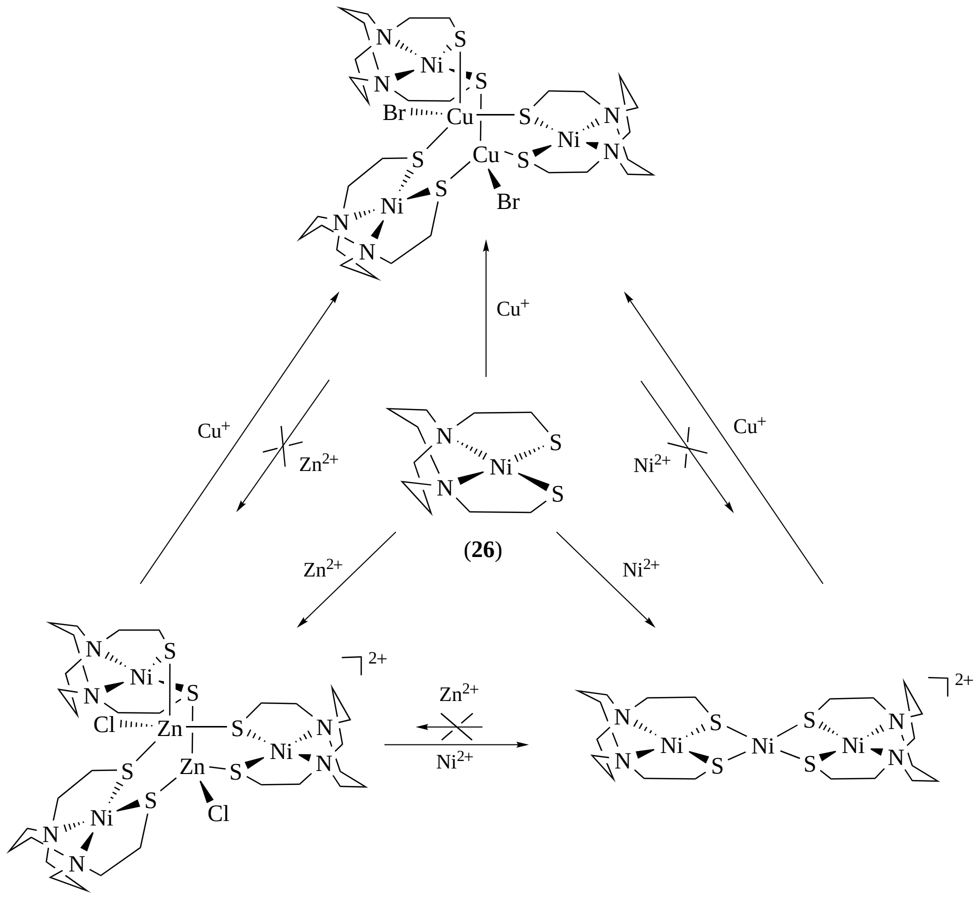


(24)

Relevant to the conflicting reports of copper versus nickel requirements for enzyme activity,[106,130] biochemical studies demonstrated the existence of a labile nickel associated with the α subunit of ACS/CODH.[131] Very recently, model studies on a metal-ion capture of a peptide-backbone, nonlabile $[NiN_2S_2]$ (**26**) unit have established the capability of such a nickel dithiolate to bind exogeneous metals. A qualitative ranking of the binding ability of complex (**26**) with Zn^{2+}, Cu^{+}, and Ni^{2+} was established by a metal-ion displacement experiment ($Zn^{2+} < Ni^{2+} < Cu^{+}$), as shown in Scheme 9.[132] A concept that the chemically most reasonable dinickel ACS



(25)



Scheme 9 The binding ability of complex (**26**) with Zn^{2+}, Cu^{+} and Ni^{2+}

active site could be compromised by copper replacement has been derived from the lability study of both Zn and Ni bound by the model complex (**26**). This accounts for the possibility of exclusion of inappropriately associated metals to ultimately achieve functioning active sites in the nickel enzyme.[133]

On the other hand, the A-cluster in the ACS subunit of the protein is also proposed to bind CO via the Ni atom prior to CO migratory insertion into a H_3C–Ni bond.[99,134] The four-coordinate [(bipy)Ni(CH_3)(SR)] and [(bipy)Ni($SCH_2CH_2CH_2$)] complexes provide a possible model for CO insertion into the H_3C–Ni bond yielding the stable acetylthiolatonickel,[135] and thialactones under CO atmosphere,[136] respectively.

5 METHYL COENZYME M REDUCTASE

5.1 Background

Methyl coenzyme M reductase (MCR) is the enzyme responsible for the microbial formation of methane by the methanogens, a class of strictly anaerobic archaebacteria.[137–140] A key component of the active site of MCR is cofactor F_{430} (Figure 4), a nickel tetrahydrocorphinoid cofactor.

X-ray crystallographic studies reveal that MCR is composed of three different subunits in an $\alpha_2\beta_2\gamma_2$ arrangement containing tightly bound 2 mol of the nickel porphinoid

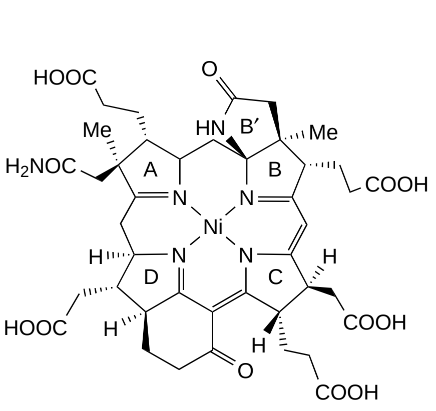


Figure 4 A schematic drawing of the active site of MCR[139,141–143]

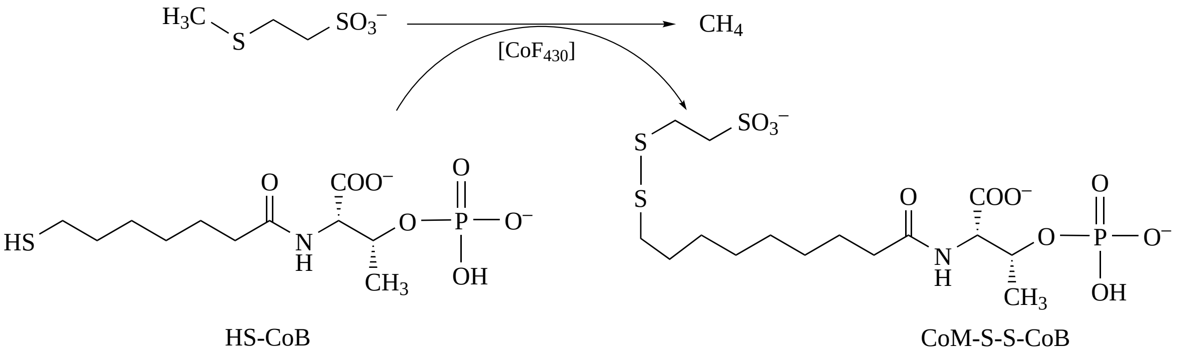


Scheme 10 The production of methane and CoM-S-S-CoB catalyzed by methyl coenzyme M reductase

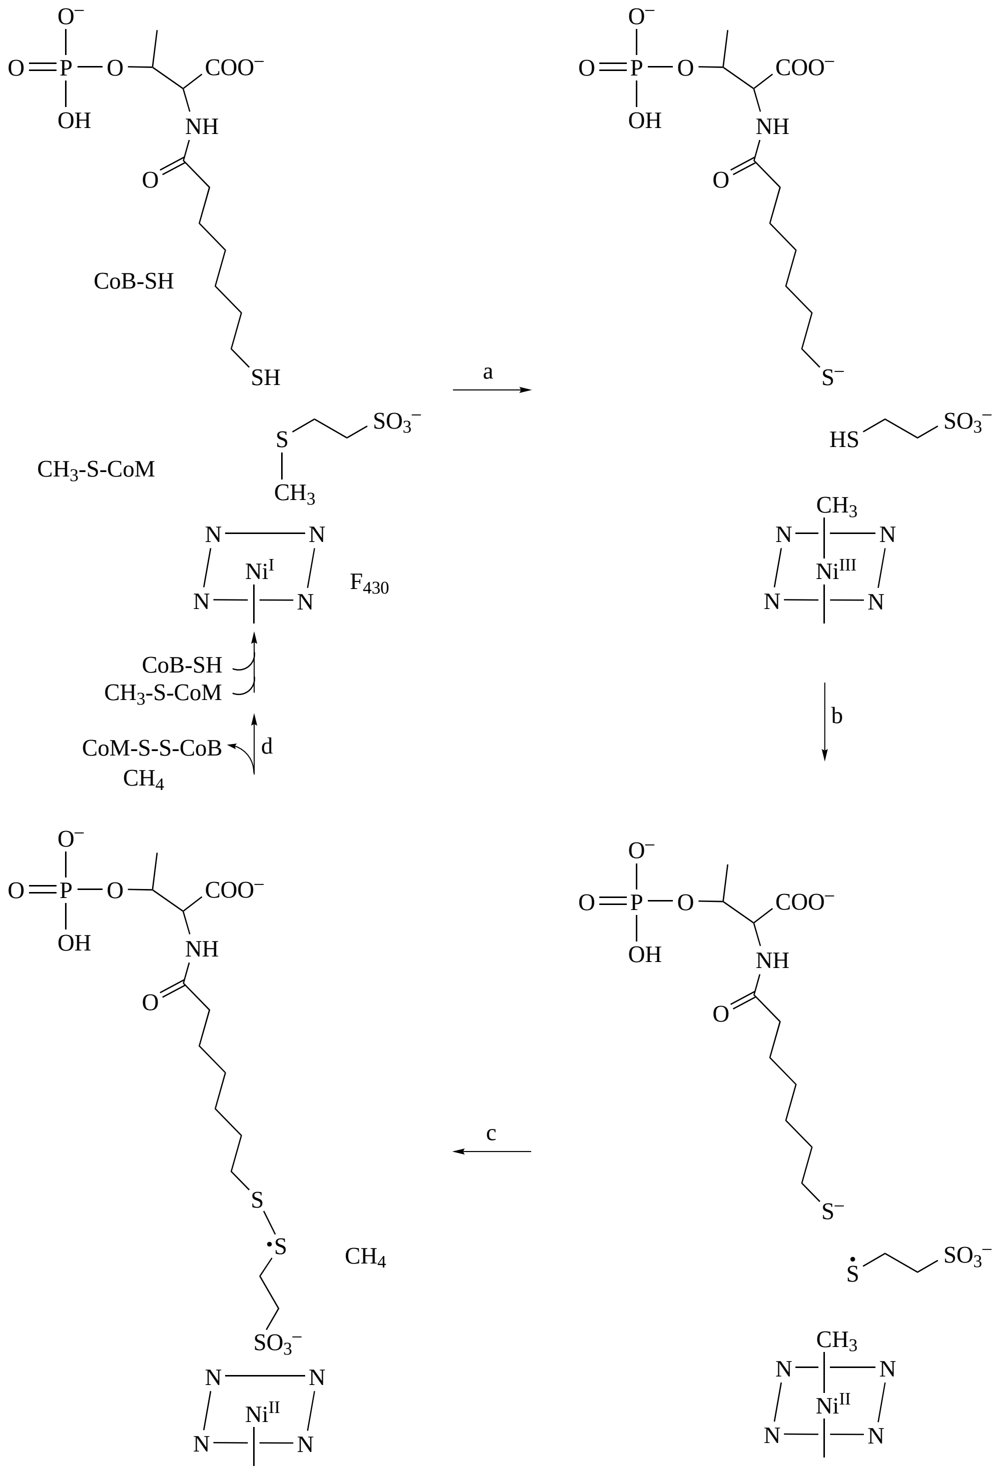
F_{430}, and cofactor F_{430} forms the base of a narrow well accommodating the two substrates.[141–143] The phosphate group of HS-CoB binds at the upper lip of the well with its thiol group located 6 Å from the central Ni atom of F_{430}.[141–143] Synthesis of methane and the heterodisulfide CoM-S-S-CoB is achieved by two-electron reduction of MeS-CoM (2-(methylthio)ethanesulfonate) by HS-CoB (7-thioheptanoylthreonine phosphate) (Scheme 10). HS-CoB serves as the electron donor, and the heterodisulfide CoM-S-S-CoB is the product of the oxidative half-reaction.[137–140]

A variety of nickel oxidation states (Ni(I), low-spin Ni(II), high-spin Ni(II) and Ni(III)) have been characterized for F_{430}.[141–146] High-resolution X-ray crystallographic structures of EPR-silent high-spin Ni(II) forms of the inactive enzyme show that the Ni sites are six-coordinate with four tetrapyrrole nitrogen ligands in the plane, the carbonyl oxygen of a side-chain glutamine in the lower axial position, and the thiolate of $^{-}$S-CoM as the upper ligand in the $MCR_{red1\text{-}silent}$ and $MCR_{ox1\text{-}silent}$ states. A sulfonate oxygen from the CoM-S-S-CoB disulfide is the upper axial ligand in MCR_{silent} state.[141–143] For the enzyme to be active, the prosthetic group has to be in the Ni(I) oxidation state, and EPR, ENDOR, resonance Raman, and X-ray absorption studies demonstrate that both the MCR_{ox1} and MCR_{red1} are Ni(I) states.[145–147] Meanwhile, XAS results indicate that the Ni(I) sites in both MCR_{ox1} and MCR_{red1} are six-coordinate. On the basis of X-ray crystallographic structures of two Ni(II) inactive forms of the enzyme, a proposed catalytic mechanism is shown in Scheme 11.[141] A nucleophilic attack of coenzyme F_{430} Ni(I) form on the methyl group of CoM leads to a Me-Ni(III) complex (Scheme 11a). Here the nucleophilic reaction of Ni(I) resulting in the activation of the carbon–sulfur bond is presumed to be facilitated by protonation of MeS-CoM. Electron transfer from the protonated CoM to the strongly oxidative Ni(III) results in the formation of a CoM thiyl radical and Me-Ni(II) intermediate. Protonolysis of the methyl group of the Me-Ni(II) intermediate, the concomitant coupling of the CoM thiyl radical and the thiolate group of CoB, accompanied by electron transfer from the generated disulfide anion radical to the Ni(II), generates methane, CoM-S-S-CoB and the second Ni(I) intermediate (Scheme 11b–c). It is proposed that a coordination of the sulfonate oxygen to nickel is prevented when nickel is present as nucleophilic Ni(I). The repulsion between Ni(I) and the sulfonate oxygen molecules might act as a driving force to push the heterodisulfide out of the channel (Scheme 11d).[141]

Density functional theory (DFT) computations suggest that either Ni(I) or Ni(III) formulations for MCR_{ox1} states are conceivable.[148,149] EPR/ENDOR studies and analyses of the XANES/EXAFS/RR data indicate that both the MCR_{ox1} and MCR_{red1} states are best described as a hexacoordinate Ni(I) species, and that the main difference between MCR_{ox1} and MCR_{red1} is a change of one axial ligand from a S donor to an O/N donor.[149,150] Studies also imply that conversion from MCR_{ox1} to MCR_{red1} involves conformational rearrangements resulting from a two-electron reversible reduction of the hydrocorphin ring of F_{430}, and these changes trigger the activation to a MCR_{red1} state that can react productively with the methyl group of Me-SCoM.[148–150] In addition, recent studies implicate that the six-coordinate Ni(I) centers in the MCR_{ox1} and MCR_{red1} states exhibit markedly different reactivities and the enhanced reactivity of MCR_{red1} is due to the replacement of a relatively exchange-inert thiol ligand in MCR_{ox1} with a weakly coordinating upper axial ligand in MCR_{red1} that can be easily replaced by incoming ligands.[148–150] Furthermore, HS-CoB is required as a second substrate and induces a change forcing the real substrate, Me-S-CoM, and Ni(I) of the prosthetic group to interact in the active enzyme MCR_{red1}.[151–154]

5.2 Structural and Functional Models

Ni^{I}-F_{430} reacting directly with MeS-CoM before/after the substrate activation, the role of the thiol cofactor HS-HTP, and the reason(s) for the enzyme specifically directing the C–S bond cleavage to the Me–S bond of Me-CoM are the principal questions to be resolved to understand how the enzyme methyl coenzyme M reductase functions.



Scheme 11 A proposed catalytic mechanism for the formation of methane and CoM-S-S-CoB by methyl coenzyme M reductase

Numerous mononuclear Ni complexes have been synthesized to investigate the possible mechanism for the formation of disulfide and methane catalyzed by the enzyme.[155–159] Two models that are perhaps relevant to the mechanistic situation of MCR are complexes (**27**) and (**28**) that feature square-planar Ni site coordinated through both the thiolate and the methyl thioether sulfur atoms,[155] and four N-donors,[156] respectively.

As interpreted in Scheme 12,[155] a sterically shielded, bifunctional model substrate containing a methyl thioether and sulfhydryl functional group could form a five-membered

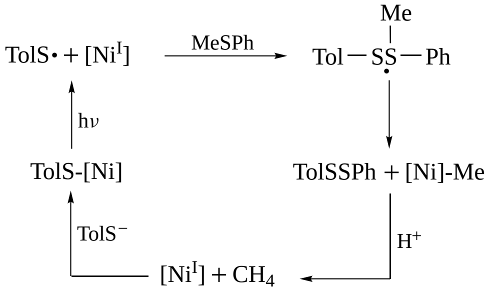
(**28**)



Scheme 13 A mechanism for methane formation involving a Ni–Me intermediate

cyclic sulfuranyl radical when this complex was irradiated with light of $\lambda > 300$ nm. The role of irradiation is interpreted as the formation of a Ni^{I}-thiyl radical pair upon excitation of a charge-transfer band of the Ni^{II}-dithiolate compound (Scheme 12a). Cyclization of the photochemically generated thiyl radical yields a sulfuranyl radical accompanied by transfer of a methyl group to Ni(I) to produce a methyl-Ni(II) intermediate (Scheme 12b–c). Here the addition of a thiyl radical to the sulfur atom of the thioether giving a sulfuranyl radical intermediate is the central step. The methyl-Ni(II) intermediate dissociates to methane and complex (**27**) through protonation. In particular, the cleavage of the carbon–sulfur bond of the aliphatic sulfide described in Scheme 12 occurred only in the presence of nickel and after excitation of the Ni^{II}-thiolate charge-transfer band.

A similar, but bimolecular, photoinduced reaction was observed on the basis of the nickel complex (**28**), *p*-toluene thiolate, and thioanisole reactants to generate methane and disulfide.[156] The thiyl radical and Ni(I) complex was prepared by the photolysis of the Ni(II) complex (**28**) and *p*-toluene-thiolate anion in acetonitrile solution. Upon irradiation ($\lambda = 350$ nm) of the mixture of complex (**28**), *p*-toluene-thiolate ion, and thioanisole in acetonitrile under argon, gas chromatography-mass spectral analysis showed the formation of methane, ditolyl disulfide $(TolS)_2$, and a mixed disulfide TolSSPh. The proposed catalytic mechanism is depicted in

Scheme 13.[156] The catalytic reaction was proposed to go through a sulfuranyl radical by addition of a thiyl radical to the sulfur atom of the thioether MeSPh. Interestingly, these studies are consistent with the proposed mechanism of the enzyme; the thiyl radical of cofactor HS-CoB resulting from one-electron reduction of F_{430} by $^{-}$S-CoB couples with Me-CoM to afford the sulfuranyl radical, CoB-S-S·(Me)-CoM. The sulfuranyl radical transfers a methyl radical to Ni^{I}-F_{430} to generate Me-Ni^{II}-F_{430} and the heterodisulfide CoM-S-S-HTP.[160,161]

1 INTRODUCTION

The organometallic chemistry of nickel has experienced rapid growth over the past decade. A number of exciting new areas have emerged, such as the reactivities of Ni(0)-carbene complexes (*see* ***Carbene Complexes***) and the polymerization of olefins catalyzed by nickel complexes (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***) of nitrogen-based ligands. In addition, the traditionally rich area of Ni-catalyzed organic transformations has undergone major developments that have expanded the scope of their applications. Altogether, the synthesis and characterization of new complexes, the discovery of new reactions, and the development of new catalytic processes has meant that a bright future awaits this area of inorganic chemistry.

The material presented in this chapter is organized in various sections according to the main ligands coordinated to the Ni atom or the type of reaction being discussed. Thus, there will be a section on the complexes of allyl, Cp, Ind, and Tp ligands (*see Tris(pyrazolyl)borates*). The increasing number of reports that have appeared on these complexes over the past decade show that they have a rich array of interesting structural and reactivity features. The main structural and bonding properties of these complexes are presented and their major reactivities are outlined.

Section 3 is devoted to the complexes of hydride, alkyl, alkenyl, and silyl ligands. Hydrido (*see* ***Hydride Complexes of the Transition Metals***) and alkyl complexes of most transition metals, and in particular those of nickel, are often involved in many catalytic processes of commercial importance; therefore, an in-depth understanding of the fundamental reactivities of these complexes is crucial to expanding their practical applications. Silyl complexes are involved in the transformations of organosilicon compounds, and for this reason their basic reactivities and structural properties are of interest.

The chemistry of zerovalent nickel complexes will be discussed in Section 4. One of the most exciting developments in this area is the recent introduction of N-heterocyclic carbene ligands. Ni complexes of these ligands have been shown to be important catalysts and reagents for a number of important organic transformations. This section will describe briefly the practical methods for preparing Ni-carbene complexes and will outline some of the catalytic reactions promoted by these complexes. This section will also describe the preparation and reactivities of other types of Ni(0) complexes.

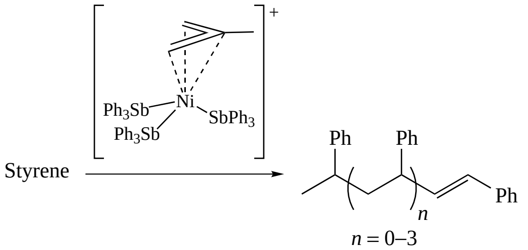
Section 5 is dedicated to discussing the polymerization and copolymerization of olefins. This aspect of the chemistry of Ni complexes has experienced a phenomenal growth and development over the past decade, beginning with the discovery of a family of diimine complexes that catalyze the polymerization of aliphatic olefins. A series of new and highly efficient catalysts were introduced in rapid progression, a great deal of new chemistry has been discovered, and a number of industrial processes have been developed on the basis of these nickel complexes. In contrast, nickel-based catalysts are not very efficient in the alternating copolymerization of CO/ethylene, but studies of this reaction have revealed very interesting patterns of reactivity which appears to be fairly unique to nickel.

The last section of this chapter is dedicated to an overview of a number of coupling reactions catalyzed by nickel complexes. Thus, we will discuss the emergence of new strategies for the efficient cross-coupling of alkyl halides with organozinc and Grignard reagents, as well as the coupling of dienes with CO_2.

2 ALLYL, CYCLOPENTADIENYL, INDENYL, AND TRIS(PYRAZOLYL)BORATE COMPLEXES

2.1 Allyl Complexes

Allyl complexes (*see Allyl Complexes*) have occupied an important position in the development of the organometallic chemistry of nickel. Thus, allylnickel complexes have had numerous applications in organic synthesis (e.g. nucleophilic attack on coordinated allyl ligands) and have been identified as key intermediates in the oligomerization and cyclization of olefins and dienes; moreover, the η^3/η^1 rearrangements of allylnickel species has helped explain the facile isomerization of olefins in the presence of nickel complexes. The vast majority of allylnickel complexes are 4-coordinate, 16-electron complexes of the type (allyl)Ni(L)X, $[(\text{allyl})\text{NiLL}']^+$, or $(\text{allyl})_2\text{Ni}$ (L and X are neutral and anionic two-electron donor ligands, respectively). A recent report has shown, however, that formally 5-coordinate and 18-electron species are thermally stable but highly reactive catalysts (turnover frequency of up to 2000/min) for the oligomerization of styrene (equation 1).[1] The unusual coordination of three $SbPh_3$ ligands and their great lability are due, presumably, to the longer, less robust Ni–Sb bonds.



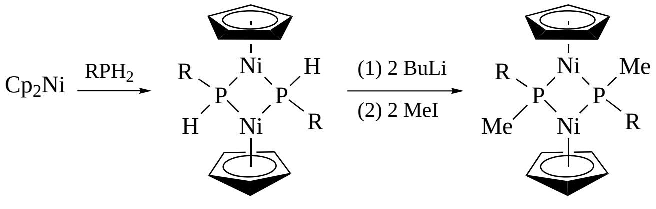
(1)

In comparison to the allyl complexes, the analogous cyclopentadienyl (Cp) complexes, with the exception of nickelocene, Cp_2Ni (*see Nickelocene*), have played a less prominent role. However, there has been a resurgence of interest over the past decade in the reactivities of CpNi complexes and this interest has extended into the chemistry of the analogous indenyl (Ind) and tris(pyrazolyl)borate (Tp) (*see Tris(pyrazolyl)borates*) complexes. Some of the major developments in this area are outlined in the following sections.

2.2 Cp Complexes

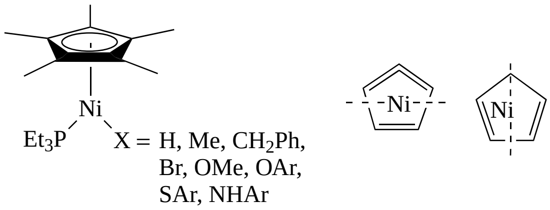
The reaction of nickelocene with primary phosphines has allowed the preparation of the phosphido-bridged dimers (**1**); deprotonation and methylation of the phosphido moiety results in the formation of the methylated derivatives (**2**) (Scheme 1).[2]

A large series of pentamethylcyclopentadienyl (Cp*) derivatives have been prepared by reacting PEt_3 with



(**1**) (**2**)

Scheme 1



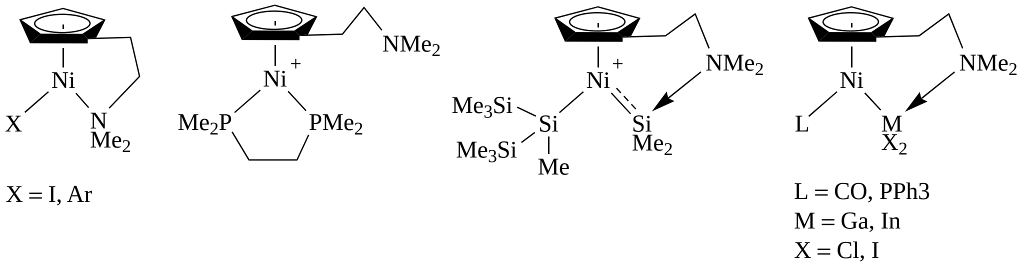
Scheme 2

Cp*Ni(acac), which was shown to be a paramagnetic, 18-electron, spin-equilibrium molecule,[3] followed by addition of a variety of reagents (e.g. MeLi, LiBr, PR_3, NaOMe, etc.).[4,5] Systematic structural studies of these complexes have led to interesting generalizations about the haptotropic distortions observed in the Cp* ring; these distortions range from a symmetrical allyl-ene to diene-yl type distortions (Scheme 2). In addition, the impact on the Ni–Cp interactions of the ligand trans influence exerted by the other auxiliary ligands has been discussed and the following approximate trans influence order has been suggested: alkyl, hydride > phosphine, methoxide > arylamide, aryloxide, arylthiolate, bromide. A study of the Ni-amido derivatives with Bronsted acids HX has led to the observation that the Ni–X bonds have a significant electrostatic component.

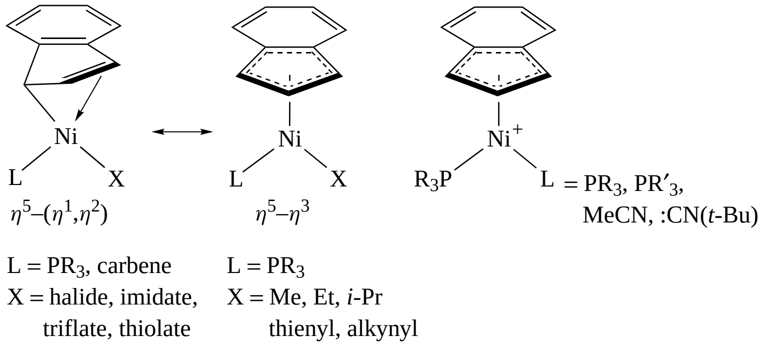
A number of interesting complexes bearing hemilabile (dimethylamino)ethyl-Cp has been reported. The tethered, hemilabile amino moiety either coordinates to the Ni center or to an unsaturated group 13/14 ligand (Scheme 3); in the absence of such unsaturated ligands or when the Ni center is coordinatively saturated, the amino moiety remains dangling.[6–8]

2.3 Indenyl Complexes

An extensive series of indenyl complexes has been prepared and their structural and reactivity features studied in-depth.[9] The detailed characterization, in solution and solid state, of complexes IndNi(L)X ($L = PR_3$ and N-heterocyclic carbenes; X = halides, imidates, alkyl, alkynyl, thienyl, triflate, etc.) and $[\text{IndNi}(PR_3)L]^+$ ($L = PR'_3$, PR_3, MeCN, CN(*t*-Bu)) has allowed an analysis of the factors affecting the Ni–Ind interaction.[10–12] As was seen for the Cp* complexes discussed

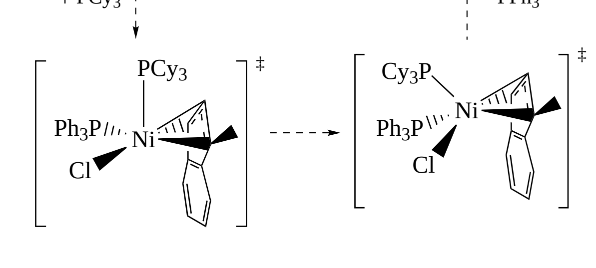


Scheme 3



Scheme 4

above, the trans influence differences of the ligands L and X is responsible for the Ind–Ni bonding mode: ligands of widely different trans influence values (e.g. PPh_3 and Cl) lead to a nonsymmetric hapticity approaching η^1, η^2-Ind, whereas ligands of similar trans influence values (e.g. PPh_3 and Me) give a symmetrical interaction ($\eta^5 - \eta^3$, Scheme 4).[13] Interestingly, the more strongly donor and covalent ligands such as Me and PPh_3 result in stronger Ni–Ind interaction (less slip-folded, shorter Ni–C bonds), whereas weaker and more ionic ligands such as halides result in weaker Ni–Ind interactions (large slip-fold distortions, longer Ni–C bonds).[14] In general, these Ind complexes appear to be less stable and more reactive than the corresponding Cp* analogues.



Scheme 5

The neutral Ni–Cl or Ni–R complexes undergo associative ligand substitution reactions (Scheme 5, *see Associative Substitution*; ***Mechanisms of Reaction of Organometallic Complexes***),[15] and react with methylaluminoxane (MAO) to generate intermediates that polymerize ethylene to high MW poly(ethylene),[16] and alkynes to *cis*, *transoid*-poly(alkynes) (Scheme 6).[17–20]

On the other hand, the cationic bis(phosphine) complexes $[IndNi(PR_3)_2]^+$ and the highly electrophilic, in situ generated cations $[Ind(PR_3)]^+$ catalyze the dimerization of ethylene[21] and oligo- and polymerization of other olefins (Scheme 7).[22,23]

The reaction of $PhSiH_3$ with the Ni–Me precursors has been shown to result in the formation of oligosilanes $(PhSiH)_n$.[24] The initial step of this reaction is believed to go through a concerted σ-bond metathesis ($K_H/K_D \sim 10$), but multiple intermediates are formed in the later stages of the catalysis, some of which result from the reductive elimination (*see Reductive Elimination*) of the indenyl ligand (Scheme 8).[25]

The indenyl complexes are also efficient precatalysts for the hydrosilylation (*see Hydrosilation*) of olefins, alkynes, and ketones.[26] This reaction is believed to involve a hydrido intermediate, which can be generated initially via different routes (Scheme 9).

A few interesting dinuclear complexes bearing $CpCMe_2Ind$ or $IndCMe_2Ind$ ligands have also been prepared (Scheme 10),[27] as have complexes bearing aminoindenyl

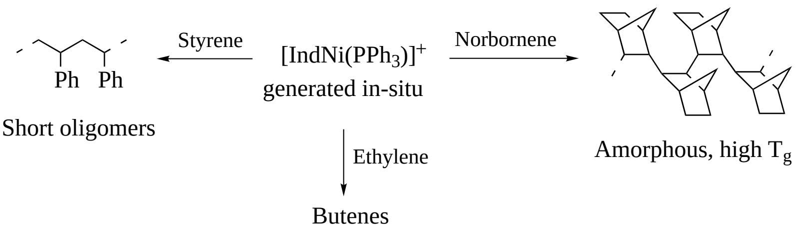
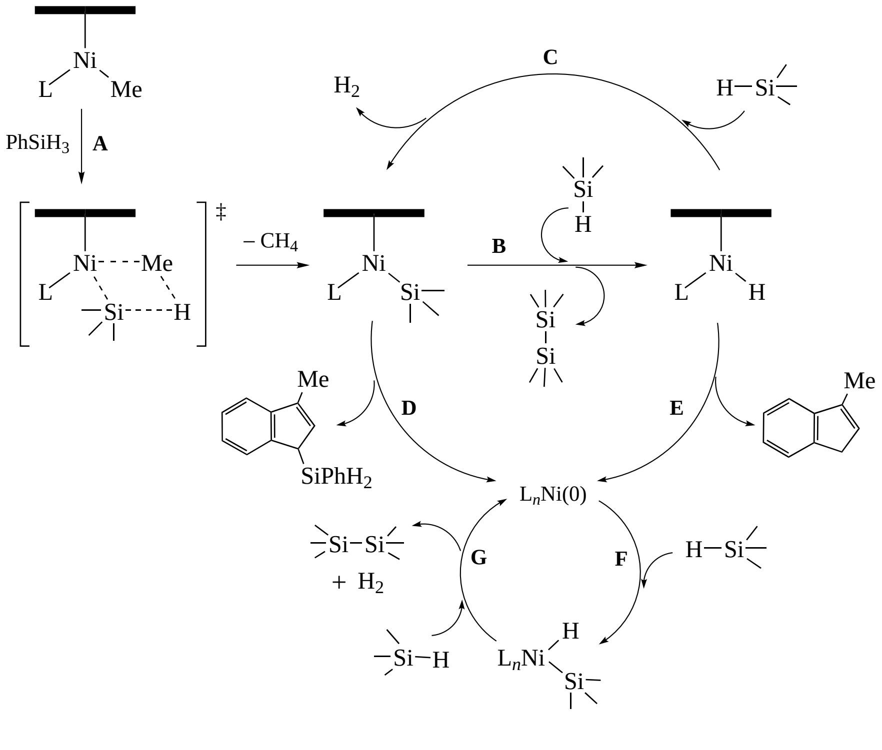
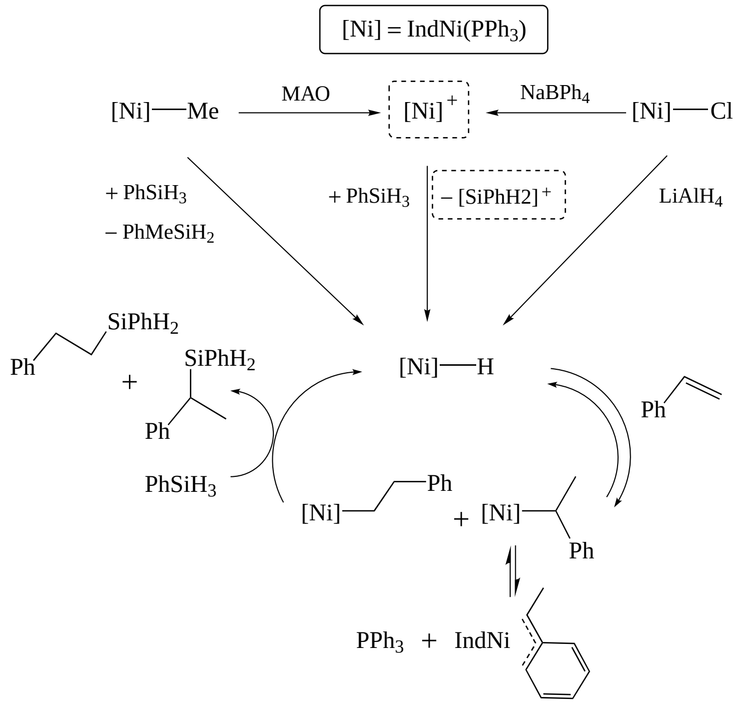


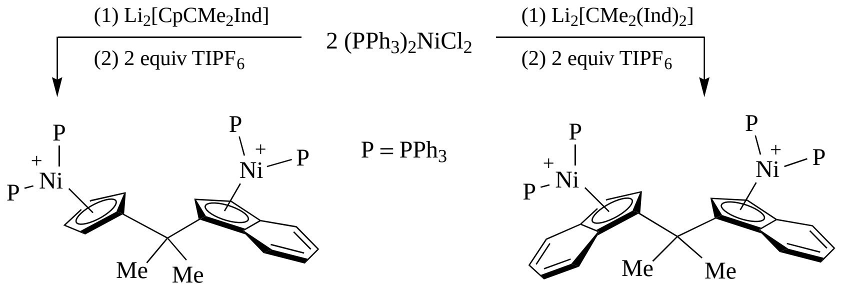
Scheme 7



Scheme 8



Scheme 9



Scheme 10

ligands (Scheme 11); the hemilabile nature of the amine moiety in the latter complexes facilitates a number of interesting catalytic reactions.[28–32]

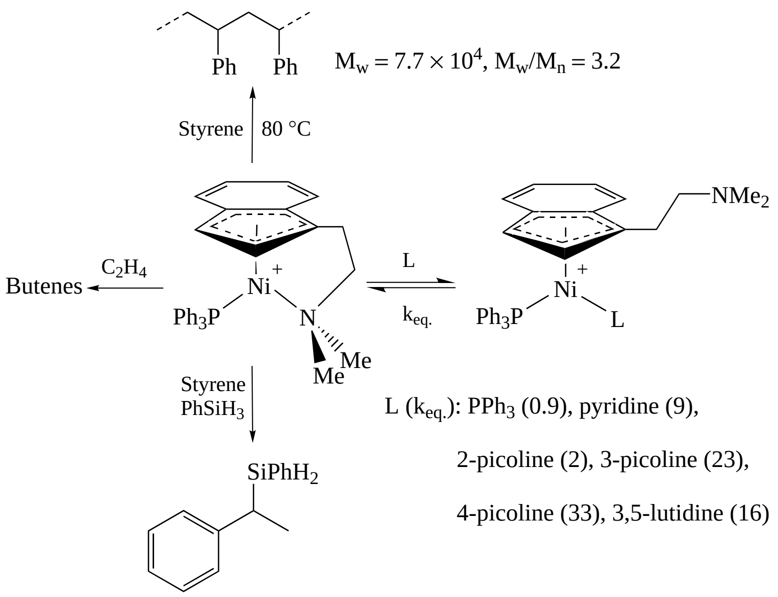
2.4 Tp Complexes

A recent report has shown that tris(pyrazolyl)borate (Tp) (*see Tris(pyrazolyl)borates*) complexes of Ni tend to form 5-coordinate, formally 18-electron complexes. The hapticity of the tris(pyrazolyl)borate ligand in these complexes appears to be more sensitive to the steric environment around the Ni center as opposed to the electronic factors (i.e. formal electron count of the complex).[33] Thus, the η^3-allyl derivative of tris{(3,5-*i*-Pr_2-pyrazolyl)borate}NiR (**3**) displays a κ^3-coordination, whereas the η^3-prenyl derivative (**4**) adopts a κ^2-coordination (Scheme 12); interestingly, carbonylation of the 4-coordinate complex (κ^3-Tp)Ni-Et (**5**) gave the 5-coordinate complex (κ^3-Tp)Ni(CO){C(=O)Et} (**6**) underlining the readiness with which extra pairs of electrons are accommodated in the presence of Tp ligands.

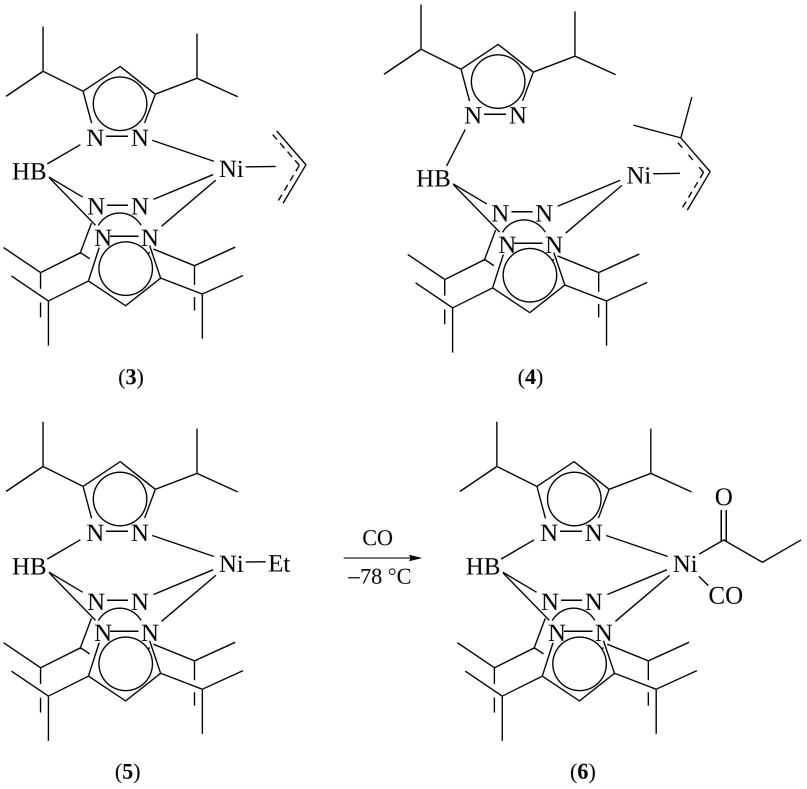
3 HYDRIDO, ALKYL, ALKENYL, AND SILYL COMPLEXES

3.1 Hydride Complexes

Nickel hydride (*see Hydrides*) species are thought to be involved in a number of catalytic reactions, and so an intimate knowledge of the thermodynamics of Ni–H



Scheme 11



Scheme 12

bonds (e.g. homolytic dissociation energy, acidity, etc.) can be valuable in understanding the mechanisms of their reactivities. A convenient method for determining metal hydride bond energies (*see* ***Bonding Energetics of Organometallic Compounds***) is based on a thermodynamic cycle that uses the pK_a values of the hydride complex and the one-electron reduction potentials of its conjugate base to estimate the free energies of all three M-H bond cleavage

reactions ($\Delta G°_{H^-}$, $\Delta G°_{H°}$, $\Delta G°_{H^+}$).[34] Thus, electrochemical and pK_a studies can help establish the energetics of the Ni–H bond in complexes such as $[HNi(diphosphine)_2]^+$, whose pK_a values can be measured fairly accurately and whose conjugate bases, $Ni(diphosphine)_2$, undergo two reversible, one-electron oxidations (Ni(II)/Ni(I), Ni(I)/Ni(0)). A number of these studies have shown that more electron-donating diphosphine ligands and those with smaller bite angles (*see Bite Angle*) increase the hydride donor ability of the Ni–H bond; the acidities are also affected by the basicity of the ligand but not the bite angles.[35]

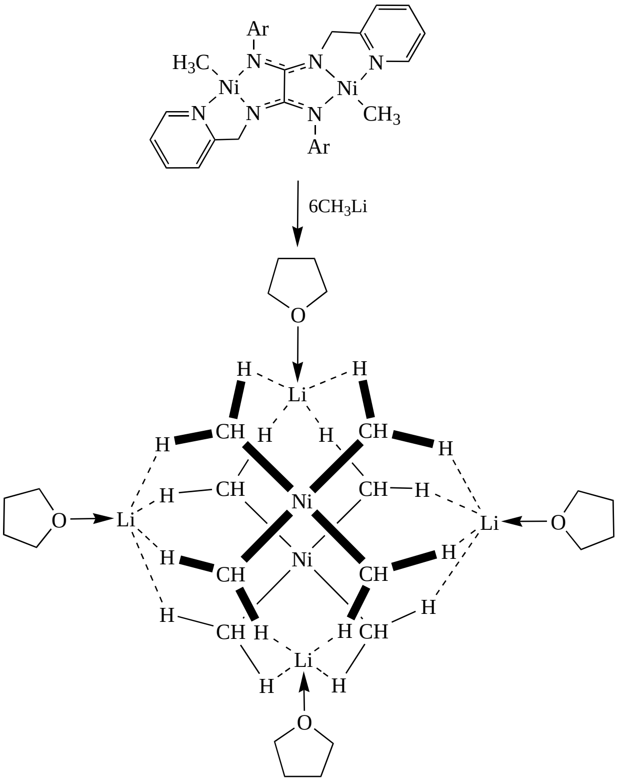
Moreover, it has been shown that a free-energy relationship exists between the $E_{1/2}$(II/I) values and the hydride donor abilities ($\Delta G°_{H^-}$) of $Ni(diphosphine)_2$; this can be justified by considering that the $E_{1/2}$(II/I) values reflect the energy of the LUMO (*see LUMO*) in $[Ni(diphosphine)_2]^{2+}$. Since the LUMO in these complexes is the antibonding $d_{x^2-y^2}$ orbital, which is the orbital involved in hydride transfer reactions, it stands to reason that the energy of this ligand (and the $E_{1/2}$(II/I) value) should correlate with the hydride donor/acceptor properties of $[Ni(diphosphine)_2]^{2+}$. The more electron-donating substituents on the ligands increase the energy of the LUMO and make the reduction potentials more negative; therefore, $[HNi(diphosphine)_2]^+$ becomes a better hydride donor. On the other hand, larger bite angles lead to greater tetrahedral distortion of the structures and lower the energy of the $d_{x^2-y^2}$ orbital; the resulting reduction in the antibonding nature of the P_σ-$d_{x^2-y^2}$ interaction increases the hydride acceptor properties of the complex. A free-energy relationship also exists between the $E_{1/2}$(I/0) values of $Ni(diphosphine)_2$ and acidities ($\Delta G°_{H^+}$) of the corresponding $[HNi(diphosphine)_2]^+$; this can be justified by considering that, to a first approximation, the $E_{1/2}$(I/0) values represent the energy of the HOMO (*see HOMO*), which would be expected to influence the basicity of $Ni(diphosphine)_2$.

An interesting, and somewhat counter-intuitive, finding of the above studies is that the values of ν(Ni–H) obtained from IR spectra correlate best with $E_{1/2}$(II/I) and $\Delta G°_{H^-}$ values; in other words, the stretching frequencies correspond more closely to the hydride transfer reaction (equation 2) than to the homolytic cleavage (*see Homolytic Cleavage*). Altogether, these findings demonstrate that $E_{1/2}$(II/I) and $E_{1/2}$(I/0) values measured for a given complex can give fairly accurate estimates of the pK_a values and the energetics of the corresponding Ni–H complex. This information is useful when selecting appropriate acids for generating Ni–H species by protonation and for predicting the stability of the Ni–H bond toward decomposition by deprotonation or formation of H_2.

$$[HNi(diphosphine)_2]^+ \longrightarrow [Ni(diphosphine)_2]^{2+} + H^- \qquad (2)$$

3.2 Alkyl Complexes

The complex $[Li(THF)]_4[Ni_2(CH_3)_8]$ (**7**) is a rare example of simple, anionic Ni-alkylate complexes. It has been prepared by reacting excess MeLi with a Ni(II) complex bearing oxalic amidinate (oxam) ligands (equation 3).[36] The stability of this homoleptic (*see Homoleptic Compound*) methyl complex towards reductive elimination is thought to be due to ineffective stabilization of the resulting Ni(0) complexes by the oxam ligands, which are poor π-acceptors. The ^{1}H and ^{13}C NMR spectra of this compound show singlets for the CH_3 (ca. −0.6 ppm) and CH$_3$ nuclei (ca. −6 ppm), respectively. The geometry around each Ni center is square planar and the relatively long Ni–Ni distance of ca. 3.17 Å indicates little or no bonding interaction. The methyl ligands occupy the vertices of a cube and the dimeric structure is maintained by Li–H–C α agostic interactions (Li–H = 2.05–2.08 Å; Li–H–C = 95–96°). The Ni–C (ca. 1.99–2.01 Å) and Li–C (2.34–2.37 Å) distances are fairly symmetrical. These complexes are thought to offer a glimpse into the presumed intermediates of cross-coupling reactions between R-X and R′M (X = halide; M = Li, MgX).

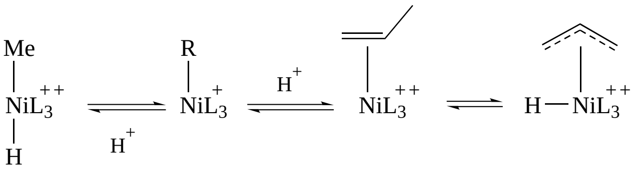


(3)

(**7**)

3.3 Protonation of Ni–R Moieties

Protonation of organometallic complexes, L_nM-R, is a reaction of fundamental importance both in the industrial applications of organometallic complexes and also in



Scheme 13

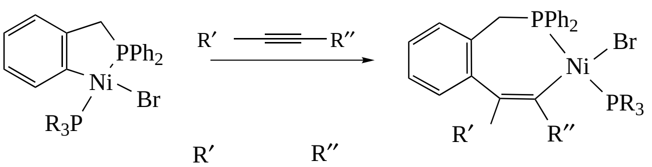
bioinorganic chemistry. In principle, protonation can occur at either the metal center or the (formally anionic) R ligand; moreover, since the added proton can move rapidly between the two sites, determining the initial site of protonation is often a complicated task.[37–39] A number of recent studies have examined the kinetics of protonating a series of $[L_3Ni–R]^+$ complexes (L_3 = triphos; R = Me, η^3-allyl) with the following findings (Scheme 13).[40,41] The Ni center in the η^3-allyl derivative was found to be ca. 10^6 times more basic than that of the analogous Me complex; this is presumably due to the electronically saturated configuration of the Ni-η^3-allyl species (18 electron). Interestingly, however, the much less basic Ni center in the Ni–Me complex is protonated first to give the (formally) Ni(IV) dication $[(triphos)Ni(H)Me]^{2+}$, whereas the precise site of attack for the Ni-η^3-allyl complex could not be determined because of the relatively small difference (ca. 30 times) between the basicities of the metal/ligand sites.

3.4 Alkenyl Complexes

The reactions of alkynes or alkenes with Ni–R bonds are important in organic synthesis, particularly when they involve metallacyclic precursors because these reactions lead to synthetically valuable poly- or heterocyclic derivatives. A crucial question in this context is the regioselectivity of the insertion reaction. To address this issue, a systematic study has been carried out on the insertion of various unsymmetrical alkynes into the Ni–C(sp^2) bond of the nickellacycle (**8**) (Scheme 14); structural analysis of the fairly stable 7-membered ring Ni-alkenyl products (**9**) indicates that the insertions are primarily governed by electronic factors.[42]

3.5 Silyl Complexes

Transition metal-catalyzed transformations of organosilicon compounds continue to make important contributions to organic synthesis and hold great promise for developing efficient routes to Si-based functional materials. The need to understand the mechanisms of these transformations and develop new methodologies has inspired researchers to probe the fundamental reactivities of silanes with a variety of transition metal complexes. The reactivities of Ni complexes with hydrosilanes have been studied quite vigorously and a number of interesting transformations have been reported recently, some of which are described below.



(**8**) (**9**)

R′	R″

CF_3	COOEt
H	$COOBu^t$
H	*t*-Bu
H	$SiMe_3$

Scheme 14

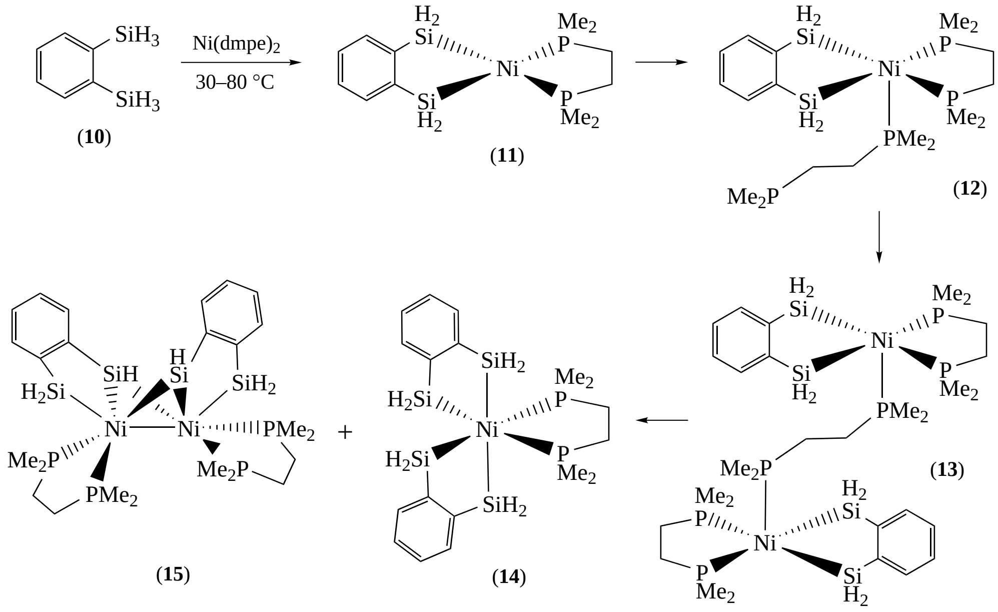
The reaction of $Ni(dmpe)_2$ (dmpe = bis(dimethylphosphino)ethane) with 1,2-disilylbenzene (**10**) has formed a number of interesting bis(silyl) species (**11–13**) that seem to be intermediates leading to the rare tetrasilyl Ni(IV) complex (**14**) and the (apparently) Ni(III)-Ni(III) dimer bearing μ-silylene moieties (**15**), as shown in Scheme 15.[43,44]

Solid-state structure determinations carried out on (**13–15**) have provided useful data for Ni–SiR_3 bond lengths. For instance, the longer Ni–Si bonds for the mutually *trans* silyl moieties in (**14**) compared to those of the silyl ligands *trans* from the phosphine ligands (2.29 Å vs. 2.25 Å) confirms the very strong *trans* influence of silyl ligands. On the other hand, the Ni–Si distances in (**15**) are fairly long (2.21–2.30 Å) even though they are not *trans* from one another; in addition, the Ni–Ni distance (ca. 2.70 Å) is longer than a usual Ni–Ni single bond, while the adjacent Si–Si distances are short enough for a weak bonding interaction (ca. 2.69 Å). The latter observations might imply that complex (**15**) can be viewed alternatively as a Ni(I)–Ni(I) species bearing two μ-silyl moieties formed by the dimerization of (**10**) (dehydrogenative formation of two Si–Si bonds), as shown in Scheme 16.

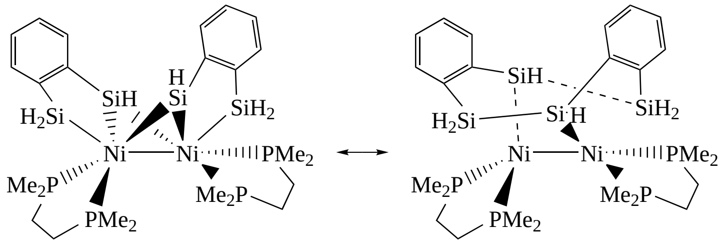
The validity of this alternative view is supported by the finding that reacting Ni(0) species with (**16**), the dimethyl analogue of (**10**), allowed the isolation of a new product (**17**) containing an 8-membered cyclic disilyl ligand that has formed by the dimerization of (**16**) (Scheme 17). The Si–Si bonds in this species (ca. 2.36 Å) were shorter than the analogous distances in (**15**).

4 Ni(0) COMPLEXES

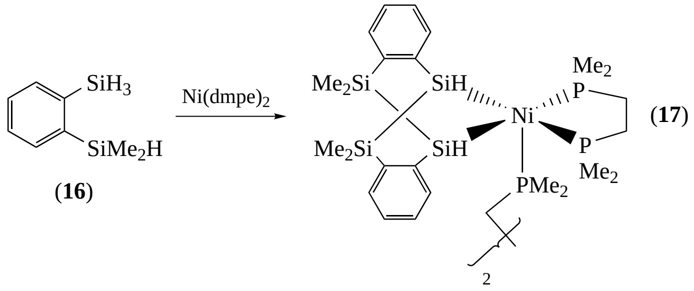
Organometallic complexes of Ni(0) display a rich array of reactivity both in stoichiometric reactions (e.g. oxidative additions (*see Oxidative Addition*), cycloadditions, etc.)



Scheme 15



Scheme 16



Scheme 17

and in catalysis (e.g. cross-coupling reactions). Curiously, however, a relatively small number of Ni(0) complexes have found practical utility as versatile precatalysts or stoichiometric reagents in organic transformations (e.g. $Ni(PR_3)_n$, $Ni(PR_3)_n(CH_2{=}CH_2)_m$, $Ni(COD)_2$, $Ni(bipy)_2$, etc.), while the reactivities of most complexes of zerovalent nickel remains unexplored. A significant development in this context has been the introduction of Ni(0) complexes bearing N-heterocyclic carbenes (*see* ***Carbene Complexes***),[45] which have spearheaded a renewal of interest in the catalytic chemistry of Ni(0) in many different directions. Some of these developments are described below, followed by an

overview of the reactivities of a number of other Ni(0) species introduced recently.

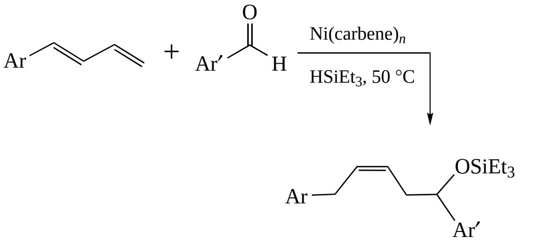
4.1 N-heterocyclic Carbene Complexes

N-heterocyclic carbenes have been used extensively over the past decade as versatile alternatives to the ubiquitous tertiary phosphines. These ligands are strongly electron donor, weakly π-acceptor, and in most cases quite bulky.[46–48] The stoichiometric reactions of Ni-carbene complexes are quite similar to those of analogous phosphine complexes; for example, oxidative addition of aryl- or alkyl-halides gives square planar bis(carbene)Ni(R)X species.[49] On the other hand, a number of side-reactions have been observed for the carbene complexes, such as the addition of electrophiles like alkyl halides to the carbene ligand instead of the metal center; it is believed that the imidazolium salts produced in this reaction form as a result of the elimination of the hydrocarbyl (*see Hydrocarbyl*) and carbene ligands. This is an important reactivity since many catalytic reactions are believed to go through such square planar Ni(II) intermediates bearing hydrocarbyl moieties; hence, side-reactions such as this might undermine the potential of carbenes in catalysis. Nevertheless, an increasing number of important reactions have already been catalyzed efficiently by Ni-carbene precursors. For instance, it has been shown that the cross-coupling of aryl bromides with phenylboronic acids (the Ni-analogue of the well-known Suzuki coupling) is catalyzed by (carbene)$_2$Ni(Ar)Br with a catalytic turnover of ca. 2000.[50]

A series of Ni(0)-carbenes have been studied in order to determine the level of electron-donation of heterocarbenes as well as the Ni-carbene bond dissociation energies. Thus, the ν(CO) values for (carbene)Ni(CO)$_3$ were used to show that the heterocarbene ligands bearing N-mesityl substituents are at least as donating as P(t-Bu)$_3$; on the other hand, the carbenes bearing N-adamantyl and N-t-Bu substituents appear to form relatively labile C–Ni bonds (BDE = ca. 40 kcal mol^{-1}) in (carbene)Ni(CO)$_2$.[51] These findings should prove important in interpreting the catalytic reactivities of Ni-carbene complexes.

Ni(0)-carbene complexes (*see* ***Carbene Complexes***) can be prepared in situ by mixing a Ni(0) precursor with the desired carbene ligand (Scheme 18). This protocol can be further simplified by the in situ generation of both the Ni(0) species and the carbene ligand from readily available starting materials, as shown below; the distinct ^{13}C NMR signal for the carbene carbon (ca. 220 ppm) can be used to monitor the formation of the target complex.[52]

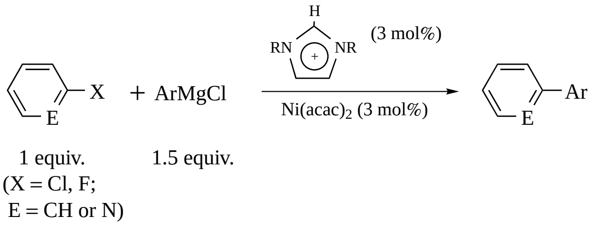
Ni(carbene)$_n$ species generated in situ have been used to effect the catalytic coupling of dienes and variously substituted benzaldehydes in the presence of HSiEt$_3$ to give the Z-homoallylic silyl ethers (**18**) in 5–20 catalytic turnovers (equation 4);[53] it is interesting to note that using PPh$_3$ analogues of the Ni(0) complexes ($n = 2$) gives the E-isomer.[54]



(4)

(**18**)

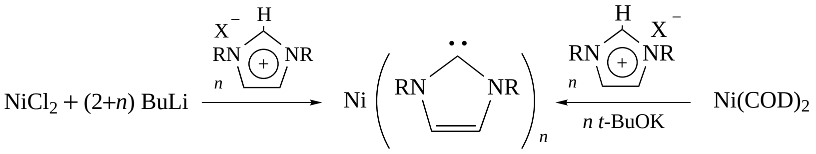
Ni(0) carbenes are also effective for the Kumada–Corriu coupling reaction between arylmagnesium reagents and aryl chlorides[55] or fluorides[56] in ca. 35 catalytic turnovers (equation 5). The yields are generally high even at room temperature (ca. 30 turnovers over 18 h); only when the aryl chloride is congested (substituents ortho to Cl) does the yield suffer. It is noteworthy, however, that very similar yields were obtained when the N-heterocarbene ligands were replaced by t-Bu$_3$P.



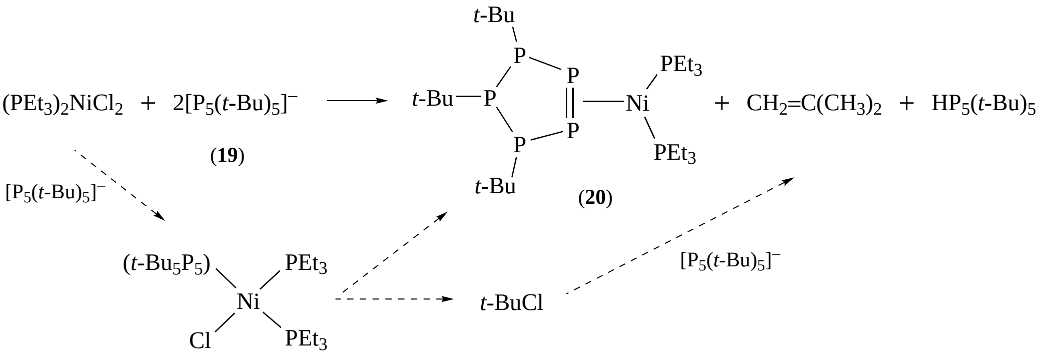
(5)

4.2 Phosphorous-containing Complexes

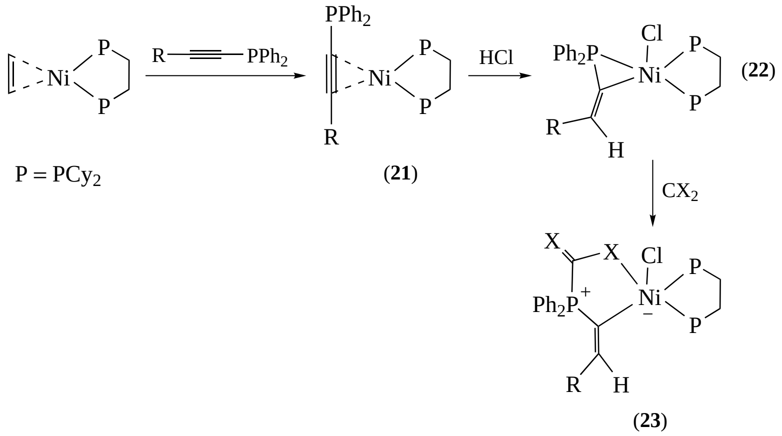
Phosphines provide suitable coordination environments for the preparation of stable yet reactive Ni(0) species. A recently introduced member of this family of complexes contains a cyclic oligophosphine ligand and was prepared by reacting the cyclic pentaphosphanide anion (**19**), [P$_5$(t-Bu)$_4$]$^-$, with a source of Ni(II) (Scheme 19); given the isolobal analogy between P and C–H, the resulting complex (**20**) can be viewed



Scheme 18



Scheme 19

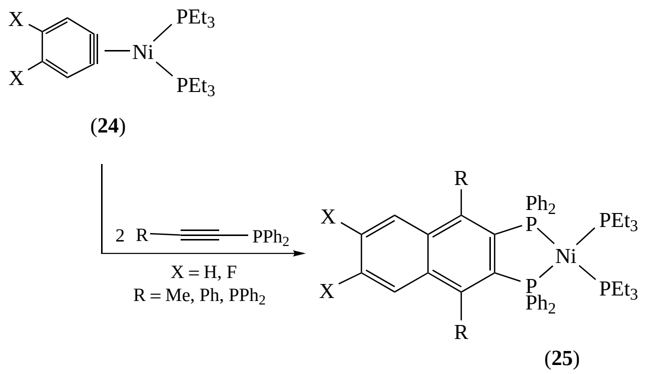


Scheme 20

as an analogue of $(PR_3)_2$Ni(cycloalkene). The solid-state structure of (**20**) has been studied by X-ray crystallography, which showed that the geometry of the Ni center is distorted trigonal planar (Et_3P–Ni–PEt_3 ca. 108°; P–Ni–P ca. 56°). The average (*t*-Bu)P–P(*t*-Bu) distance of 2.20 Å is in the expected range for P–P single bonds, whereas the shorter P–P distance of 2.12 Å implies that the P atoms bonded to Ni are multiply bonded; therefore, (**20**) can be justifiably considered a formally 16-electron Ni(0) species.

A recent report has described a series of Ni(0)-alkynylphopshine complexes (**21**) featuring the unusual coordination of the alkyne moiety in preference over the phosphine moiety (Scheme 20).[57] The reaction of these Ni(0)-alkyne complexes with HCl and the isolation of the resulting Ni(II) η^2-vinyl complexes (**22**) has provided a rare opportunity to study alkyne insertion reactions. The Ni–P bond in (**22**) undergoes another insertion (*see Insertion*) by CO_2 or CS_2 to give 5-coordinate, zwitterionic (*see Zwitterion*) complexes (**23**).

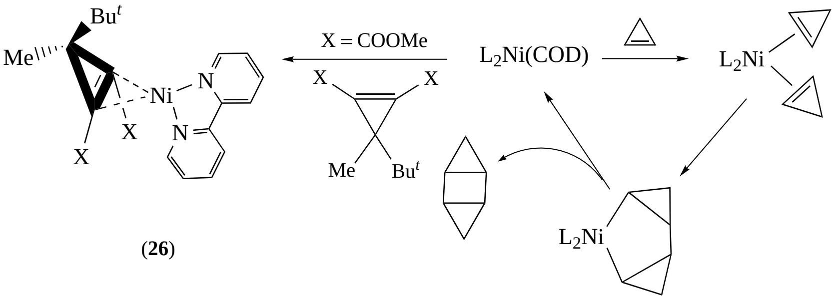
Alkynylphosphines have also been shown to undergo an interesting double insertion with Ni(0)-benzyne complexes. Thus, two equivalents of Ph_2P-CC-R insert into the Ni-benzyne bond in (**24**) to form a series of novel naphthalene-based bis(phosphine) ligands coordinated to the Ni center (**25**, equation (6)).[58]



(6)

4.3 Cyclopropene-containing Complexes

A number of Ni(0) complexes containing a cyclopropene ligand have been prepared and shown to catalyze the oxidative coupling of cyclopropene derivatives to compounds with a cyclobutane core (Scheme 21). A recent study of the kinetics of these reactions has led to the isolation



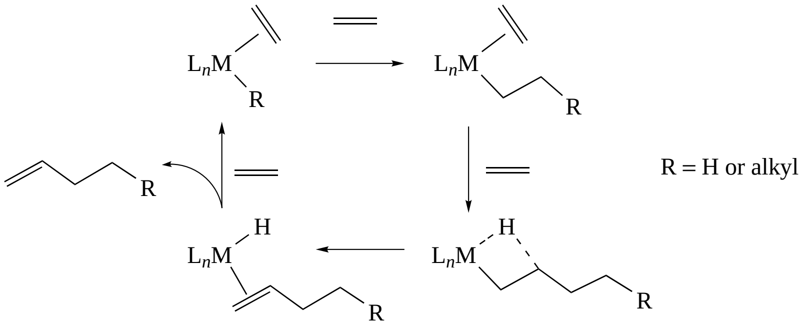
Scheme 21

of a putative intermediate (**26**).[59] Thus, the reaction of (bipy)Ni(COD) with 3-methyl-3-(*t*-Butyl)-1-cyclopropene-1,2-dimethyl dicarboxylate forms the Ni(0)-cyclopropene compound (**26**), which crystallizes in a trigonal planar structure. It is interesting to note that the carboxylate substituents are bent out of the coordination plane, while the *t*-Bu group is *endo* with respect to the Ni center; this orientation is presumably favored over the alternative *cis* disposition of the *t*-Bu and carboxylate substituents, which would engender greater steric (*see Steric Effect*) repulsions.

5 CATALYTIC POLYMERIZATION AND COPOLYMERIZATION OF OLEFINS

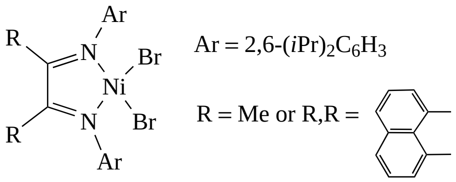
The study of olefin polymerization reactions catalyzed by complexes (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***) of late transition metals experienced a significant progress during the 1990s and the rapid pace of progress continues unabated during the present decade. The driving force for the intense activity in this area is the belief that, in comparison to catalytic systems based on early metal complexes (e.g. group 4 metallocenes), systems based on the less electrophilic late transition metal complexes will allow the development of polymerization protocols that are tolerant of olefinic monomers possessing polar functional groups. The incorporation of such units in ethylene-based copolymers is expected to furnish new macromolecules possessing novel structural properties and promising applications. On the other hand, the main obstacle for the development of efficient catalytic systems based on late metals was the well-documented propensity of late transition metal complexes in general, and Ni-based catalysts, in particular, to favor oligomerization over polymerization.[60] This behavior stems from the readiness with which alkyl complexes of nickel (and of most late transition metals) undergo β-H elimination (*see β-Hydride Elimination*) reactions; these reactions in effect rearrange the alkyl moiety into a (new) olefin, which is then expelled from the metal's coordination sphere, as shown in Scheme 22. The L$_n$M-H species generated in this sequence can then undergo an insertion reaction with another molecule of olefin to restart the oligomerization process; this olefin is usually the monomer, which is present in the reaction mixture in higher concentrations and is less bulky.

In light of the above, it is generally assumed that the key to extending the olefin homologation (*see Homologation Reactions*) process beyond dimerization or oligomerization is to retard the above-described β-H elimination (*see β-Hydride Elimination*) (or de-insertion) and chain-transfer reactions. This objective was achieved most spectacularly when it was demonstrated, in 1995, that a family of Ni(II) complexes bearing α-diimine ligands (**27**) had unexpectedly



Scheme 22

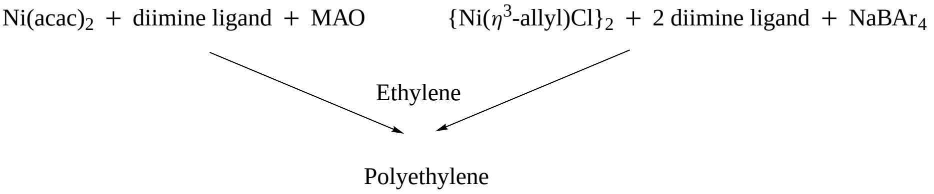
high activities for the polymerization of ethylene.[61] (NB: These complexes and their Pd(II) analogues have been trademarked Versipol catalyst systems by DuPont.) This reactivity was later extended to other terminal, aliphatic olefins (propylene, 1-hexene, 1-octene, etc.).[62]



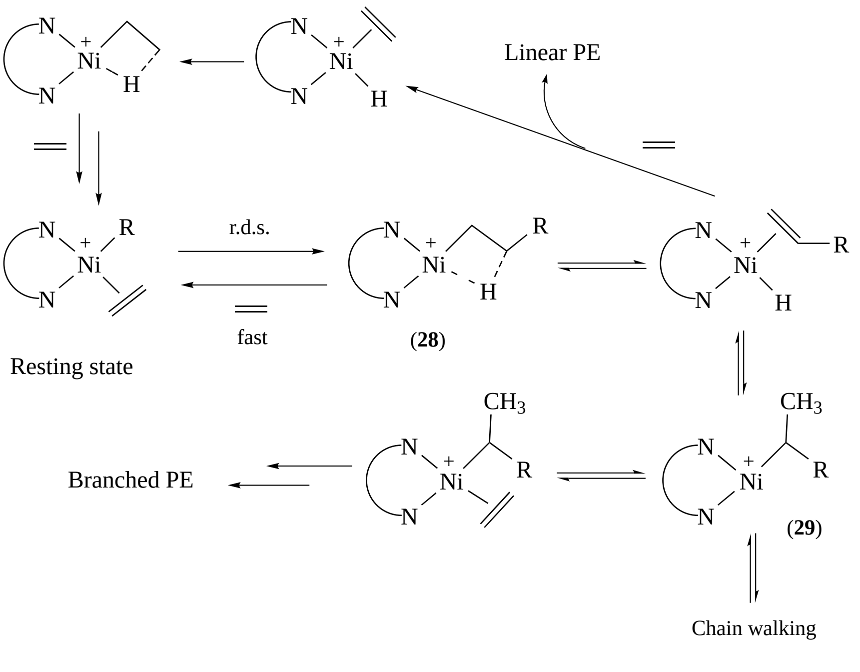
(**27**)

It is noteworthy that this family of complexes had been known for decades,[63] but what made the newly introduced derivatives excellent catalysts for polymerizing ethylene was the incorporation of very bulky aryl substituents (e.g. 2, 6-(i-Pr)$_2$C$_6$H$_3$) on the diimine nitrogens. Solid-state structural and computational studies have indicated that the aryl substituents orient themselves approximately perpendicular to the coordination plane, thus placing the ortho substituents above and below this plane. It seems, therefore, that the role of these substituents is to provide steric crowding around the axial plane above the Ni center, which in effect blocks the interaction of the growing alkyl chain with the d_{z^2} orbital, thereby hindering the β-H elimination step. Other crucial features of these systems include their cationic nature and the use of noncoordinating counter anions during the ionization step; together, these factors increase the electrophilicity of the central metal and provide an open coordination site for the uptake and insertion of the monomer.

In a typical polymerization experiment, the (diimine)NiX$_2$ precursor is generated in situ and reacted with 100–1000 equivalents of methylaluminoxane (MAO, $\{MeAlO\}_n$) in toluene (μmol conc. in Ni) under a small pressure of ethylene (typically 1 atm) at about 35 °C (Scheme 23). Typical activities are hundreds of kg of poly(ethylene) (PE)/mol Ni.h, although they can be one or two orders of magnitude higher under optimized conditions. The molecular weights of the resulting PE can range from 3 to 1000 $\times$ 10^3 Daltons, and the polymer



Scheme 23



Scheme 24

microstructure can vary from highly linear and crystalline to fairly branched and amorphous. In general, PE samples obtained with Ni catalysts are less branched in comparison to the corresponding Pd systems.

The mechanism of the polymerization reactions catalyzed by the Ni(diimine) system has been studied in detail both experimentally[64] and by computational methods.[65–69] Since a number of cationic species of the type [(diimine)Ni(n-alkyl)(olefin)]$^+$ can be observed throughout the reaction, it is believed that these intermediates are formed in relatively rapid steps (e.g. rapid monomer uptake) and consumed in relatively slow steps (e.g. the migratory insertion of the monomer into the Ni-alkyl bond). Therefore, such species represent the catalyst resting state and their reactions are considered to be rate-limiting (Scheme 24). This type of reactivity also implies that the chain growth is zero-order with respect to the concentration of ethylene, although this is not the case with higher α-olefins. The barrier to the insertion reaction has been estimated (by low-temperature NMR techniques (*see **Structure & Property Maps for Inorganic Solids***)) to be ca. 13–14 kcal mol^{-1}, which is ca. 4–5 kcal mol^{-1} lower than the barrier for the insertion step for the analogous Pd complexes. Some of the computational studies[70] have produced rate data that are in close agreement with these values.

As mentioned earlier, the very bulky N-substituents tend to hinder the chain-transfer or β-H elimination (*see β-Hydride Elimination*) steps; moreover, the larger steric bulk is thought to destabilize the resting state with respect to the insertion transition state. In other words, the bulky substituents favor the chain growth process by both accelerating the propagation step (insertion of the monomer) and by retarding the termination steps (the chain-transfer or β-H elimination steps). The formation of branched PE can be rationalized as follows: the 14-electron intermediate [(diimine)Ni(n-alkyl)]$^+$ generated by the insertion process (**28**) can either trap a monomer and undergo another insertion reaction leading to linear chain growth, or it can be stabilized by agostic C–H–Ni interactions (*see Agostic Bonding*) that can produce [(diimine)Ni(branched-alkyl)]$^+$ intermediates (**29**) via successive β-H elimination/reinsertion steps. The intermediate with the branched-alkyl moieties can then trap monomer and undergo insertion to give branched PE. This process is dubbed 'chain-walking'.

Another remarkable character of this class of Ni complexes is their tendency to promote living polymerization of α-olefins at low temperatures and with low concentrations of the monomer. Thus, the low-temperature polymerization of propylene leads to a material whose number average molecular weight (M_n) increases almost linearly as a function of time and propylene consumption, reaching values of $M_n = 160\,000$ Daltons and polydispersities of ca. 1.13.[71] This character allows these Ni catalysts to produce A-B-A type block copolymers composed of semicrystalline and amorphous segments, which is used to prepare thermoplastic elastomeric polymers. The Ni catalysts can also polymerize internal cyclic olefins such as cyclopentene, giving high molecular weight materials ($M_w \sim 250\,000$ Daltons) that are melt-processable to strong, clear films.

The relative insensitivity of this class of Ni catalysts to polar functional groups, and especially their low oxophilicity, is another important characteristic. This property has been exploited for the development of novel polymeric materials that might find new applications. For example, 1-hexene has been copolymerized with 6-(2-ureido-4-[1H]-pyrimidinone)hex-1-ene (**30**) to generate a new poly(olefin) elastomer (equation 7).[72] The dimerization (through H-bonding) of the pyrimidinone moieties forms noncovalent crosslinks that bestow unique properties to the otherwise amorphous poly(1-hexene) matrix.

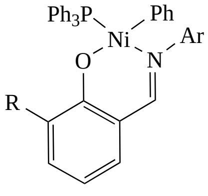
5.1 Ni-based Neutral Catalysts for Olefin Polymerizations

Following the successful development of the above-discussed cationic systems, there has been a surge of interest to develop neutral, single-component systems not requiring cocatalysts such as MAO. As before, it was anticipated that the reduced electrophilicity of noncationic systems and their tolerance for polar functionalities on the olefinic monomers will further facilitate the use of olefinic monomers bearing polar groups. The Ni complexes (**31**) based on the salicylaldiminato ligand were found to be promising catalysts for this purpose,[73] particularly when a bulky substituent was placed *ortho* to the OAr position, because this feature allowed the catalysis to proceed without the customarily required

initiators/cocatalysts.[74] Evidence from experimental studies indicates that the main role of the bulky Ar-substituent is to induce the dissociation of the PPh_3 ligand, thereby opening up a coordination site around the Ni center; computational studies are in accord with this proposal.[75]

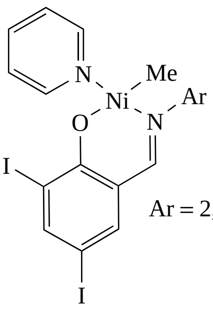


(**31**)

Ar = 2,6-(*i*Pr)$_2$C$_6$H$_3$

R = H, Ph, *t*-Bu, 9-phenathrenyl, 9-anthracenyl

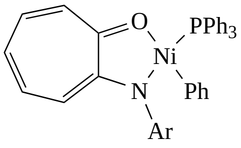
In addition to ethylene, the precatalysts (**31**) homo- and copolymerize styrene and norbornene and copolymerize ethylene with α-olefins (e.g. 1-hexene, 1-octene, etc.) or functionalized norbornenes (e.g. 5-norbornen-2-ol). Remarkably, the polymerization of ethylene can proceed in the presence of various polar molecules such as ethers, ketones, esters, amines, alcohols, and even water! This tolerance of extremely polar media has been exploited to carry out Ni-catalyzed polymerization of ethylene in aqueous emulsions.[76–78] This type of polymerization protocol leads to so-called polymer latexes, which consist of stable aqueous dispersions of surfactant-stabilized microparticles of the polymer having diameters in the range of tens or hundreds of nm. In addition to the obvious advantage of using aqueous media for polymer synthesis, the polymer latexes produced by emulsion polymerizations have also many varied applications (e.g. in coatings). In a particularly attractive approach to applying emulsion polymerization protocols to metal-catalyzed reactions, hydrocarbon solutions of the Ni-based system (**32**) were dispersed in water/surfactant mixtures and exposed to ethylene pressure; this led to PE latexes consisting of long chains (M_w ca. 10^5 Daltons) and having average particle sizes of 50–350 nm in diameter.[79]



Ar = 2,6-(*i*Pr)$_2$C$_6$H$_3$

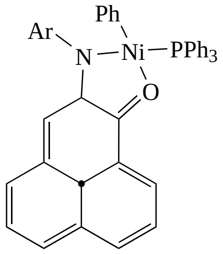
(**32**)

Recent reports have described other neutral, single-component Ni catalysts based on the N–O ligands 2-anilinotropone (**33**)[80] and 2-anilinoperinaphtenone (**34**).[81] There are a number of structural similarities between these and the above-described salicylaldiminato-based systems in that they all incorporate N–O ligands in addition to PPh_3 and Ph ligands (Ph *trans* to O, PPh_3 *trans* to N). On the other hand, there are also important differences such as (a) the greater localization of the negative charge on the N-atom in the new systems as opposed to on the O atom in the salicylaldiminato system, and (b) the formation a 5- as opposed to 6-membered chelate metallacycles (*see Metallacycle*). The latter feature results in different bite angles: O-Ni-N angles of ca. 83° vs. ca. 94° and O-Ni-P angles of ca. 95° vs. ca. 87° for the 2-anilinotropone (**33**) and salicylaldiminato (**34**) systems, respectively. The activities of the new complexes are up to ca. 60 000 kg PE/h.mol of Ni, which is comparable to, or higher than, those of the best salicylaldiminato systems, but their lifetimes are shorter. The tropolone system (**33**) has the interesting property of tolerating many functional groups (ether, THF, water, NEt_3, etc.) in addition to being fairly insensitive to the presence of added PPh_3 ligand; thus, even the presence of 5 equivalents of PPh_3 has essentially no effect on the activities.



Ar = 2,6-(*i*Pr)$_2$C$_6$H$_3$

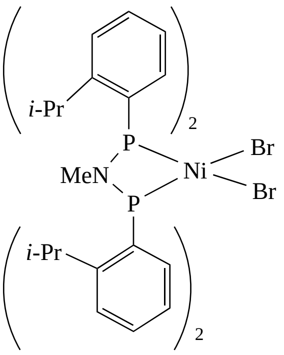
(**33**)



(**34**)

Although most of the Ni-based catalyst systems displaying high activities in the polymerization of ethylene bear N-based ligands, there have been a few reports on the catalytic reactivities of P-based Ni complexes. Recall that the nickel indenyl complexes IndNi(PR_3)X discussed earlier polymerize ethylene to high MW PE with activities ranging from 50 to 700 kg PE/mol of Ni.h ($P_{ethylene} = 5-10$ atm).[16] Higher activities up to 2000 kg PE/mol of Ni.h ($P_{ethylene} = 8$ atm) have been obtained from $LNiBr_2$ (**35**) with L representing the chelating bis(phosphine) MeN{P(2-*i*-Pr-C_6H_4)$_2$}$_2$.[82] Both of these systems require cocatalysts/activators such as MAO, and in both cases it has been shown that the presence of $AlMe_3$ in the reaction mixture lowers polymerization activities. Like the other Ni-based systems described above, these catalysts are fairly insensitive to polar functional moieties present in the polymerization medium.

As discussed earlier, the electronically and coordinatively unsaturated cations $[IndNi(PR_3)]^+$, which are generated from the corresponding Ni-X precursors in the presence of excess MAO or other halide abstractors such as $AgBF_4$, promote exclusively the dimerization of ethylene. The 1-butene



(**35**)

produced during the polymerization reaction is incorporated into the PE chains, leading to ca. 5% ethyl branches along the essentially linear PE produced by this system. The PE obtained from the bis(phosphine) system is also essentially linear but contains a small number of different branches (mostly Me branches but longer homologues are also detected), indicative of the chain-walking mechanism.

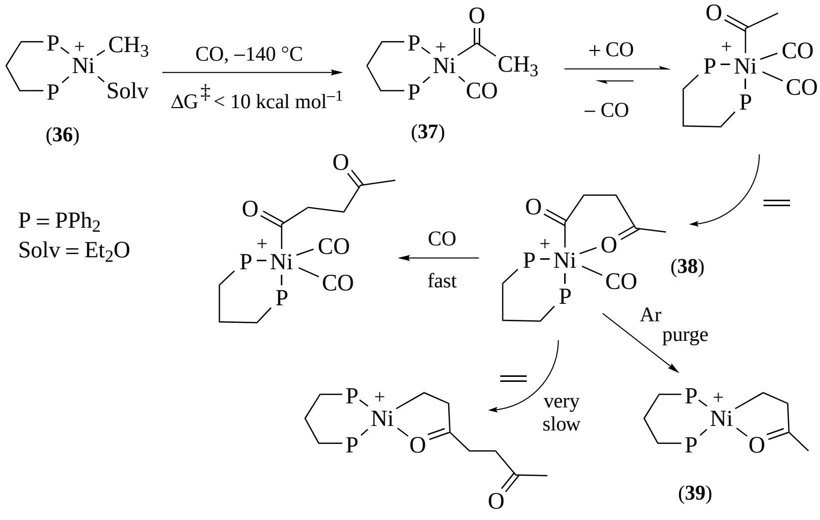
5.2 Alternating Copolymerization of CO and Ethylene

The alternating copolymerization of CO and ethylene has been studied in much detail over the past two decades.[83] Although a number of Ni-based systems are known to catalyze this reaction,[84,85] comparative studies have shown that Pd-based systems are by far the most active catalysts for this reaction. The lower activity of the Ni-based systems is somewhat surprising because the requisite CO and ethylene insertion steps are expected to be energetically more facile for the Ni-based systems. A recent study has shown that the energy barrier for CO insertion into the Ni–Me bond is less than 10 kcal mol^{-1} (Scheme 25),[86] significantly lower than the barrier of ca. 15 kcal mol^{-1} in the analogous Pd complexes; this finding supports the results of computational studies that predict barriers on the order of 4–7 kcal mol^{-1} for simplified Ni systems.[87] The reaction of the Ni-acyl complex (**37**), which is formed from the initial CO insertion into the Ni–Me bond in (**36**), with ethylene gives a new Ni-acyl species (**38**) instead of the expected Ni-alkyl intermediate; this is presumably caused by the very facile insertion of CO into the Ni-alkyl bond arising from the ethylene insertion. Since the CO insertion is reversible, argon-purging of the reaction solution for an extended period produces a new Ni-alkyl species bearing a pendant, chelating acyl moiety (**39**). It appears, therefore, that the facile uptake and insertion of CO stabilizes the catalyst resting state in the Ni-based systems, making these systems less efficient catalysts relative to the Pd-based systems. Moreover, the Ni-catalyzed copolymerization reaction seems to involve stable, 5-coordinate intermediates, in contrast to the almost exclusive involvement of 4-coordinate species in the Pd-based systems.

6 OTHER CATALYTIC REACTIONS

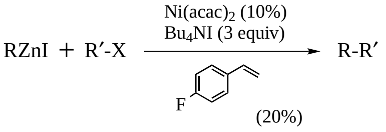
6.1 Ni-catalyzed Cross-coupling Reactions

The Ni-catalyzed cross-coupling of organic halides with various other organometallic reagents (e.g. RLi, RMgX, XZnR, etc.) plays an important role in organic synthesis. A number of recent reports have introduced important developments in this area, which promise to improve the potential of Ni-catalyzed routes for making new C–C bonds. For example, it was shown in 1998 that diorganozinc (*see* ***Zinc: Organometallic Chemistry***) reagents can be coupled with alkyl halides (Negishi reaction) if a suitable π-donor



Scheme 25

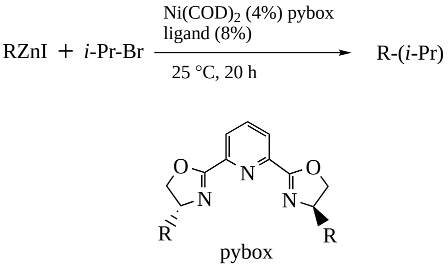
ligand was used to induce the reductive elimination of the product from the postulated diorganonickel intermediates (equation 8).[88] This protocol has been revised more recently to extend the coupling reaction to RZnI, which are less reactive than ZnR_2 but also more tolerant of functional groups; thus, ethers, esters, ketones, amides, and nitriles can be tolerated.[89] The presence of Bu_4NI is essential for this protocol; the role of this additive is not clear, but it might coordinate to RZnI to form a more nucleophilic organozinc anion.



(8)

R = alkyl; X = Br, I
R′ = alkyl groups bearing functional groups

The cross-coupling of more hindered secondary and tertiary alkyl halides has also been studied. Thus, secondary alkyl halides can be cross-coupled with organozinc reagents in the presence of the so-called 'pybox' ligands (equation 9).

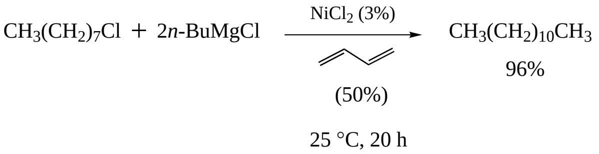


(9)

pybox

An interesting development concerning the mechanistic aspects of the Negishi cross-coupling reaction was the recent report that $ZnBr_2$ can abstract a bromide atom from $L_2Ni(R)Br$, generating $[L_2NiR]^+$ cations (Scheme 26). Since both ZnX_2 and organyl halides of nickel are proposed intermediates in the Negishi reaction, this finding is likely to have important consequences for the future developments in this area.

In another development, it was shown that simple Ni(II) or Ni(0) precursors (e.g. $NiCl_2$, $Ni(acac)_2$, $Ni(COD)_2$, etc.) can catalyze the coupling of primary alkyl halides with Grignard reagents (Kumada–Corriu reaction).[90] This otherwise challenging coupling of two sp^3-C centers is facilitated by the presence of various 1,3-butadienes; this feature allows even the normally unreactive alkyl chlorides to be coupled in very good yields and low catalyst loadings (equation 10). The precise mechanism of this reaction is not known, but free radical-based routes have been excluded; a tentative proposal has invoked the involvement of Ni(IV) intermediates.



(10)

6.2 Ni-catalyzed Coupling of Carbonyl Compounds with Alkynes or 1,3-dienes

A number of new Ni-catalyzed protocols have been developed recently for the coupling of carbonyl compounds and unsaturated substrates such as alkynes or 1,3-dienes.[91–94] For instance, a three-component intramolecular coupling (alkyne/aldehyde/hydrosilane) has led to the formation of bicyclic N-heterocycles. A number of similar inter- and intramolecular coupling reactions have been developed into useful synthetic routes (Scheme 27).

6.3 Ni-catalyzed CO_2 Additions

A novel Ni-promoted route has been developed for using CO_2 as a natural source of acid/ester moieties in building organic molecules. This reaction, which provides an attractive method for preparing a number of mono- and di-carboxylic acid derivatives, proceeds by the oxidative cycloaddition of CO_2 to conjugated dienes as exemplified in the transformations shown in Scheme 28.[95] The reaction of $Ni(COD)_2$ (in stoichiometric amounts) with the diene and CO_2 (1 atm) is believed to produce the oxo-π-allyl nickel intermediates (**40**) that can be hydrolyzed or transmetallated (*see Transmetalation*) with zinc reagents; the presence of two equivalents of 1,8-diazabicylco-[5.4.0]undec-7-ene (DBU) is essential for the success of the transformation. It is not known why $ZnMe_2$ leads to dicarboxylation whereas $ZnAr_2$ gives arylative carboxylation.

1 INTRODUCTION: SURVEY AND GENERAL TRENDS

Niobium (formerly called columbium) and tantalum are *Transition Metals* having a considerable affinity for oxygen donor groups; they are thus called oxophilic (*see Oxophilic Character*). They occur as mixed-metal oxides such as columbites (Fe/Mn)(Nb/Ta)$_2$O$_6$ and pyrochlore NaCaNb$_2$O$_6$F. Their discovery in minerals extends back to the beginning of the nineteenth century, when they were believed to be identical and called tantalum. Rose showed that at least two different elements were involved in the minerals, and named the second one niobium. Their separation was resolved around 1866, especially by Marignac. These metals often display similar chemical behavior as a result of nearly identical atomic radii (1.47 Å) due to the lanthanide contraction (*see* ***Periodic Table: Trends in the Properties of the Elements***) and of similar ionization energies (*see Ionization Potential*); (Nb 6.67 eV, Ta 7.3 eV). Their separation is, nevertheless, possible and was long based on the greater tendency of tantalum to form insoluble anionic MF_7^{2-} complexes. Their modern separation uses liquid–liquid extraction into isobutyl methyl ketone from hydrofluoric acid.[1]

The chemistry of niobium and tantalum ranges from oxidation states +V to −III. No species of oxidation state −II is known so far (Table 1) and the chemistry is dominated by the higher oxidation states, especially V. By contrast with the 3d transition metals, the $[M(H_2O)_6]^{n+}$ ions are unknown and the aqueous chemistry of the higher valence states is dominated by the formation of homo- and heteroisopolyanions (*see* ***Polyoxometalates***). They have an extensive lower oxidation state aqueous chemistry based on hexanuclear clusters. Most recent developments have been in their nonaqueous chemistry in intermediate oxidation states since these species are able to promote C–E (E = O, S, N) cleavage and N$_2$ activation reactions. Niobium is more prone to reduction than tantalum. In their higher oxidation states, niobium and tantalum tend to resemble titanium and zirconium (*see* ***Titanium: Organometallic Chemistry*** and ***Zirconium & Hafnium: Inorganic & Coordination Chemistry***) rather than vanadium, but in their lower states they are closer to molybdenum and tungsten (*see* ***Molybdenum: Inorganic & Coordination Chemistry*** and ***Tungsten: Inorganic & Coordination Chemistry***). This is illustrated by their tendency to give multiple bonds with nonmetals such as oxygen, sulfur, nitrogen, or carbon (for the last *see* ***Niobium & Tantalum: Organometallic Chemistry***) and to form hexanuclear clusters. Niobium and tantalum are among the largest early transition metals; they can easily accommodate a large number of ligands and display large coordination numbers (*see* ***Coordination Chemistry: History***).[1] Hexacoordination and heptacoordination are the most common, but higher coordination numbers such as eight or even nine and ten have been observed; as a result, their derivatives often have a dynamic coordination sphere and are fluxional (*see Fluxional Molecule* and *Stereolability*).[1,2]

Niobium finds use in the production of stainless steels for high temperatures, and in superconducting magnets. The high corrosion resistance of tantalum results in its use for chemical plants. The binary and ternary oxides of these elements arouse increasing interest as electronic ceramics. Their full potential as reagents in organic synthesis lies in the development of their lower oxidation state chemistry as compared to other oxophilic early transition metals. Niobium pentoxide has been used in heterogeneous *Catalysis* either as catalyst or as support (*see* ***Oxygen: Inorganic Chemistry***).

Both metals are active in NMR (spin 9/2 for ^{93}Nb, 7/2 for ^{181}Ta) and have high sensitivities, but their major drawbacks are their large quadrupole moments that often result in broad signals (several kHz) in low symmetry environments, and thus application of NMR remains limited, especially for tantalum. ^{181}Ta is a nucleus with interesting characteristics

Table 1 Oxidation states and common stereochemistries of Nb and Ta compounds

Oxidation state	Coordination number	Idealized geometry	Examples

for *Mössbauer Spectroscopy* and this technique has been applied for the study of sulfide intercalation compounds.[2]

2 OXIDATION STATE V

2.1 Halogens as Ligands: Pentahalides and their Anionic and Neutral Adducts

Niobium and tantalum pentahalides MX_5 are known for all halogens including iodine.[1] They are predominantly covalent (*see Covalent Bonds*), and all are sensitive to moist air, water, or hydrolytic solvents. Pentahalides, especially chlorides, provide the most convenient entry to the molecular chemistry of these elements. They are commercially available and can be prepared by reactions between metals, oxides, or halides and the appropriate halogenation reagent at high temperatures. NbI_5 is the less stable pentahalide (dissociation at 200 °C) and must be prepared and sublimed in the presence of excess iodine. In the solid state, the metals are hexacoordinate; this is achieved by association of MX_5 units as tetramers for MF_5, as discrete dimers for MCl_5 and MBr_5, and as layers of dimers for TaI_5 and β-$NbBr_5$. The dimers can be viewed as two octahedra sharing an edge (Figure 1). In the vapor phase, dissociation into monomers occurs for the dimers, while the pentafluorides exist as a mixture of monomers, dimers, and trimers.

MF_5 and MCl_5 are strongly electrophilic (*see Electrophile* and *Electrophilic Reaction*) and catalyze Friedel–Crafts reactions. The HF/TaF_5 system is a superacid catalyst and has been used in the selective acid-catalyzed isomerization and hydrogenolysis of cycloalkanes. Oligomerization and polymerization of alkynes with Nb^V and Ta^V halides as catalysts have been reported (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***).[1]

Pentahalides form adducts with nearly all types of neutral or anionic donors.[1–5] The high Lewis acidity of MF_5 is illustrated by facile fluoride transfer and formation of anionic adducts. Species such as MF_{5+n}^{n-} ($n = 1$–4) and $M_2F_{11}^-$ have been detected in HF solutions of the metals using a selective fluoride ion electrode or by ^{19}F NMR. These complexes

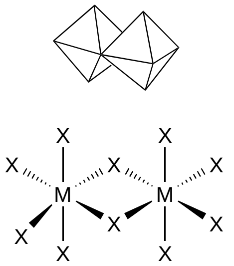

Figure 1 Association of octahedra: molecular structure of the dimeric pentahalides $M_2(\mu\text{-}X)_2X_8$ (X = Cl, Br, I)

can be extracted by organic solvents. Niobium and tantalum pentafluorides form double salts (*see Double Salt*) with most ionic fluorides (*see Ionic Bonds*) by mixing of the constituents in the molten state, or by addition of a fluoride to the oxides in aqueous HF. The fused salt baths used in the electrolytic production of the metals contain mainly the $MF_7{}^{2-}$ and $MF_8{}^{3-}$ anions, whose structure has been solved by X-ray diffraction (*see* ***Diffraction Methods in Inorganic Chemistry***). $MF_7{}^{2-}$ display luminescence properties (*see* ***Luminescence***). Mixed-metal fluoroanions and mono- or dioxofluoro complexes are known.[1–5] Facile corrosion of borosilicate glass by $Cp_2{}^*TaF_3$ giving a ionic tetrafluoroborate complex has been observed.[6]

The higher halides MCl_5 and MBr_5 show much less affinity for Cl^- and Br^- than does MF_5 for F^-. Halogen transfer reactions are nevertheless observed, mostly when these MX_5 halides are allowed to react with AX (A^+ = alkali metals, NH_4, NR_4, PPh_4, $AsPh_4$), thus giving $A^+MX_6{}^-$. The octahedral symmetry of the $MX_6{}^-$ anions is favorable for obtaining sharp ^{93}Nb or ^{181}Ta NMR lines and explains their use as NMR references for these nuclei. Mixed-halide anions have been recognized by ^{93}Nb NMR on mixtures of $NbCl_5$ and $NbBr_5$ in acetonitrile.

The pentahalides form coordination compounds MX_5L_n ($n = 1$ or 2, generally) with a large variety of Lewis bases L. The monoadducts MX_5L are octahedral, monomeric, and generally nonelectrolytes. Stability constants have been determined by proton NMR (*see* ***Stability Constants & their Determination***). Bis adducts MX_5L_2 have also been isolated for many oxygen, sulfur, nitrogen, and phosphorus donors. The MF_5L_2 adducts are mostly ionic in solution, while molecular seven-coordinate species appear to be equally likely in the solid. IR data have shown greater acceptor capacity for NbF_5 than for TaF_5 toward the phosphoryl ligands.[3] Analogous chloride and bromide complexes are essentially molecular.

The pentahalides form mono or bis adducts with O-donors such as aliphatic or crown ethers, phosphine or arsine oxides, ketones, dialkyl esters, and amides. These reactions have mostly been investigated with MCl_5. Abstraction of oxygen from the ligands giving oxotrihalide adducts, $MOCl_3L_2$, can be promoted by heating (for ethers), by an appropriate solvent, or by an excess of ligand as for ketones or phosphine oxides (equation 1). The formation of oxychlorides appears more favorable in the case of niobium.

$$M_2X_{10} + 6O{=}ER_n \longrightarrow 2MOX_3(O{=}ER_n)_2$$
$$X = Cl, Br;\ E = P, As(n = 3), S(n = 2) \quad (1)$$

Pentahalides form essentially 1:1 adducts with sulfur, selenium, and tellurium donors, including phosphine sulfides and selenides. IR, Raman (*see Raman Spectroscopy*), and NMR studies of the complexes formed with mixed-donor O,S ligands showed bonding to occur via sulfur exclusively.[1] The ionic $[NbCl_4(\eta^2\text{-}S_2R_2)][NbCl_6]$ complexes are volatile and act as a single-source precursor to mixed-Nb_2O_5/NbS_2 films

using *Metal–Organic Chemical Vapor Deposition* (MOCVD; *see* ***Tin: Inorganic Chemistry***) techniques.[7]

Niobium and tantalum halides also form adducts with numerous N-donors. Their reactions with pyridine and related ligands (bipyridine, phenanthroline, 7-azaindole[3]) depend critically on the reaction conditions. Indeed, aromatic amines have a tendency to reduce the metal to oxidation state IV especially for niobium but the reduction can be prevented, even at rt, by an appropriate choice of the solvent (equations 2a–c). Imide adducts $M(NR)Cl_3L_2$ are obtained with primary or secondary amines.[8]

$$M_2X_{10} \xrightarrow{\text{bipy}} \begin{cases} \xrightarrow{\text{MeCN, rt}} MX_4(\text{bipy}) & (2a) \\ \xrightarrow{\text{MeCN, 0 °C}} MX_5(\text{bipy})(\text{MeCN}) & (2b) \\ \xrightarrow{C_6H_6\text{, rt}} MX_5(\text{bipy}) & (2c) \end{cases}$$

M = Nb; X = Cl
M = Ta, X = Cl, Br

Complexes with P- or As-donors are obtained in nonpolar media. The tendency toward increasing coordination numbers follows the decrease in the ligand's *Cone Angle* (*see* ***P-donor Ligands***). $NbCl_5$ forms adducts with β-P_4S_4 and P_4Se_3, coordination occurs via the phosphorus atom.[3] Complexes such as $TaBr_5$(diars) have been reformulated as ionic $[TaBr_4(\text{diars})_2][TaBr_6]$ species.

2.2 Oxygen Donors

Anionic oxygen donors include ligands derived from dioxygen, that is, oxo (O^{2-}) and peroxo ($O_2{}^{2-}$) groups (*see* ***Dioxygen & Related Ligands***), alkoxides, and potential chelating ligands such as β-diketonates, carboxylates, or oxyanions of inorganic acids.

2.2.1 Compounds Containing the Oxo Ligand: Oxyhalides and Derivatives

Oxyhalides such as MOX_3 (X = F, Cl, Br, I) or MO_2X may be prepared by halogenation of the oxides or controlled reaction of the pentahalides with dioxygen. $NbOCl_3$, the most studied, is a *Polymer* in the solid state as characterized by a strong, broad IR band at 770 cm^{-1} attributed to Nb–O–Nb stretching. A band at 997 cm^{-1} in the Raman spectrum of gaseous $NbOCl_3$ is attributed to a terminal Nb=O, consistent with a monomeric *Square Pyramidal* geometry.[1] As a result of the oxophilic character of Nb and Ta, incorporation of oxygen into the coordination sphere is frequent. Its origin can result from adventitious water or oxygen or from oxo abstraction reactions involving the solvent or a ligand. Most of the compounds that can be formally considered as resulting from substitution of MOX_3 thus derive from more complex reactions involving precursors without metal oxo bonds.

A variety of anionic oxohalo complexes has been reported. Oxofluoro complexes are formed more readily for Nb than for Ta, this difference is the basis of the classical method of separation of the two metals. K_2TaF_7 precipitates before $K_2NbOF_5{\cdot}H_2O$ during the concentration of the oxides in aqueous HF. Oxo anions of the higher halides include mainly $[MOX_5]^{2-}$ (X = Cl, Br), $[MOCl_4]^-$, $[MO_2Cl_2]^-$. The oxo ligand can adopt a variety of coordination modes. Dinuclear anions such as $[Ta_2Cl_{10}O]^{2-}$ and $[M_2Cl_9O]^-$ with nearly linear M–O–M bridges have been obtained, mostly by adventitious hydrolysis.[1–5] The latter is characterized by an asymmetrical M···O–M bond (1.76 and 2.08 Å) and can be seen as a complex between $NbOCl_4{}^-$ and $NbCl_5$.[7] A tetranuclear niobium–alkyne anion was shown to encapsulate a μ_4-O oxo ligand with an uncommon planar *Stereochemistry*.[2]

Numerous 1:1, 1:2, and 1:3 neutral adducts are known for $NbOCl_3$. While complexes with N-donors such as amines, nitriles, or with phosphines derive mostly from direct reaction between oxyhalides and the ligands, many MOX_3L_2 complexes have been obtained by oxygen abstraction from O-donors by pentahalides. This reactivity can be exploited for an easy entry into oxychloride chemistry via the *Labile* $NbOCl_3(MeCN)_2$ complex (**1**) (equation 3).[1,2]

$$Nb_2Cl_{10} + 2(Me_3Si)_2O \xrightarrow{\text{MeCN, rt}} \underset{\mathbf{(1)}}{2NbOCl_3(MeCN)_2} + 4Me_3SiCl \qquad (3)$$

Tetranuclear monoadducts with asymmetrical M···O–M bridges related to those of $[M_2OCl_9]^-$ have been characterized; but most structural data concern monomeric $NbOCl_3$ bis adducts. In such derivatives, the metal is octahedrally surrounded with the neutral ligands cis to each other, one being trans to the oxo bond, which is short (typical Nb=O *Bond Length* ~1.70 Å). The coordination polyhedron is distorted as a result of the niobium–oxygen multiple bond (*see Valence Shell Electron Pair Repulsion Model*).[1]

The stabilizing effects of the bulky and strong electron donor pentamethylcyclopentadienyl ligand Cp* permitted investigation of the stepwise hydrolysis, in the solid state as well as in solution, of Cp^*MCl_4. The oxide ligand can be progressively introduced via hydrates or hydroxo derivatives, giving structurally characterized dinuclear or trinuclear aggregates.[9] These bulky ligands were also able to stabilize the simultaneous presence of oxo and hydride ligands on tantalum. Nonhalide oxo derivatives can be stabilized as monomers with bulky O- or N-donor ligands such as tri-*t*-butylsiloxide (silox), bistrimethylsilylamide, tropolone,[1,2] or as tetramers with trispyrazolylborate ligands.[10]

In aqueous solutions, numerous orthometallates ($MO_4{}^{3-}$), metametallates (MO^{3-}), and polyoxometallates, especially $[Nb_6O_{19}]^{8-}$, are known (*see* ***Polyoxometalates***). Peroxo derivatives are other species obtained from aqueous solutions. Orthoperoxometallates precipitate from alkaline solutions of

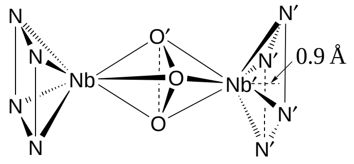

Figure 2 Coordination polyhedron of the $M_2(\mu\text{-}O)_3(\text{porp})_2$ dimers

niobates or tantalates on addition of H_2O_2.[1] In the $Nb(\eta^2\text{-}O_2)_4{}^{3-}$ ion, all peroxide groups are linked side-on to the metal (*see Side-on Coordination*). Perhydrolysis of alkoxides in the presence of organic bases provides a clean route to peroxo anions. The peroxometallates release O_2 progressively in mild conditions, and explosively at 80 °C. They are converted into orthoperoxo acids by H_2SO_4. The yellow color that is developed for niobium has been used in colorimetric titration. Displacement of the peroxo ligands with chelating O- or N-donors (*see Chelating Ligands*) gives di- and triperoxo complexes. For the bisperoxo compounds, the coordination polyhedron corresponds to a distorted dodecahedron (*see Dodecahedral*), the two peroxo groups displaying an unusual cis geometry. Peroxo complexes with N-oxide derivatives of polycarboxylic acids, $[Nb(\eta^2\text{-}O_2)_2(LO_2)]^{3-}$ (L = edta) or pdta (propylenediaminetetracetate) have been reported.[11] Anionic and neutral peroxohalo derivatives, mainly peroxofluoro ones, are known; their structure has been investigated by X-ray diffraction as well as by ^{19}F NMR. A cyclopentadienyl monoperoxide catalyzes the conversion of cyclohexene into its epoxide in the presence of H_2O_2.[1]

Most *Porphyrin* complexes are niobium oxo derivatives such as NbOZ(porp) (Z = F, OAc, acac). Tantalum porphyrin derivatives are scarcer. The hydrolysis of $M(\text{porp})Cl_3$ afforded oxo dimers, $M_2(\text{porp})(\mu\text{-}O)_3$ (**2**) of an unusual structure since two M(porp) units are linked together through three oxo bridges (Figure 2). Structure determinations by X ray have shown that the metal lies always above the plane of the porphyrin ring and that the axial ligands have a cis geometry with respect to the ring. The redox chemistry of the Nb oxo dimer (**2**) was investigated by chemical and electrochemical means (*see* ***Electrochemistry: Applications in Inorganic Chemistry***). The photochemically reduced Nb porphyrin derived from (**2**) is able to reduce O_2 and to achieve the catalytic and exclusive epoxidation of alkenes, without additional reactant;[9,12] it is the first example of such an activation (*see* ***Oxygen: Inorganic Chemistry***). Attempts to get $Ta(\text{OEP})Cl_3$ from $TaCl_5$ lead to $[Ta(\text{OEP})_2][TaCl_6]$, a sandwich compound (OEP = octaetylporphyrin). Half-sandwich alkyl Ta compounds including a cationic species were also prepared.[13]

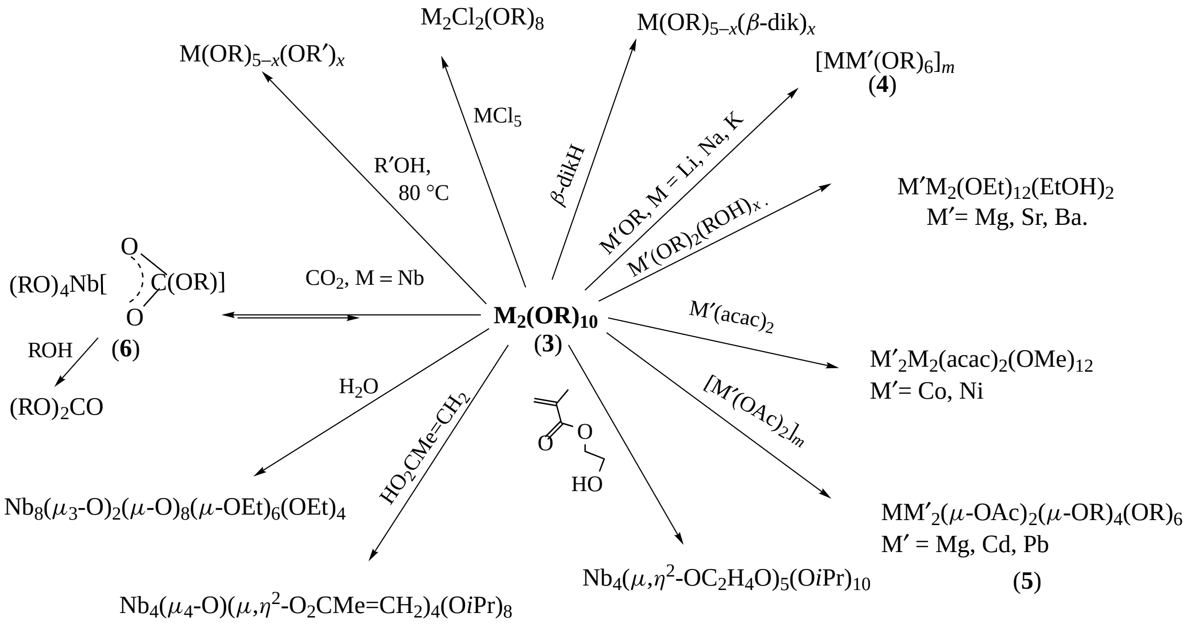
2.2.2 *Alkoxides*

Homoleptic alkoxides (*see Homoleptic Compound*) $M(OR)_5$ (**3**; R = Me, Et, Pr, etc.) derive from MCl_5 by reaction with alcohols (the reaction is driven to completion by a base that acts as proton acceptor) or with alkali alkoxides (equation 4) or from anodic dissolution of the metal in alcohol.[1] Transesterification reactions extend the range of available alkoxides, giving, for instance, trialkylsiloxides $M(OSiR_3)_5$ and heteroleptic alkoxides $M(OR)_{5-x}(OR')_x$ (*see Heteroleptic Compound*).

$$M_2Cl_{10} \xrightarrow{C_6H_6} \begin{cases} \xrightarrow[]{\text{1. xs. ROH} \quad \text{2. } NH_3\ (-NH_4Cl)} \\ \xrightarrow[-\,5NaCl]{5\ NaOR} \end{cases} \underset{(\mathbf{5})}{M(OR)_5} \qquad (4)$$

Alkoxides are usually highly soluble, volatile, monomeric (R = 2,6-dialkylaryl) or dimeric (R = Me, Et, Ph), depending on the size of the R group. The terminal M–OR bond lengths (about 1.90 Å) are shorter than the sum of the covalent radii (2.27 Å). This suggests electron donation from oxygen p_π orbitals to the metal empty d_π orbitals $[O(p_\pi) \rightarrow M(d_\pi)]$ and thus π-bonding (*see π-Bond*). π-Bonding is confirmed by rather large M–O–C angles. Despite a high thermodynamic stability, the M–OR bond is labile; for the dimers, bridges may open and close reversibly, leading to fluxional behavior in solution. The electroattractive OR groups make metal alkoxides very prone to nucleophilic attack (*see Fluxional Molecule*) and they react with a variety of organic hydroxy derivatives such as β-diketones (*see Diketones*), thio-β-diketones, β-hydroxyesters, diols and polyols, silanols, alkoxyamines, Schiff bases (*see Schiff Base*), and simple and functional, including polymerizable, carboxylic acids.[14,15]

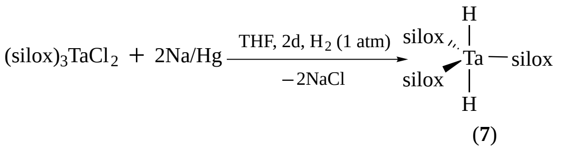
Metal alkoxides are extremely sensitive to hydrolysis, and one of their applications is their use as precursors for advanced materials via hydrolysis–polycondensation reactions and the formation of polynuclear oxoalkoxides as intermediates in the ***sol–gel*** process (*see* ***Sol–Gel Synthesis of Solids***). Most of their modification by hydroxy derivatives has been related to the need to reduce their reactivity for those applications.[16] Their volatility, comparable to the β-diketonates, makes them suitable for the elaboration of coatings by MOCVD.[16,17] By contrast with the pentahalides, alkoxides (**3**) do not easily form complexes with Lewis bases, although complexes can be detected in solution in the presence of the parent alcohol or hard donors (amines, phosphine oxides) (*see* ***Hard & Soft Acids and Bases***). However, they react easily with other metallic derivatives (alkoxides, carboxylates, β-diketonates, etc.) giving heterometallic (mixed-metal) oxo or non-oxoalkoxides[14–17] Such derivatives are attractive precursors for ternary or quaternary oxides by sol–gel reactions as they allow homogeneity to be achieved at a molecular level and their structure may preform the macromolecular framework of the ceramic. $[LiNb(OEt)_6]_\infty$ (**4**) and (**5**) are examples of compounds having structures related to the materials lithium niobate and $M'Nb_2O_6$ (M′ = Mg, Cd, Pb), respectively. Scheme 1 collects some of their reactivity patterns.



Scheme 1 Some examples of the reactivity of $M(OR)_5$ (all reactions at rt unless otherwise stated)

$[Nb(OR)_5]_2$ (R = Me, Et, allyl) react reversibly with carbon dioxide to form an O,O-hemicarbonate (**6**) then the organic carbonate.[18] $Ta(OEt)_5$ was reported as a catalyst for lactide polymerization whereas $(EtO)_2TaL$ (L = tris(2-oxy-3,5-dimethylbenzyl)amine) failed to act as a single site initiator.[19] The homoleptic Nb and Ta alkoxides have also been used for access to mesoporous (*see* ***Porous Inorganic Materials***) oxides using surfactants,[20] or to nanostructured oxides using organogelators as structure-directing agents.[21] Mesoporous Nb_2O_5 could be converted into a metallic niobium oxide molecular sieve which, reacting at rt with N_2 to form a nitride, provides the first example of such a process mediated by a molecular sieve.

Halide alkoxides $M(OR)_{5-x}X_x$ ($x = 1–4$, X = Cl or Br mainly) result essentially from reaction of MX_5 with ROH or with trimethylsilyl reactants. They display reactivity patterns comparable to (**3**) but they are more prone to form complexes. $M(OR)_4Cl$ species are the least common. The most relevant results in organometallic chemistry of Nb and Ta have been associated with ancillary, bulky alkoxide ligands (*see* ***Niobium & Tantalum: Organometallic Chemistry***).[22] Of particular interest are the halide alkoxides based on groups such as 2,6-alkylaryloxides[14] or tri-*t*-butylsiloxide.[14,23] They are able to sterically saturate metal centers in monomers while leaving them electron deficient (*see Electron Deficient Compound*), and unusual structural and reactivity patterns have been observed in different oxidation states. Substitution reactions of the halides afforded alkylaryloxides, which catalyze the hydrogenation of arylphosphines. Stable aryloxide hydrides such as $TaH_2(2,6\text{-}tBu_2C_6H_3O)_2Cl(PMe_2Ph)_2$ for instance have been isolated.[14,24] They react with olefins and alkynes, the product depending on the ancillary ligand. A Ta^V hydride showing hydrodeoxygenation (HDO) of the tridentate aryloxide has been reported.[25] The isolation of Ta^V species containing resolved 3,3′-disubstituted-1,1′-bi-2,2′-naphtoxides has been achieved with chloride or dimethylamide as ancillary ligands.[26] Nb aryloxides associated with AlR_3 or *Grignard Reagents* are catalyst precursors for the polymerization of monoalkyl-substituted alkynes. The bulkiness around the metal (controlled by the number of OAr-ligands) prevents side reactions and enhances the molecular weight (MW) of the polymer.[14] The reduction of $(silox)_3TaCl_2$ under H_2 offered a mononuclear dihydride (**7**) in high yield (equation 5).[24] The presence of terminal hydride ligands for (**7**) is supported by a vibration at $1725\,cm^{-1}$ in the IR and a signal at low field in the NMR (*see* ***Hydride Complexes of the Transition Metals***).



(5)

(**7**)

Calix[4]arenes have been used as a preorganized set of O-donor atoms. Monomeric or dimeric species were obtained depending on the calixarene substituents.[27] They were used to develop the organometallic chemistry of Nb and Ta in various oxidation states, the electron reservoir of the Nb=Nb bond is able to activate small molecules including N_2 (*see* ***Niobium & Tantalum: Organometallic Chemistry***).

2.2.3 *Diketonates, Carboxylates, and Related Derivatives*

Homoleptic pentavalent β-diketonates are unknown, the volatility of heteroleptic derivatives such as $M(thd)_4X$ ($X = Cl$, OR) allows their use as a source of the metal oxides in MOCVD.[16,17] Ionic species such as $[Ta(thd)_4][TaCl_6]$ have also been obtained.

The reaction between pentahalides or alkoxides and carboxylic acids gives oxochloro- or oxoalkoxocarboxylates. *Chiral* tantalum cyclopentadienyl carboxylates mediate acylation reactions of amides, giving dipeptides in good yield with high stereochemical purity.[28]

Derivatives of heterocyclic carboxylic or α-hydroxyacids have been obtained in aqueous media. For instance, niobic and tantalic acids dissolve in aqueous solutions of oxalic acid giving mono-, bis-, or trisoxalato compounds, depending on pH and concentrations.[1,2] The species isolated for Nb are oxooxalato derivatives with the oxo ligand in the axial position of a pentagonal bipyramid (*see Pentagonal Bipyramid*).[1] The solubility of Ta_2O_5 in oxalic acid solutions is much lower than that of Nb_2O_5 due to polymeric species. The intense coloration of the complexes formed with ligands such as 4-(2-pyridylazo) resorcinol or ascorbic acid are interesting for the spectrophotometric determination of Nb or Ta[1,2] (*see* ***Analytical Chemistry of the Transition Elements***). Compounds with inorganic oxyanions (*see Oxoanion*) (nitrates, sulfates, phosphates, etc.) have been reported. The interest in the sulfates arises from processes using sulfuric acid in the treatment of minerals.[1] Various sulfato species (mainly oxo ones) were isolated from the $M_2O_5-SO_3-H_2O$ system.[1] The coordination polyhedron of $K_7M(SO_4)_6$, obtained from solutions of M_2O_5 in molten $K_2S_2O_7$, consist of six monodentate sulfato ligands.[2] Crystalline phosphate hydrates display a layer structure able of hosting various molecules.[1] An NbX_6^- anion based on the 'teflate' $OTeF_5$ ligand has been reported; the steric hindrance provides kinetic stabilization in the presence of electrophilic cations that might expand its use as a counterion (*see Counter Ions*).

2.3 Complexes with Sulfur, Selenium, and Tellurium Donors

Numerous neutral complexes of the pentahalides with S-donors have been described. Anionic S-donor ligands are mainly represented by sulfides (S^{2-}), disulfides (S_2^{2-}), thiolates (RS^-), dialkyldithiocarbamates ($R_2dtc = S_2CNR_2^-$; *see Dithiocarbamate*), and dialkyl thiophosphates ($S_2P(OR)_2^-$) (*see* ***S-donor Ligands***).

2.3.1 *Thio-, Seleno- and Tellurohalides Derivatives*

Thio- and selenohalides MEX_3 ($E = S$, Se) are accessible by the reaction of antimony chalcogenides with pentahalides at rt in CS_2. $NbSCl_3$ can also be conveniently obtained by reacting the pentachloride with hexamethyldisilathiane in CH_2Cl_2;[1,2] the reaction is comparable to that depicted in equation (3). A few neutral mono or bis adducts of the thiohalides have been described. X ray has established the presence of a terminal Nb=S bond (2.09 Å). Vibrations of the M=S moiety in the IR have been reported around 550 cm^{-1} for Nb, while a wider range (435–505 cm^{-1}) has been observed for the tantalum derivatives. Multidendate amino ligands $[(NH)_3N = (Me_3SiNHC_3H_6)_3N]$ allowed to stabilize $TaE(N_3N)$ derivatives ($E = S$, Se, Te) prepared by reacting the Ta chloroamide and $(THF)_2LiESi(SiMe_3)_2$.[3] The one-dimensional solid $[Ta(Te_2)_2]_4[PtI_6]I_2$ synthesized from the elements at high temperature consists of $[Ta(\mu, \eta^2\text{-}Te_2)_2]$ chains separated by PtI_6 groups and iodine atoms.[3,4]

2.3.2 *Thiolate, Dithiocarbamate Derivatives, and Chalcogenometallates*

Anionic six-coordinate homoleptic thiolates were isolated with monodentate arenethiolate or with bidentate ethylene-1,2-dithiolate ligands and with various cations.[29] The coordination sphere often tends toward a trigonal prismatic geometry (*see Trigonal Prism*), as observed for $[Nb(SC_2H_4S)_3]^-$ or for $[Nb(SC_6H_4Me\text{-}p)_6]^-$. Neutral homoleptic thiolates $M(SR)_5$ are limited ($R = C_6F_5$ or $SC_6H_3Me_2$-2,6). The Nb arylthiolate was converted into NbS_2 by thio sol-gel whereas it acted as a precursor to NbS films by chemical vapor deposition (CVD).[30] Oxo- and halothiolates have also been reported. X-ray data have shown that the extent of the S to M π-bonding in these electron-deficient thiolates is reduced compared to the O to M π-bonding in aryloxides. Reactions with thiolates (equation 6) or dialkyldithiocarbamates are often versatile and compounds having M=S or $M(S_2)$ bonds might be obtained by activation and cleavage of the C–S bond.[1,29] These reactions are dependent on the experimental conditions;[1] they might be assisted by water and be relevant to hydrodesulfurization (*see* ***Hydrodesulfurization & Hydrodenitrogenation***). Niobium sulfido and bis-sulfido dithiocarbamates were obtained by reacting $NbO(dtcEt_2)_3$ with boron sulfide.[4,29]

$$Nb_2Cl_{10} + 6NaSR \xrightarrow{\text{RCN, rt}} \begin{cases} \xrightarrow{R = Ph} Na[Nb(SPh)_6] \\ \xrightarrow{R = t\text{-Bu}} Na[Nb(S)_2(S\text{-}t\text{-Bu})_2] + Na[Nb(S)(S\text{-}t\text{-Bu})_4] + \cdots \end{cases} \quad (6)$$

Homoleptic Ta dithiocarbamates result from *Insertion* of CS_2 into the tantalum–nitrogen bond of $Ta(NR_2)_5$; in the case of niobium, similar reactions proceed with reduction to Nb^{IV}.[1] Halodithiocarbamates can be either molecular or ionic and the existence of *Coordination Isomers* $NbCl_3(Et_2dtc)_2$ and $[Nb(Et_2dtc)_4][NbCl_6]$ has been established.[2,31] ^{93}Nb NMR spectroscopy has been used to identify the various dithiocarbamates in solution. The dithiocarbamate ligand is bidentate and its small bite (*see Bite Angle*) favors high coordination numbers of seven or eight.

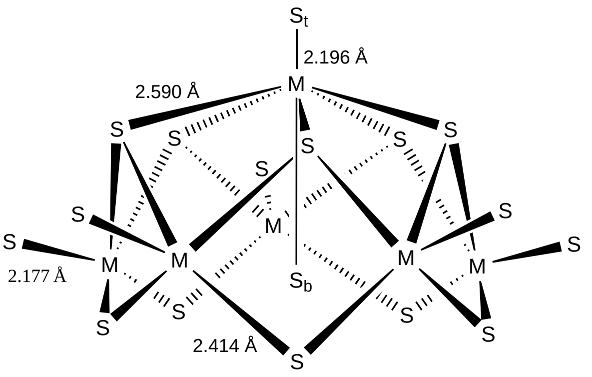


Figure 3 Structure of the $M_6S_{17}{}^{4-}$ thiometallates. The bond length order is M–S terminal < M-μS < M-μ_3-S < M–S_b (S_b being inside the cage)

The lability of the pentalkoxides has been exploited for the synthesis of *Thiometallates* at rt. This is an interesting alternative to the high-temperature reaction between the elements, often difficult to control. Hexamethyldisilathiane is used as a source of sulfur, and soluble $[MS_4]^{3-}$ (**8**) and $[M_6S_{17}]^{4-}$ (Figure 3) salts were obtained depending on the counterion (equation 7). Li^+ allows the stabilization of small, highly charged, nucleophilic $[MS_4]^{3-}$ species, the simplest chalcogenoniobates and -tantalates structurally characterized.[1,29]

$M(OEt)_5 + 3X + 4(Me_3Si)_2S$ (MeCN):
- X = NEt_4Cl (crossed out) → $(Et_4N)_3[MS_4]$ (**8**) + $5Me_3SiOEt + Me_3SiCl$
- X = NEt_4Cl → $(Et_4N)_3[M_6S_{17}]$
- X = LiOMe → $Li_3(MS_4) + 5Me_3SiOEt + 3Me_3SiOMe$

(7)

Thiometallates (**8**) and $Ta_6S_{17}{}^{4-}$ serve as synthons, for instance, for the preparation of mixed-metal clusters involving iron[2] or copper and silver, respectively.[1,32] The discrete polynuclear $Ta_2S_{11}{}^{4-}$ and $Nb_4Se_{22}{}^{6-}$ anions, prepared by traditional solid-state routes, have a structure related to that of polynuclear Mo oxysulfide anions. Nb–Cu chalcogenido clusters stabilized by phosphines could be prepared directly from $NbCl_5$ (equation 8). The anion (**9**), for instance, is based on two Cu_3NbS_3Cl heterocubane units linked by three μ_3-chlorine.[33]

$NbCl_5 + CuCl + 3PEt_3$ (MeCN):
- $(Me_3Si)_2S$, NEt_4Cl → $(NEt_4)[Cu_6Nb_2S_6Cl_5(PEt_3)_6]$ + ··· (**9**)
- $(Me_3Si)_2Te$ → $[Cu_6NbTe_3(Te_2)_2(PEt_3)_6][CuCl_2]$ + ····

(8)

Soluble mixed-chalcogenido Nb/Se/E complexes (E = S, O) have been reported.[34] The differences in structures and *coordination geometries* between sulfides and selenides as ligands for Nb have been attributed to their redox properties as well as to size. The presence of terminal Se–H ligands in the metal coordination sphere might be due to the need to avoid accumulation of excessive negative charge around the $Nb(Se)_3L^{2-}$ units (L = SH, SeH, OMe).

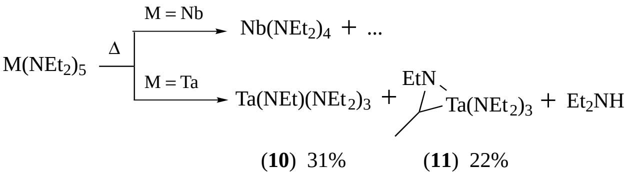
A variety of sulfide and selenide clusters have been obtained from $CpMCl_4$ and silylated or Li chalcogenides.[32] The $Cp^*TaS_3{}^{2-}$ unit offers an example of a moiety with three terminal sulfides that might serve as a building block for more complex structures.[9] The presence of the bridging pentasulfide μ,η^2-$S_5{}^{2-}$ ligand, derived from octasulfur, has been established by X-ray diffraction in dinuclear anionic or neutral niobium derivatives such as $[Nb_2(OMe)_2(\eta^2\text{-}S_2)_2(\mu,\eta^2\text{-}S_2)(\mu\text{-}O)(\mu\text{-}\eta^2\text{-}S)_5]^-$.[2,9,35]

2.4 Nitrogen Donors

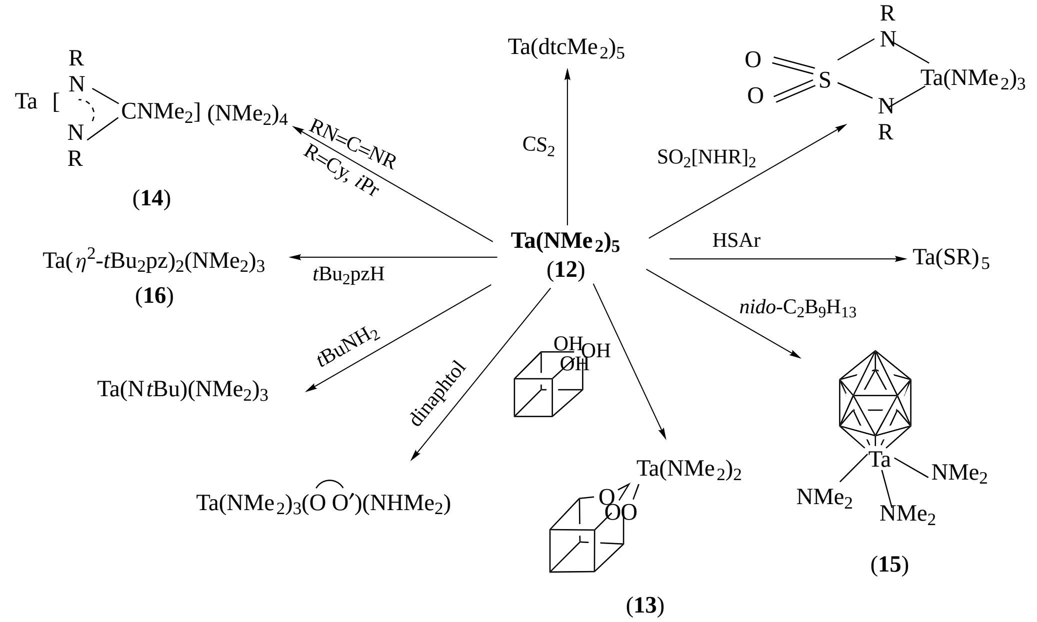
Anionic N-donor ligands comprise essentially amido ($NR_2{}^-$), imides or nitrenes (NR^{2-}); amidinates or guanidinates [$(RN)_2CX^-$, X = R′ or NR′ respectively]; azides ($N_3{}^-$); or nitrides (N^{3-}).

2.4.1 *Amido and Imido Derivatives*

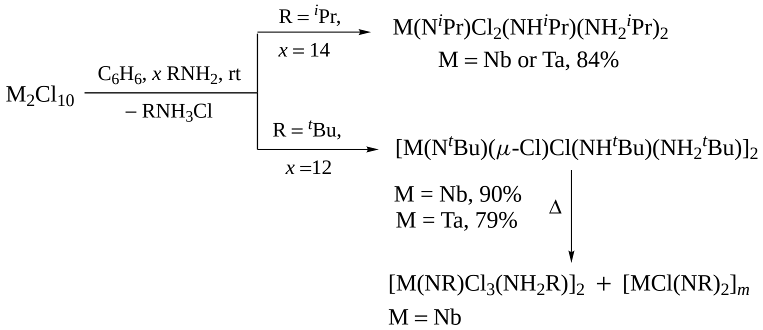
Homoleptic Nb^V and Ta^V dialkylamides, $M(NR_2)_5$, have been obtained from the pentahalides and lithium amides. By contrast with alkoxides, they are generally monomers (even for NMe_2) as a result of the steric demand of the dialkylamido ligand. They are volatile but less stable thermally than the pentaalkoxides. The steric congestion around the metal is reduced during thermolysis by loss of ligands. This is achieved for niobium by reduction to $Nb(NR_2)_4$ (favored by the length of the alkyl chain); in the case of tantalum, oxidation state V is retained and the pentaamides are converted into a mixed imido amide $Ta(NR)(NR_2)_3$ (**10**) (equation 9). Formation of the imide ligand occurs through β-H abstraction and intramolecular metallation although *Cyclometallation* reactions are uncommon with metals having a d^0 electronic configuration (*see Electron Configuration*). The azametallacycle (**11**) was isolated and used as a MOCVD metal source for obtaining films of cubic TaN as well as of amorphous Ta_2O_5 at low temperature.[35]



(9)



Scheme 2 Some reactions of $Ta(NMe_2)_5$ (all reactions at rt unless otherwise stated)



Scheme 3 Synthesis and reactivity of chloroimide complexes

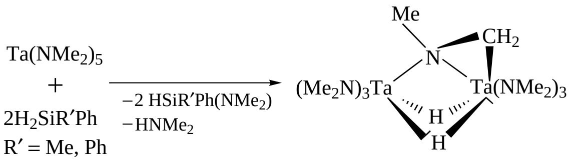
Halodialkylamido derivatives are accessible by several methods, especially reactions between pentahalides and amines or trimethylsilyl reactants. They are obtained as dimers or as monomeric adducts in the presence of an excess of amines. A common feature of these derivatives is the hexacoordination of the metal. The MNC_2 units are planar with short M−N distances (≈1.86 Å), and thus suggest strong π-bonding by interaction of the nitrogen p_π orbitals and empty d_π orbitals of the metal.

The $M–NR_2$ bond is labile and Nb and Ta dialkylamides $M(NR_2)_5$ (**12**) are valuable starting materials (Scheme 2). They can easily undergo substitution or *Insertion* reactions. Insertion of CO_2, CS_2, and COS in $M(NR_2)_5$ has been observed, giving dialkylcarbamates, dithiocarbamates, or monothiocarbamate derivatives, respectively. In the case of niobium, the insertion of CS_2 is accompanied by reduction. Insertion of CO_2 is catalyzed by amines resulting from adventitious hydrolysis. Monodentate as well as bidentate carbamato ligands have been observed by X ray and can be distinguished in solution by IR, but not by NMR owing to fluxionality.[9,36] Nb and Ta derivatives based on bidentate or polydentate amido ligands have been reported. (**12**) allowed access to the first tantalasilsesquioxanes (**13**) (*see* ***Silicon: Organosilicon Chemistry***).[37] (**12**) are source to guanidinate(−1) (**14**) or to guanidinate(−2) complexes by reaction with carbodiimides, or by protonation of the amido groups with trialkylguanidines respectively.[38] The acidic *carborane nido*-$C_2B_9H_{13}$ (*see* ***Boron: Metallacarbaboranes***) reacts with (**12**) to generate three-legged piano stool $M(C_2B_9H_{11})(NMe_2)_3$ complexes (**15**), where the dicarbollide acts as a *spectator ligand*.[39]

Imido ligands are implicated in catalytic processes; they may act as NR transfer reactants or as intermediates on chemical routes to nitrides by CVD. Among the variety of routes available, reactions between MCl_5 and primary amines (Scheme 3), trimethylsilyl or lithium reactants and aminolysis of $M(NR_2)_5$ with primary amines are the most selective

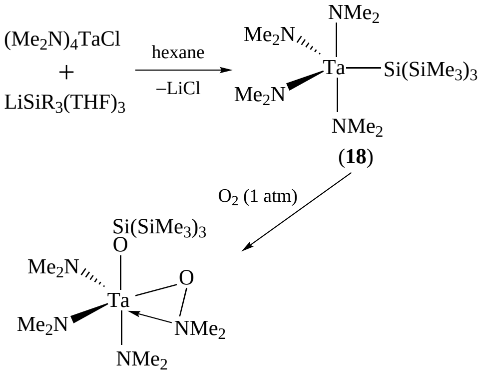
ones. The formation of the M≡NR bond proceeds via H abstraction. It is favored by proton acceptors, either excess of the amines, of ligands such as phosphines, or of an inorganic base (silicates, $ZnCl_2$, ...)[40] and many efforts have been devoted to high-yield syntheses of $M(NR)Cl_3L_x$ complexes (R = Ar, *t*Bu, $SiMe_3$) with labile, inert ligands. The donor capability of the various R groups have been compared, *t*Bu is more efficient toward d^0 metals than $SiMe_3$, itself better than the Cp ligand.[41] Decomposition patterns of chloroimide complexes have been examinated in relation to CVD of metal nitrides.[8] The decomposition of $MNCl_2$ into NbN and Ta_3N_5 respectively, is consistent with the CVD results.

The reaction between $Ta(NMe_2)_5$ and silanes yielded an unusual dihydride imine complex (**17**) through β-H abstraction between amide ligands (equation 10).[42] The first Cp-free silyl (**18**) and disilyl Ta derivatives have been reported. They are potential precursors to Ta–N–Si ternary materials. Unusual oxidation products such as (**19**) could be stabilized (equation 11).[43]



(10)

(**17**)



(**18**)

(11)

(**19**)

Imido amides or imido alkoxides are known, especially with bulky NAr groups.[1,22] Their utility has been demonstrated in the preparation of M^{III} imido alkyne compounds. The electrophilic, transient (t-Bu_3SiNH)Ta(=NSi-t-Bu_3)$_2$ was active in hydrocarbons C–H activation reactions.[22] Metal–imide bonds are short (1.75 Å) with M–N–C angles close to linearity. These data are consistent with an M–N *Bond Order* somewhat greater than two, and reflect the π donation of the nitrogen lone pair with a formal bonding M≡NR, the imido ligand being described as a 4e donor. In the imido alkoxides, the OR ligand is oriented cis to the imide, thus allowing to maximize the number of interactions between these ligands, and the d^0 metal is thus able to reach 18e (*see Effective Atomic Number Rule*).

The oxo and organoimide ligands are *Isoelectronic*, but imides have higher thermal stability and solubility than their oxo analogs. They are characterized by a vibration around 1350 cm^{-1} in the IR. ^{15}N NMR data have been reported for M^V and M^{III} imides, the latter appear at higher fields. The action of alcohols generally removes the imido ligand, giving alkoxides, while that of carboxylic compounds results in the formation of oxo derivatives.[1]

2.4.2 Dinitrogen Activation

Niobium and tantalum belong to the metals that are able to bind dinitrogen.[44] The development of this area was first due to Schrock and coworkers, who in 1982 could obtain stable tantalum μ-N_2 compounds in high yields by reducing *Alkylidene* complexes under dinitrogen at normal pressure.[1,22] This route can be circumvented in a 'single pot' synthesis by reacting the pentahalides with silylated hydrazines (equation 12).

$$M_2Cl_{10} + (Me_3Si)XNNX(SiMe_3) \xrightarrow{CH_2Cl_2,\ THF} [MCl_3(THF)_2](\mu\text{-}N_2)$$

M = Nb, X = $SiMe_3$, (**20**) (60%)

M = Ta, X = H (**21**) (30%) (12)

Complexes (**20**) and (**21**) are *synthons*, either by *Ligand* exchange or by chlorine substitution. The latter reactions offered, for instance, thiolate or diethyldithiocarbamate (**22**) derivatives (Figure 4); the first dinitrogen complexes in which the coligands are exclusively S-donors, significant in light of the predominant sulfur ligation of the enzyme nitrogenase (*see* ***Nitrogenase: Metal Cluster Models***).

The usual structural feature of Nb or Ta nitrogen complexes is the presence of a bridging μ-η^2:η^2 dinitrogen ligand (*see Bridging Ligand*) involved in a nearly linear M–N–N–M arrangement. The N–N bond lengths (1.39–1.25 Å) are longer than in free dinitrogen (N≡N, 1.0976 Å), suggesting a bond order between one and two. The M–N bonds (1.85 – 1.75 Å) are also much shorter than the usual M–N single bond (typically 1.95–2.05 Å) and close to the

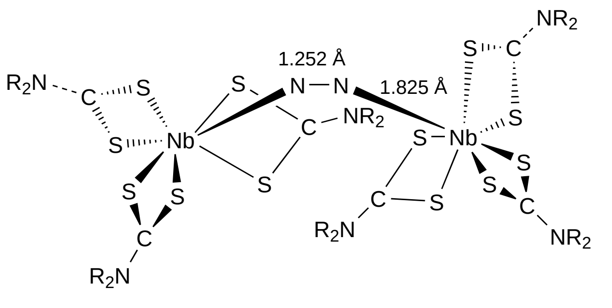


Figure 4 Molecular structure of the dinitrogen complex $Nb_2(\mu\text{-}N_2)_2(dtcR_2)_6$ (**22**)

distances found in imido derivatives. As a result, these dinitrogen complexes, which are specific for early transition metals, have been formulated as M=N–N=M systems or hydrazido(4−) derivatives. ^{15}N labeling has established that the Ta=N–N=Ta group is characterized in the IR by an absorption around 845 cm^{-1}, consistent with partial reduction of N_2. This description of the Mμ-N_2 bridge is supported by the reactivity of these adducts, which behave as imido complexes. Protonation of bridging dinitrogen by various hydracids gives hydrazine only (equation 13) and has been studied kinetically in the dithiocarbamates (**22**).[44] In the presence of excess acid, protonation proceeds irreversibly via hydrazido(2−) complexes that have been detected in the case of niobium (Scheme 4).[1,2,9] Ta complexes containing the methylhydrazido(1−) ligand have been studied with the aim of understanding the role of related derivatives as intermediates in the conversion of hydrazido(2−) complexes to hydrazine. A 4e reduction of N_2, as well as further reduction into a nitride, has also been achieved with a Nb^{III}-calix[4]arene containing a very reactive Nb≡Nb unit.[45] Cleavage of N_2 was also promoted by the low-valent species derived from the reduction of $[Nb(^{R}\text{-L})Cl_2]_2$ ($^{R}\text{-L}^{3-}$ = linked aryloxide). The reactions are dependent on the nature of the R substituent.[46]

$$[Ta(Et_2dtc)_3]_2(\mu\text{-}N_2) + 4HX \xrightarrow{S,\ rt} 2Ta(Et_2dtc)_3X_2 + N_2H_4$$

(**22**) 100%

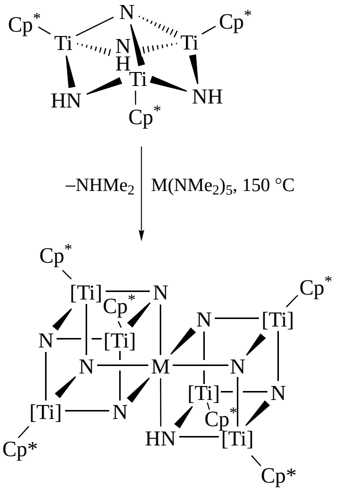
X = Cl, Br, I; S = CH_2Cl_2, THF or MeCN (13)

A facile process for the preparation of Nb and Ta dinitrogen complexes supported by aminophosphine ligands was reported recently.[47] The reaction of the Ta^{IV} diamagnetic hydride ($[NPN]_2Ta_2(\mu\text{-}H)_4$) (**23**) ([NPN] = $PhP(CH_2SiMe_2NPh)_2$) with N_2 provided a Ta^{V} species (**24**) with an unprecedented side-on end-on dinuclear bonding mode. The N–N distance (1.319 Å) is consistent with the bridging dinitrogen as $(N_2)^{4-}$. The hydride ligands force the metal centers so close together (Ta···Ta 2.830 Å) that the usual end-on dinuclear bonding mode becomes impossible (Scheme 5). This strongly activated N_2 is amenable to functionalization such as Si–N (**25**) or B–N (**26**) bond formation for instance.

2.4.3 Miscellaneous

The azides and nitrides (*see* ***Nitrogen: Inorganic Chemistry***) further illustrate the ability of niobium and tantalum to form M–N multiple bonds. The stability of the azides, although poor, is higher for Ta and for ionic derivatives than for Nb and neutral ones.[1] Their M–N distances are longer than expected for a single bond. Reactions analogous to the Staudinger reaction (*see* ***Phosphorus: Organophosphorus Chemistry***), giving compounds containing the phosphineiminato M=N=P group, are the salient feature of their reactivity. These heteroimido derivatives could also be obtained from penta- or oxyhalides and trimethylsilyl or lithium reagents.[48]

Nitrides can be obtained by decomposition of the azides, but thermolysis of the pentahalides with ammonium salts appears more general. Recent synthetic pathways involve the cleavage of N_2[45] or decarboxylation of a Nb isocyanate.[49] The solid-state characterization of the $[M_2NX_{10}]^{3-}$ anions shows a linear symmetrical M=N=M bridge. Neutral halide nitrides are polymeric.[1,2] Heterometallic nitrides based on a corner-shared double cube $NbTi_6N_8$ core (**27**) have been described (equation 14).[50]



(14)

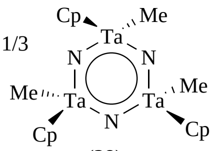
(**27**)

$M(\mu_3\text{-}N)(\mu_3\text{-}NH\{Ti_3(\eta^5\text{-}Cp^*)(\mu_3\text{-}N)\}_2$

A number of pentavalent trispyrazolylborate derivatives (*see Tris(pyrazolyl)borates*) have been reported, especially for niobium.[51] Most of them are monomeric Tp^*MCl_2X (X = O, NR) derivatives. η^1 and η^2-pyrazolato (**16**) or 1,2,4-triazolato derivatives have been prepared as potential sources of nitrides for CVD.[52] The reactions between dilithium 1,4-diaza-1,3-diene and pentachlorides have been investigated.[53]

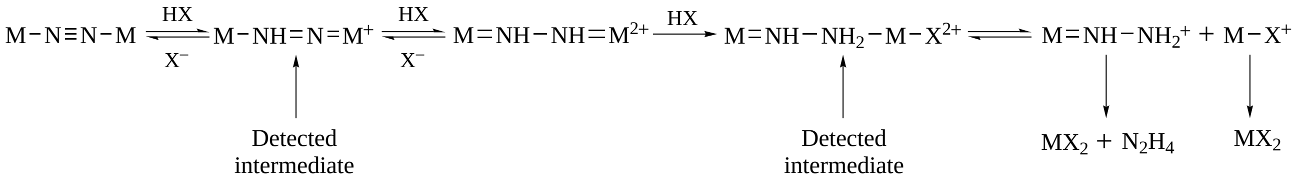
Ammonolysis of $NbBr_5$ followed by heat treatment was used for access to ceramics, that is, nitrides or carbonitrides. Applied to Ta alkyl derivatives, ammonolysis provides a low temperature route to TaN; the cubic form is obtained instead of the more stable hexagonal one.[54] Similar reactions for Cp^*TaMe_4 give a cyclic trimer (**28**) (equation 15), whose delocalized six-membered ring (Ta–N av. 1.88 Å) is related to that of phosphazenes (*see* ***Phosphorus–Nitrogen Compounds***). The thermal ring opening of the chloride analog of (**28**) offered the first soluble polymer based on a Ta–N backbone.[2,3]

$$Cp^*TaMe_4 + xs.NH_3 \xrightarrow[-CH_4]{C_6H_6\quad rt,\ 2d} 1/3$$

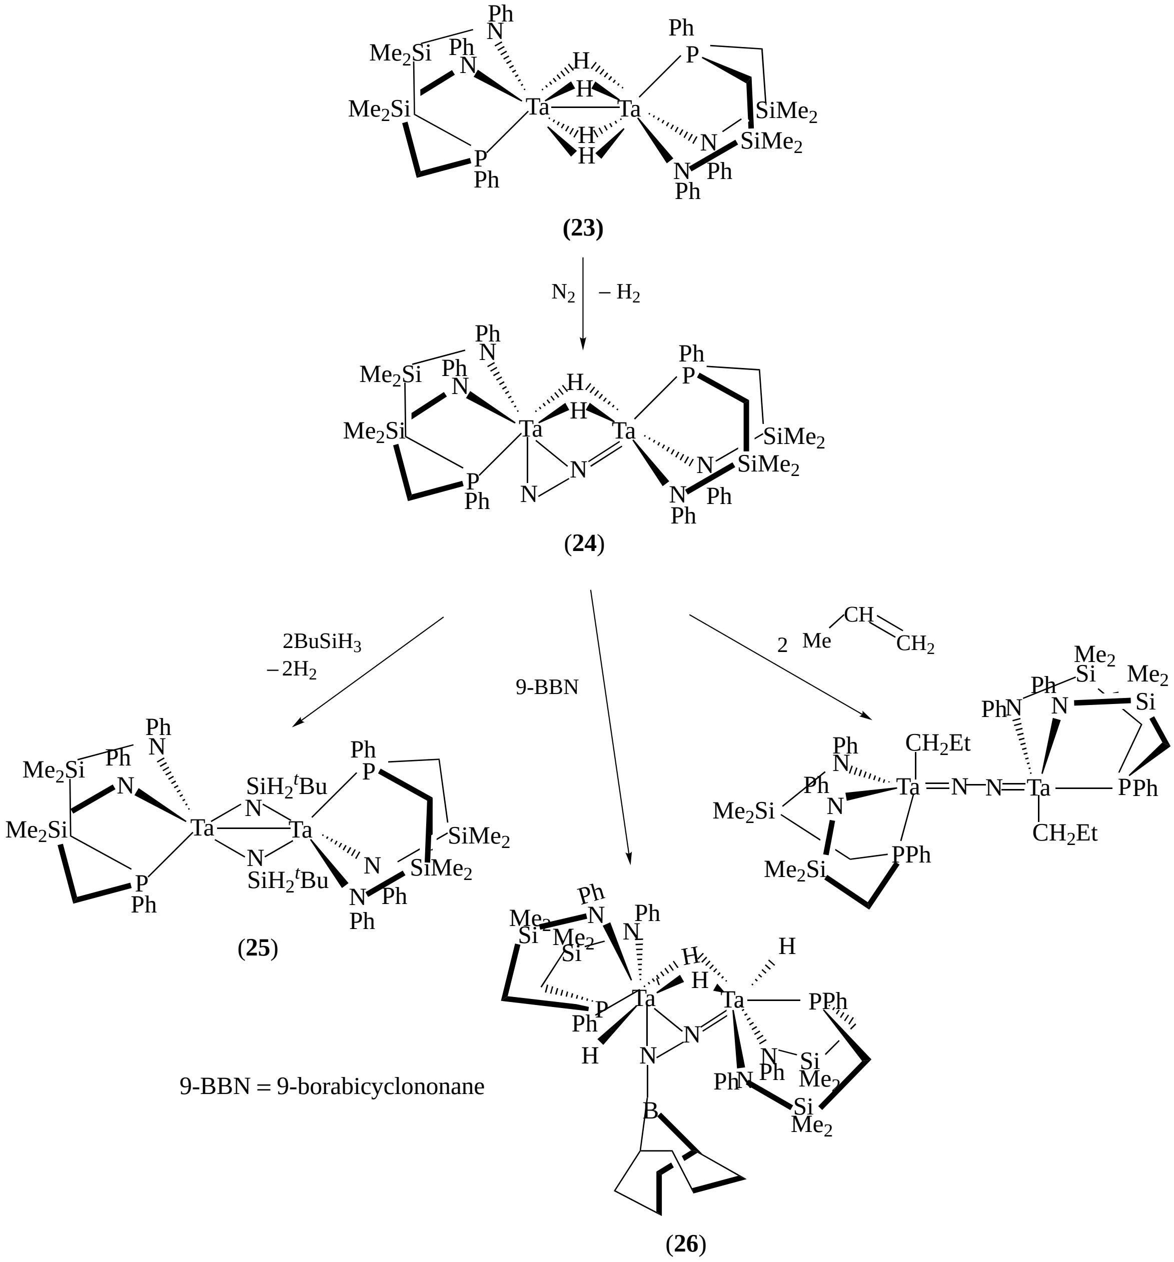


(15)

(**28**)



Scheme 4 Mechanism of the production of bridging dinitrogen in niobium and tantalum dithiocarbamate complexes (R_2dtc, etc. Omitted for clarity)



Scheme 5 Activation and functionalization of dinitrogen by Ta derivatives[47]

Neutral and anionic *Pseudohalide* complexes have been reported. While most of the thiocyanates were considered to be N-coordinated, ^{93}Nb NMR spectra of $Nb(NCS)_6^-$ were reinterpreted in terms of a mixture of N- and S-coordinated isomers.[1,2]

2.5 Phosphorus and Arsenic Donors

Nb^V and Ta^V derivatives are hard acids and their complexes with P- or As-donors are limited. Tertiary phosphines, especially PMe_3, have been widely used to stabilize low-valent derivatives. C–H activation reactions, promoted by the formation of thermodynamically stable Ta–H, Ta–C, and Ta=C bonds have resulted in metallacycles based on unusual anionic phosphorus donors.[22] Nucleophilic Ta^V phosphinidene complexes could be stabilized by a tripodal tetradentate $[NN_3]$ amido ligand.[9,55] The terminal PR ligand reacts smoothly with aldehydes, providing a general synthesis of phosphaalkenes RP=C(H)R′ and act thus as a phospha-Wittig reactant (*see* ***Phosphorus: Organophosphorus Chemistry***).

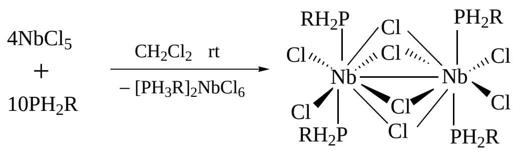
3 OXIDATION STATE +IV

The niobium and tantalum tetrahalides MX_4 are all known, except TaF_4, whose nonexistence is consistent with the fact that $[TaF_5]_4$ should be the least reducible halide of these elements.[1] They are dark solids, obtained by reduction of the pentahalides by H_2 or more often by metals (Al or M) at high temperatures. With the exception of NbF_4, all tetrahalides disproportionate thermally (*see Disproportionation*); this can be overcome by a high pressure of the pentahalides during the preparation. Except NbF_4, they are all essentially diamagnetic (*see Diamagnetism*) as a result of a one-dimensional (1D) polymeric structure based on dinuclear M_2X_8 units with two types of metal bridging (short and long), being responsible for their semiconducting properties (*see* ***Semiconductors***).

3.1 Halogens as Ligands: Tetrahalides and their Adducts

Numerous adducts, mostly of type MX_4L_2 (X = Cl, Br, I), are known with nitrogen, phosphorus, arsenic, oxygen, and sulfur donors. They are synthesized by reaction of solid tetrahalides with the ligand or by reduction of pentahalides with the ligand, mainly bidentate or heterocyclic N-donors or phosphines. $NbCl_4(THF)_2$ (**29**) is of particular value since the lability of the THF molecules makes it a useful *synthon* in Nb^{IV} chemistry.

The MX_4L_2 adducts with monodentate ligands are generally monomeric, and thus paramagnetic (*see Paramagnetism*). In the absence of X ray, electron spin resonance (ESR) (*see Electron Paramagnetic Resonance*) can be used to gain structural information. The ESR spectra of the Nb derivatives, for instance, are characterized by 10 lines as a result of the coupling of the unpaired electron with the metal of spin $I = 9/2$. The hyperfine coupling parameters of the d^1 distorted octahedral MX_4L_2 complexes generally decrease with increasing ligand basicity. Reduction of $NbCl_5$ with primary phosphines (equation 16) gave dinuclear diamagnetic Nb^{IV} adducts (**30**) whose structure is similar to that of the $Nb_2(\mu\text{-Cl})_4Cl_4(PR_3)_4$ derivatives obtained from $NbCl_4$.[1] (**30**) were used as precursors to NbP films by CVD.[56] Octacoordination is also found for monomeric MX_4 bisadducts involving bidentate ligands such as $MCl_4(dmpe)_2$, which have been widely used for access to lower oxidation states.



(16)

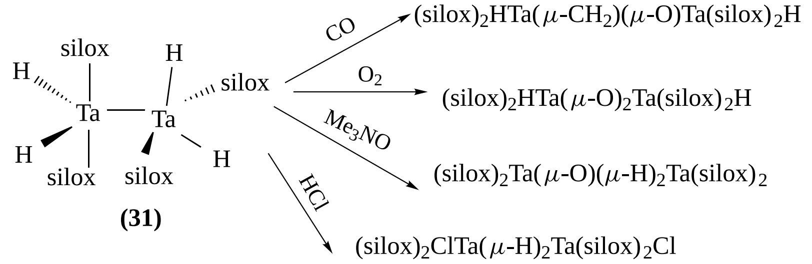
(**30**)

3.2 Solvolysis Products of the Tetrahalides

Compounds that can be considered as *Solvolysis* products from the tetrahalides can result from direct substitution reactions of MX_4 or their complexes but also from the reduction of M^V derivatives or from oxidative addition of M^{III} complexes especially in the case of Ta.[1]

Nb^{IV} alkoxides were first reported to form during the electrochemical synthesis of $Nb(OEt)_5$, starting from the metal or during the electrolytic reduction of $NbCl_5$ in alcohols. Alcoholysis of $Nb(NR_2)_4$ generally leads to $Nb(OR')_5$, but oxidation state IV could be retained with bulky R′ groups such as adamantyl. Structurally characterized diamagnetic dimeric Nb chloroalkoxides and tetrameric oxochloroalkoxides have been obtained from trivalent halide adducts and alcohols.[1,2,9] $[Nb_2(OMe)_9]^-$ results from further substitution. All compounds have a Nb–Nb single bond (2.78–2.89 Å). The first Nb^{IV} enolate has been reported.[57] The reductive coupling of Nb^V salophen derivatives led to dimers linked through C–C and Nb–Nb bonds. Each of those bonds can be used as a reversible source of a pair of electrons for reduction, for instance, of diphenyldiazomethane.[58] These reactions offer a close analogy with those observed for the reduced Nb calix[4]arene species.[45]

The reduction of $MCl_3(silox)_2$ in the presence of H_2 (1 atmosphere) gives siloxohydrides (**31**), shown by MW measurements to be dinuclear (Scheme 6).[23,24] Multinuclear NMR (^{1}H, ^{13}C, ^{29}Si) and IR account for an unusual geometry: M–M bonding without bridging ligands. The Ta species is able to promote CO deoxygenation, and C–H and C–C bond formation, and thus tracks the



Scheme 6 Some reactions of the dinuclear Ta^{IV} hydridosiloxide (**31**)

critical sequence of the *Fischer–Tropsch Process* (*see* ***Carbonylation Processes by Homogeneous Catalysis***). The reduction of Nb 2,6- or 2,4,6-aryloxides under H_2 gave η^4-cyclohexadiene complexes by intermolecular hydrogenation. Hydrogenation occurs exclusively at the ortho-Ph group.[14]

Monomeric, paramagnetic chlorohydrides such as $MH_2Cl_2(PR_3)_4$ derive from facile oxidative addition of H_2 to $MCl_2(PR_3)_4$ complexes. Of these 17e dodecahedral complexes, (**32**) is the most interesting (equation 17). Its thermolysis in solution offers a quadruply bridged hydride (**33**) and it can also be reduced to a monomeric Ta^{III} 16e species (**34**).[1,22] Ta^{IV} hydrides display a hydridic character (*see* ***Hydride Complexes of the Transition Metals***), as shown by the reduction of CO by cyclopentadienyl derivatives.[1] (*see* ***Niobium & Tantalum: Organometallic Chemistry***)

$$\underset{(\mathbf{32})}{TaH_2Cl_2(PMe_3)_4} \xrightarrow{C_6H_{12},\ 80\,^{\circ}C,\ 1\ n} \underset{(\mathbf{33})}{Ta_2Cl_4(PMe_3)_4(\mu\text{-}H)_4}$$

$$\underset{(\mathbf{32})}{TaH_2Cl_2(PMe_3)_4} \xrightarrow[-NaCl]{Na/Hg} \underset{(\mathbf{34})}{Ta_2ClH_2(PMe_3)_4} \qquad (17)$$

Homoleptic and chloro β-diketonates have been reported for both metals. They derive from the reaction of β-diketones (or their alkali derivatives) with either M^{IV} or M^{III} halide complexes. They are generally monomeric and thus paramagnetic; their structures have been proposed on the basis of UV or ESR data and less often X-ray data.

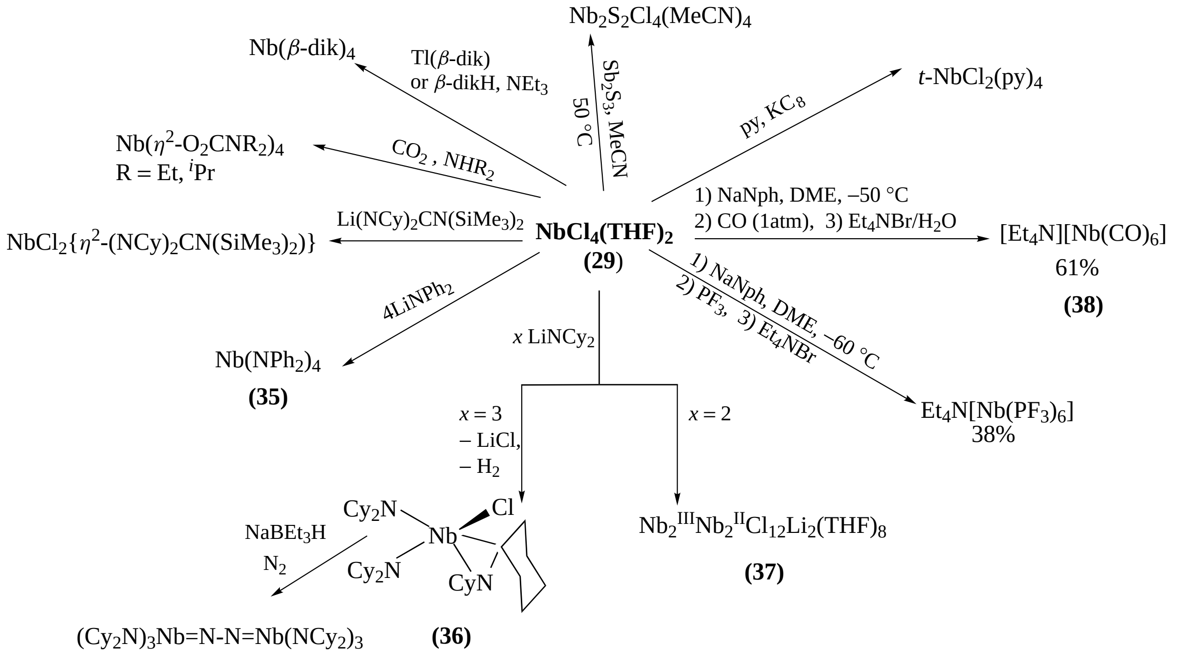
Monomeric, paramagnetic Nb^{IV} dialkylamides $Nb(NR_2)_4$ have been obtained as highly air-sensitive liquids by spontaneous reduction of the pentaamides. The thermal decomposition of $Nb(NEt_2)_4$ in the presence of ammonia gave Nb_3N_4 films.[35] Whereas Nb^{IV} amides (**35**) can also be obtained from $NbCl_4(THF)_2$,[59] those of Ta^{IV} derive mostly from the reduction of $Ta(NR_2)_2Cl_3$ by Na/Hg.[60] Organometallic $Nb(NR_2)_2R'_2$ species as well as compounds based on terdentate diphosphino- and diamidoamido ligands are known for Nb.[5,59] Reaction of (**29**) with three equivalents of Cy_2NLi afforded the first Nb^{IV} aziridine (**36**) by metallation of one of the cyclohexyls. Attempts to reduce (**36**) with $LiBEt_3H$ under N_2 lead to a Nb^V–N_2 end-on complex.[61] Scheme 7 summarizes some examples of the reactivity of $NbCl_4(THF)_2$. An amide based on staggered $TaCl(NCy_2)_2$ moieties first considered as a Ta^{III} species has been reformulated as a Ta^{IV}one, $Ta_2(\mu\text{-}H)_2Cl_2(NCy_2)_4$, because of hydride ligands.[62] The high reactivity of the dinuclear Ta amide supported by the bulky $9H$-carbazole is illustrated by its hydrogenolysis giving a hexahydride,[9,22] whose structure is representative of the $Ta_2^{IV}(\mu\text{-}H)_4$ core observed with the chlorides (**33**). Eight-coordinate arylformamidinates $M[ArNC(H)NAr]_4$ have been reported for both metals.[63] Binuclear Nb^{IV} bis-pyrazolylborate derivatives are known.[54] A paramagnetic Nb_2–N_2 complex was obtained by reduction of a Nb^{III} chloride precursor supported by a bis-(amidophosphine) $[N_2P_2]$ macrocycle.[64]

The unstable $Nb(PCy_2)_4$ derived from a Nb^{III} precursor remains the only homoleptic dialkylphosphide of those elements.[1] Ta^{IV} phosphinidene bridged dimers stabilized by CpR or Cp* ligands are known.[55]

The few data available on thiocyanates indicate N-coordination in the solid.[1] The octacyanometallate $Nb(CN)_8{}^{4-}$ has been used for supramolecular magnetic architectures by self assembly with ML^{2+} complexes ($M = Ni^{II}$, Mn^{II}, $L =$ N-donor macrocycle).[65]

3.3 Sulfur, Selenium, and Tellurium Donors: Chalcogenohalides and their Adducts

The interest in the chalcogenides has been stimulated by a possible use of disulfides as cathodes in lithium batteries. Niobium and tantalum homoleptic ME_4 chalcogenides are only stable as tetratellurides; large halide anions are, however, able to stabilize a variety of chalcogenohalides, especially for Nb, the corresponding Ta chemistry being less developed.[2,65] The synthetic and structural chemistry of chalcogenide-rich derivatives is complex. Many of them are low-dimensional solids and display interesting physical properties (*see* ***Chalcogenides: Solid-state Chemistry***). As for most Nb^{IV} halides, a common feature is the occurrence of chains in which the metal is present as pairs (alternate short and long Nb–Nb distances, about 3.1 and 3.7–3.9 Å, respectively) that causes diamagnetism as well as semiconducting properties. These chains are connected by a wide variety of fragments. IR and Raman studies established the presence of E–E or M–E



Scheme 7 Some reactions of $NbCl_4(THF)_2$

bonds that were confirmed by X-ray studies. Compounds such as NbS_3, for instance, have to be considered formally (they are covalent) as $Nb^{IV}(S–S)_2{}^{2-}S^{2-}$.

Chalcogenohalides have been synthesized by solid-state high-temperature reactions. A series of isomorphous $Nb(E_2)X_2$ (E = S or Se, X = Cl, Br, I) halides have been obtained.[1,2] The molecules may be described as cage-shaped $Nb_2(E_2)_2$ units with μ-η^2:η^2 dichalcogeno ligands between adjacent Nb atoms and an extended $[Nb_2(\mu\text{-}E_2)_2Cl_{8/2}]_\infty$ structure by sharing all chlorine. The vibrations of the S_2 groups of NbS_2Cl_2 occur at 588 cm^{-1} in the IR; they are higher than those of the Nb=S group. Chalcogeno-halides containing selenium are often mixed-valence (*see* ***Mixed Valence Compounds***) $Nb^{IV}Nb^{V}$ derivatives, as established by X-ray and photoelectron spectroscopy (*see* ***Photoelectron Spectroscopy of Transition Metal Systems***).[1] Compounds such as $Nb_3Se_5Cl_7$ or $Nb_6Se_{20}Br_6$, actually $Nb_2{}^{IV}Nb^{V}(Se_2)_2SeCl_7$ and $Nb_4{}^{IV}Nb_2{}^{V}(Se_2)_{10}Br_6$, respectively, illustrate this behavior. $NbSe_2Br_2$ was obtained in conditions that lead to $[Ta(Se_2)_2]_2[TaBr_6]$ for Ta.[5] The structure of the latter is based on 1D positively charged chains of $Ta(Se_2)_2$ (and thus oxidation state of 4.5 for Ta, which leaves 0.5 e for the Ta–Ta bond) separated by $TaBr_6{}^-$ anions.

NbS_2Cl_2 has been used as starting material. It gave access to thiocyanates and to $[Nb_2(\mu,\eta^2\text{-}S_2)_2(H_2O)_8]^{4+}$, the first structurally characterized, in 1997 only, aqua-Nb^{IV} complex. The water molecules are labile and the $Nb_2(\mu,\eta^2\text{-}E_2)_2{}^{4+}$ core (E = S, Se) afforded a new series of Nb^{IV} diamagnetic β-diketonates dithiocarbamates, dithiophosphates, and xanthates.[66] Depopulation of π^* orbitals leaves the $S_2{}^{2-}$ ligands susceptible to nucleophilic attack giving a product assumed to be $[Nb_2(\mu\text{-}S)_2(H_2O)_8]^{4+}$.

The first Nb or Ta tellurium halide, $Nb_2Te_8I_{12}$ was described in 1993. Its structure is characterized by two $[Te_2(\mu\text{-}I)_2I_4]^{2-}$ ligands coordinated to a $Nb_2(\mu\text{-}Te_2)_2{}^{4+}$ center. The discrete $Nb_2Se_4(Te_2I_6)_2$ molecule has a similar structure.[67] New types of structures have been reported for instance for $Nb_4(\mu,\eta^{2-}Te_2)_4Te_4I$: tetranuclear butterfly clusters are assembled via iodide bridges into 1D infinite chains.[3,4]

Chalcogenide halide adducts obtained directly from M^{IV} compounds remain scarce. $Nb_2(\mu\text{-}S)_2X_4(MeCN)_4$ (**39**), result from reaction between NbX_4 (X = Cl, Br) and Sb_2S_3 in MeCN. Attempts to synthesize $NbSeBr_2$ adducts led to reduction of the metal and formation of a mixed valence cluster (**40**) (equation 18). Formally, two Se^{2-} ions form an $(Se_2)^{2-}$ ion with release of 2e, which reduce two Nb^{IV} to Nb^{III} atoms, giving a $Nb_2^{IV}Nb_2^{III}$ aggregate. (**40**) is best described as a central $(MeCN)_2Br_2Nb^{IV}(\mu,\eta^2\text{-}Se_2)(\mu\text{-}Se)Nb^{IV}Br_2(MeCN)_2$ fragment linked by long bromide bridges to two $NbBr_3$ units (Figure 5). The tetravalent metals Nb(1) are connected by Nb–Nb bonding but no interaction is observed between the Nb^{III} centers, Nb(2) and Nb(3).

$$4NbBr_4(MeCN)_2 + Sb_2Se_3 \xrightarrow[-SbBr_3]{\text{MeCN, 50 °C, 7 d}} 2Nb_4Br_{10}(Se_2)(Se)(MeCN)_4 \ (\mathbf{40}) \qquad (18)$$

The reaction of $NbSBr_3$ in neat THT proceeds with disproportionation; two S^{2-} ligands are oxidized to $(S_2)^{2-}$

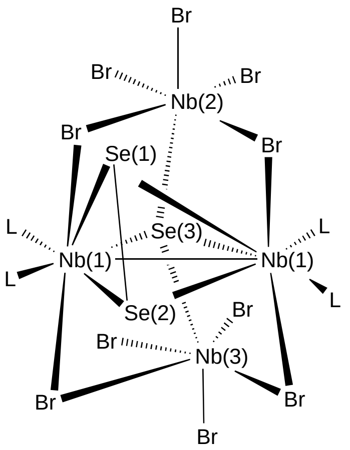


Figure 5 Molecular structure of the mixed-valence cluster (**40**)

giving (**41**) (equation 19). Its most salient feature is the Nb(μ-S)(μ-S_2) ring. While similar reactivity patterns were observed for $NbSX_3$ and other S-donors such as Me_2S, no evidence for reduction was found in the case of Ta.[1]

$$NbSBr_3(THT)_2 \xrightarrow{THT} \underset{(\mathbf{41})}{Nb_2(\mu\text{-}S)(\mu\text{-}S_2)Br_4(THT)_4} + NbBr_5(THT)_2 \quad (19)$$

The $TaCp_2$ or Nb(tBuC_5H_4)$_2$ moieties allowed to stabilize a number of telluride and selenide units such as Te_n^{2-} (n = 1,4), η^2-$TeCH_2$, η^2- Se_2H, and so on, which were used as ligands toward metal carbonyls.[2,68] ^{77}Se and ^{125}Te NMR data were reported.

4 OXIDATION STATE +III

The development of the chemistry of niobium and tantalum in their lower oxidation states, three or less, has long been precluded by the lack of convenient starting materials. Indeed, stoichiometric trihalides MX_3 (X = Cl, Br) are only incidental compositions. They are obtained by reduction of the pentahalides or disproportionation of the tetrahalides, and are polymeric and rather inert.

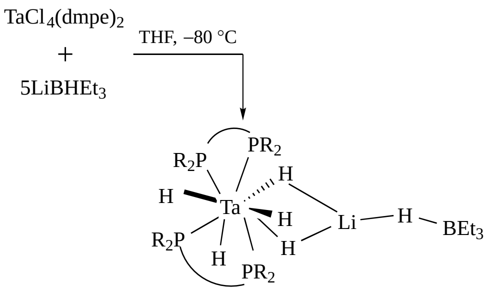
4.1 Halogen as Ligands

4.1.1 Anionic and Neutral Complexes: Synthesis and Characterization

A new area in niobium and tantalum chemistry was opened with the discovery that the reduction of MX_5, MX_4, or their complexes to yield molecular trihalides can be achieved easily by reductants such as sodium amalgam in the presence of ligands when carried out in strictly anaerobic conditions. The first trivalent complexes, $Nb_2X_6(THT)_3$ (X = Cl, Br, I), based on tetrahydrothiophene, were obtained in high yield (equation 20) in 1973.

$$2NbX_4(THT)_2 + 2Na/Hg \xrightarrow[rt]{C_6H_6} Nb_2X_6(THT)_3 + 2NaX + THT$$
$$X = Cl, Br, I \quad (20)$$

Similar reductive routes allowed to obtain a large variety of soluble Nb and Ta complexes, mostly chlorides, involving monodentate sulfur, nitrogen, or phosphorus donors. The complexes formed can be highly dependent on the experimental conditions, especially the nature of the starting material, of the solvent, or of the reductant. Borohydrides that act as dual reagents can give access to metallic species incorporating various boron ligands.[63,69] The Ta^V Lewis acid–base adduct (**42**) (equation 21) with a Li···H–Ta interaction[24] and the *nido*-metalloborane $Ta_2(\mu, \eta^4\text{-}B_2H_6)[ArNC(H)NAr]_4$ formed by reacting $TaCl_5$ with $LiBH_4$ and N,N'-diarylformamidinato lithium are examples of complex reactivity patterns. THF ring opening also can generate unanticipated products such as the Ta^{III} [(η^5-Cp)$_2$Ta(μ-H)$_2$AlH]$_2$(μ-O-n-Bu)$_2$ adduct, where the butoxides bridge the Al centers.[24]



(21)

(**42**)

Although stable, monomeric, paramagnetic MX_3L_3 adducts could be isolated and characterized (ESR, X ray), the formation of diamagnetic compounds involving M–M bonding is more frequent affording di- or tetranuclear neutral adducts[70] or anionic trinuclear clusters. Indeed, while the TaX_n–PR_3 (R = Et, Me) system offers mono- or dinuclear derivatives, the niobium system appears more prone to formation of discrete di or trinuclear anions, the counterion being derived either from the reductant (as $[Mg_2(\mu\text{-}Cl)_3(THF)_6]^+$) or from the ligand (as the phosphonium cation HPR_3^+). The metal is generally heptacoordinate, counting the M–M bond. Dinuclear adducts are the most common with monodentate as well as with bidentate LL donors, their formulation being $M_2X_6L_n$ (n = 3 or 4) and $M_2X_6(LL)_2$, respectively. Their structure is based on confacial or edge-sharing bioctahedra (Figure 6), as also found for the anionic complex $M_2X_9^{3-}$. The short

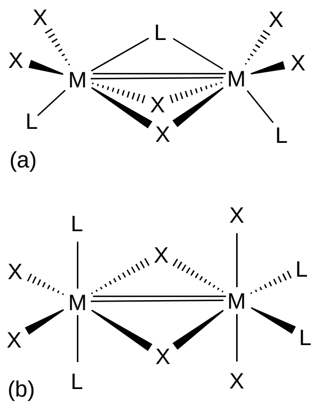


Figure 6 Frameworks of the dinuclear M^{III} halide adducts: (a) $M_2X_4(\mu\text{-}X)_2(\mu\text{-}L)L_2$ (L = Me_2S, THT); (X = Cl, Br, I); (b) structure of $Ta_2Cl_4(\mu\text{-}Cl)_2(PR_3)_4$

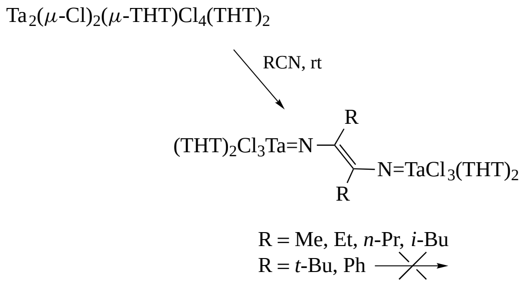
M–M distances (2.7 Å) were considered to reflect the strong metal–metal bonding of a formal double bond. Longer M–M distances (≈2.97 Å) are found in the trinuclear monocapped clusters $[M_3(\mu_3\text{-}Cl)(\mu\text{-}Cl)_3Cl_6L_3]^-$, which have a structural unit related to that of the Nb_3X_8 (X = Cl, Br, I) halides.[1] The solubility (in nonpolar media) and diamagnetism of the dinuclear $M_2X_6L_n$ adducts allowed their characterization in solution by NMR (^{1}H, ^{31}P). By contrast, the complexes formed with bidentate ligands are often of poor solubility. The trivalent adducts display a wide range of colors, but information on their electronic absorption spectra remains scarce.

4.1.2 *Reactivity of the Halide Complexes*

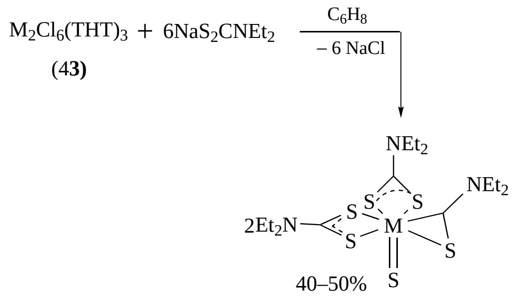
The $M_2Cl_6L_n$ complexes with monodentate S or P ligands were first used as starting materials. The lability of the M–S bond allowed to expand the range of M^{III} adducts, especially with bidentate donors, by ligand exchange reactions. The formation of mixed ligand adducts in which the bridging S-donor is retained suggests that the terminal ligands are more labile than the bridging ones.[1,70] Exploration of the reactivity of adducts based on O- or N-donors such as $NbCl_3$(dme) or $Nb_2Cl_6(tmeda)_2$ is more recent.

Oxidative addition represents the main trend in the reactivity of the d^2 complexes, either as monomers or dimers, and these compounds are thus good precursors of M^V and dinuclear M^{IV} derivatives. Oxidative reactions can occur in the course of ligand exchange reactions, such as with hydrazines[2] or nitriles, as well as during chlorine substitution. They are assisted by the tendency to form strong M=E multiple bonds (E = O, S, or N) and can lead to novel ligands either by C–E cleavage or by C–C coupling, the latter being favored by unsaturated ligands (isonitriles, nitriles, alkynes, etc.). This results in a rich inorganic and organometallic chemistry with applications in organic synthesis.[22]

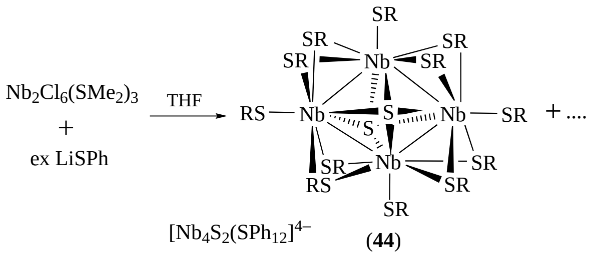
The reaction between $Ta_2Cl_6(THT)_3$ and acetonitrile illustrates these features. It proceeds quantitatively with formation of a new bridging ligand 1,2-dimethyl-1,2-diimidoethylene, which formally derives from the coupling of two MeCN molecules (equation 22). The M–N bond distances imply an imide character.[1] The reaction between (**43**) and Na diethyldithiocarbamate provides another example of unusual reactivity with formation of a sulfide S^{2-} and a thiocarbamyl $SCNEt_2^-$ ligand as a result of the oxidative addition of one C–S bond to the M^{III} metal (equation 23).[1] By contrast, similar reactions applied to $NbCl_3$(dme)(RC≡CR′) afforded Nb(dtcR$''_2$)$_3$(RC≡CR′).[31] C–S cleavage is also observed for the synthesis of thiolates from $Nb_2Cl_6(SMe_2)_3$ (equation 24). The square $Nb_4(\mu_4\text{-}S)_2$ core of (**44**) is also found in Nb^{III} thiolate phosphine complexes obtained from $NbCl_5$.[29] Similar reactions applied to $TaCl_5$ lead to $Ta_2S_2Cl_4(PR_3)_4$. Numerous investigations with the formamidinate $[ArNC(H)NAr]^-$ ligand have illustrated its versatility resulting in C–N cleavage with formation of arylimido NAr^{2-} or formimidoyl $HCNAr^{3-}$ ligands, and coupling reactions.[71] All these reactivity patterns show the difficulty of an unequivocal formulation of the compounds in the absence of an X-ray structure.



(22)



(23)



(24)

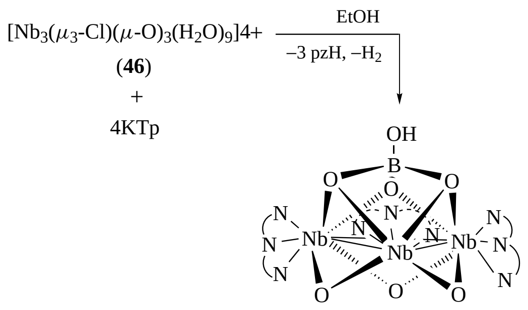
The easy access, on a large scale, to $NbCl_3$(dme), by reduction of $NbCl_5$ by tributyltin hydride, has prompted its use as a reactant in organic chemistry; it offers a convenient

route to 2-amino alcohols via the coupling of imines with aldehydes or ketones.[22] Other low-valent derivatives promote the stereoselective functionalization of C≡C bonds.

M^{III} halide complexes based on mononuclear, dinuclear, tetranuclear, and hexanuclear frameworks polymerize and cyclize alkynes via different activation modes. The reactivity of the THT adducts (**43**) with alkynes RC≡CR′ depends on R and R′.[1] A common feature is the formation of strong M–C bonds and thus of a metallacycle exhibiting properties of a metallacyclopropene. A manifestation of the reactivity of the coordinated alkyne as a dianionic ligand is its reductive coupling with ketones or aldehydes. Such reactions may be applicable for C–C bond formation in the synthesis of new carbonyl compounds. The $Ta(OAr)_3$ fragment provides a template for alkyne cyclotrimerization via metallacyclopentadiene and arene derivatives (*see Arene Complexes*); such reactions can provide some insight into the mechanism of the C–C coupling of alkynes (*see* ***Niobium & Tantalum: Organometallic Chemistry***).

The dinuclear M=M chloride adducts with monodentate phosphines react cleanly with H_2, Cl_2, or HCl, giving dinuclear diamagnetic M^{IV}derivatives. The oxidative addition of H_2 to $Ta_2(\mu\text{-}Cl)_2Cl_4(PMe_3)_4$, for instance, occurs under mild conditions, giving an air-stable dinuclear Ta^{IV} hydride $Ta_2(\mu\text{-}Cl)_2(\mu\text{-}H)_2Cl_4(PMe_3)_4$. This reactivity is associated with the presence of a M=M bond and is not a general property of Nb^{III} or Ta^{III} derivatives. The monomeric hydride (**34**), resulting from reduction of (**32**) (equation 17) and characterized by neutron diffraction (*see* ***Diffraction Methods in Inorganic Chemistry***), is a useful synthon in Ta^{III} and Ta^{I} chemistry.[1]

Substitution reactions generally proceed with retention of the M–M bond (*see* ***Polynuclear Organometallic Cluster Complexes***). Trivalent compounds derived from such reactions are represented mainly by chloroalkoxides, chlorocarboxylates, carbamates, and formamidinates. A chiral, ionic Ta^{III} compound $[K(THF)_6][Ta(pyt)_4]$ (pyt = Pyridine-2-thiol) has been isolated starting from $TaCl_5$.[63] The reaction between $M_2Cl_6L_3$ (L = THT or Me_2S) and alkali carboxylates provides either dinuclear derivatives resulting from substitution or, in the case of niobium, bi-oxo-capped trinuclear clusters such as $[Nb_3(\mu_3\text{-}O)_2(O_2CR)_6(THF)_3]^+$. The reaction between $Nb_2Cl_6(THT)_3$ and inorganic aqueous acids (with exclusion of O_2) has extended this class of compounds, well known in the chemistry of molybdenum and tungsten. In all compounds with a $Nb_3(\mu_3\text{-}O)_2$ framework known presently, the number of core electrons available for Nb–Nb bonding is four, giving a bond order of 2/3 (Nb–Nb 2.84 Å av) (*see* ***Metal-mediated Protein Modification***). Among these complexes, the red–brown sulfato compound, which can be obtained by reduction of Nb^V in aqueous sulfuric acid, has a history that goes back to early attempts to separate and characterize niobium and tantalum; it was reported as early as 1912 but its formulation, $[Nb_3(\mu_3\text{-}O)_2(\mu,\eta^2\text{-}SO_4)_6(H_2O)_3]^{5-}$ (**45**), was only established by X-ray studies.[9] Electrochemical data on (**45**) and on the oxomethanesulfonate analog are available.[72] The air-sensitive trinuclear cluster (**46**) derived from $NbCl_3$(dme) and aqueous HCl gives, by reacting with KTp, a μ_3-hydroxotrioxoborate-capped mixed-valence $Nb^VNb_2^{IV}$ cluster (**47**) (equation 25). The borate cap is lost by oxidation, thus affording the $[Nb(=O)(\mu\text{-}O)Tp]_4$ species.[10]

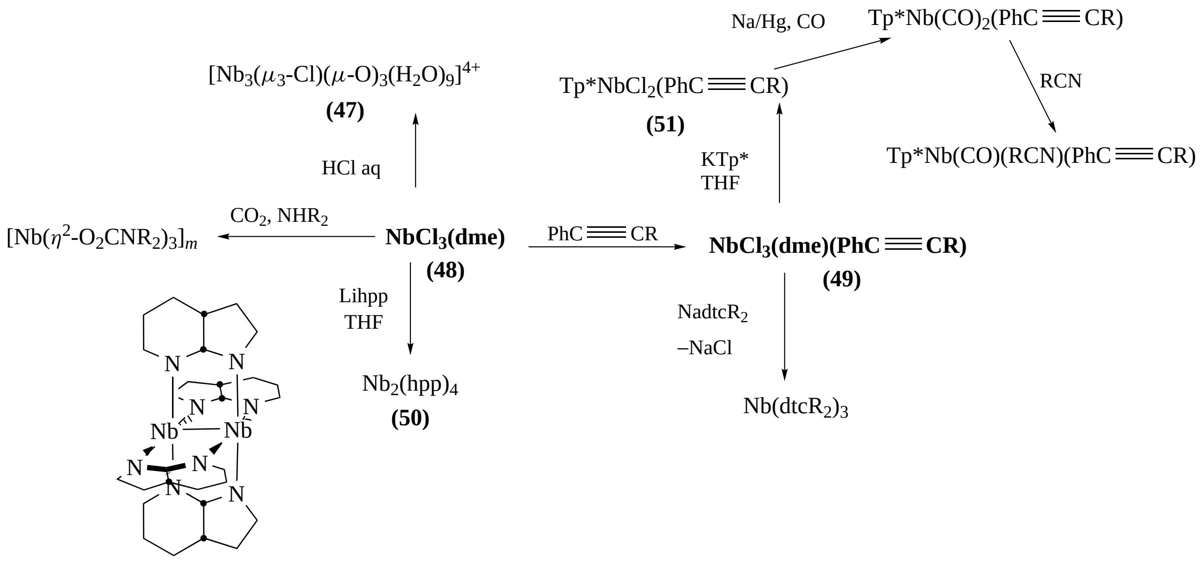


(Tp)$_3$Nb$_3${μ_3-BO$_3$(OH)}(μ-O)$_3$ (**47**) (25)

$NbCl_3$(dme) (**48**) is an useful starting material (Scheme 8). The reaction between KTp (or Tp*) and $NbCl_3$(dme)(PhC≡CR) (**49**) afforded an entry into Nb^{III} trispyrazolylborate chemistry.[51] As for other M^{III} alkyne species, metallocyclopropene tautomeric forms with a d°, Nb^V configuration should be taken into account. An α-agostic interaction is preferred over the more common β-one due to the bulky Tp* ligand in their alkyl derivatives. Alkyne coupling products have been obtained. Some of those derivatives polymerize ethylene at rt in the presence of $B(C_6F_5)_3$. $NbCl_3$(dme) and $NbCl_3$(dme)(PhC≡CR) were also used to form complexes of α-keto stabilized phosphorus ylides.[73] Ta-alkyne analogs $TaCl_3$(RC≡CR′)(LL) LL = dme, bipy, tmeda, $(py)_2$ have only become available recently.[74]

4.2 Reactivity of d^2 Derivatives Supported by Ligands other than Halogens

The monomeric M^{III} centers supported by bulky O-donors such as siloxide or aryloxide are extremely effective in reduction, cleaving numerous C–E bonds (E = O, S, halides, etc.), and exhibit unusual coordination behavior. A manifestation of the electrophilic behavior of $Ta(silox)_3$ (**51**) is its cleavage of CO (equation 26), giving an oxo derivative and a dinuclear carbide (**53**). The reducing power of (**52**) is also illustrated in the unusual coordination found for both pyridine and benzene. In coordination to these aromatics in a η^2 fashion (η^2-N,C for pyridine as shown in Figure 7), the metal can achieve its highest formal oxidation state. X-ray as well as NMR data indicate an interruption of the heterocycle π-system.[22,23] The nucleophilic attack on a similar η^2-N,C coordinated pyridine supported by a Ta aryloxide fragment led to a regioselective C–N bond cleavage, providing models for hydrodenitrogenation (HDN).[22] Oxygen vs sulfur ligation for the ancillary ligands has been discussed.[75] $Nb(silox)_3(PMe_3)$ (**54**), a masked Nb^{III} species, promoted ring



Scheme 8 Reactivity of Nb^{III} dme halide adducts

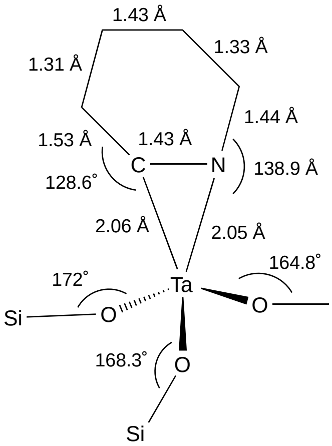


Figure 7 The unusual η^2-N,C coordination mode for pyridine in $Ta(silox)_3$(pyridine)

opening of 3,5-lutidine with participation (cyclometallation) of a silox ligand, a rare example for this typically ancillary ligand.[76] Although desoxygenation of small molecules such as CO or NO (**52**) is very fast, (**54**) was more effective for desoxygenation of OPR_3 (R = Me, Ph) giving $MO(silox)_3$.[23]

$$\underset{(\mathbf{52})}{Ta(silox)_3} + CO \xrightarrow[1\ atm]{C_6H_6,\ rt} (silox)_3Ta{=}O + \underset{(\mathbf{53})}{(silox)_3Ta{=}C{-}C{=}Ta(silox)_3} \qquad (26)$$

As already mentioned, stepwise cleavage of the N≡N bond was assisted by the very reactive Nb=Nb unit (2.659 Å) of a Nb^{III}-calix[4]arene.[45] A 4e reduction gives a Nb^{IV} complex with a bridging hydrazido N_2^{4-} anion [Nb≡N 1.747 Å, N–N 1.390 Å], further 2e reduction using Na lead to a nitride.

5 CLUSTERS WITH NONINTEGRAL OXIDATION STATES

The chemistry of reduced Nb and Ta halides is rich in clusters with various structures. The metal atoms assemble with metal–metal distances close to those in the metal into triangular and tetranuclear clusters but the dominant structural motif is that of the octahedral M_6X_{12} and Nb_6I_8 types.[1,2] Binary, ternary, and quaternary compounds all crystallize in that type. The M_6 clusters are characteristic of the chemistry of the lower oxidation states of Nb and Ta, although not restricted to them. These electron-deficient clusters are based on metal ions with average oxidation numbers between III and I.

The trinuclear clusters derive formally from the M_3X_8 halides, which remain unknown for tantalum.[1] Coordination compounds whose structure is related to that of these halides are represented by tetranuclear clusters such as the $Nb_4Cl_{10}(PMe_3)_6$ complex, the $CsNb_4Cl_{11}$ subhalide,[1] or the mixed–valence $Nb_2^{II}Nb_2^{III}Cl_{12}Li_2(THF)_8$ (**37**) cluster.[77] Their structure consists of Nb_3 units fused into a centrosymmetric rhombus with the capping μ_3-ligands on opposite sides and a planar Nb_4 arrangement (Figure 8).[1] Trimetallic halide cations stabilized by hexamethylbenzene have been obtained by Friedel–Crafts reductive synthesis.[1] Similar frameworks have been observed for oxo Cp*Nb derivatives obtained by reductive aggregation, although their metal oxidation state is higher (Nb_3^{13+} core).

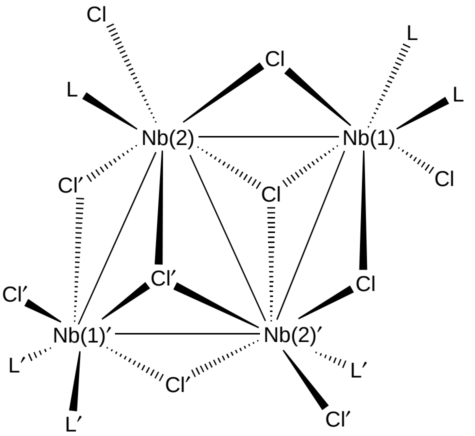

Figure 8 Assembly of trinuclear monocapped units into tetranuclear frameworks: the structure of $Nb_4Cl_{10}(PMe_3)_4$

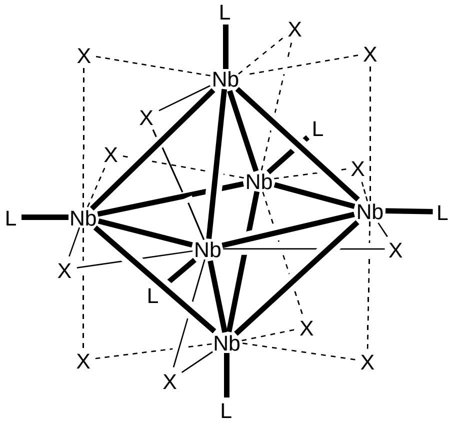
The lowest halides obtained under strongly reducing conditions, often in aqueous media, or by thermal disproportionation of the higher halides, correspond mostly to the compositions M_6X_{15} (M = Nb, X = F; M = Ta, X = Cl, Br, I), M_6X_{14} (M = Nb, X = Cl, Br; M = Ta, X = Br, I), and Nb_6I_{11}. These high-electron density metal complexes are either insulators or semiconductors[78] and have attracted attention recently for their potential as X-ray contrasting agents.[79] They are actually built up of two types of octahedral clusters; $[M_6X_{12}]^{q+}$ ($q = 2-4$) units can be described as M_6 clusters whose edges are capped by 12 'inner' (bridging) ligands X^i and, in addition, six 'outer' or 'centrifugal' ligands X^a occupy the pseudo quaternary axes of the M_6 core (Figure 9a), thus leading to the general formula $[M_6X^i_{12}]X^a_6$. The $[M_6X_8]^{q+}$ ($q = 2, 3$) cluster is built up of an M_6 core whose faces are capped by eight inner (μ_3-) ligands and six outer ligands (Figure 9b). Since these compounds can be obtained in aqueous media, their discovery is old, but their correct formulation had to await modern structural X-ray methods. $[Ta_6Cl_{14}]\cdot8H_2O$, the first subhalide hydrate, was prepared as early as 1907, but it was formulated as $TaCl_2\cdot2H_2O$.

The fast and quantitative *Disproportionation* of Nb or Ta with their pentahalides in the presence of an alkali halide has long been used. This synthesis is assisted by the stabilization of the cluster through complexation with the $[M_6X_{18}]^{4-}$ anion. The relative stabilities of the other possible clusters depend on the alkali metal.[1] Replacement of the group V metals as reductant by gallium or Ga_2Cl_4 (actually Ga^+ $GaCl_4^-$) has afforded a convenient, cheap, lower temperature route to the $[M_6X_{12}]^{2+}$X = Cl, Br core.[79]

$[Nb_6X_{12}]^{q+}$ and $[Ta_6X_{12}]^{q+}$ clusters are redox-promiscuous possessing five ($q = 1-5$) and four ($q = 1-4$) accessible oxidation states respectively. Disproportionation reactions therefore complicate ligand-substitution chemistry. The hydrates, being more soluble than the anhydrous lower halides, are useful starting materials. The high lability of the 'centrifugal' ligands allows access to mixed halides, hydrates,



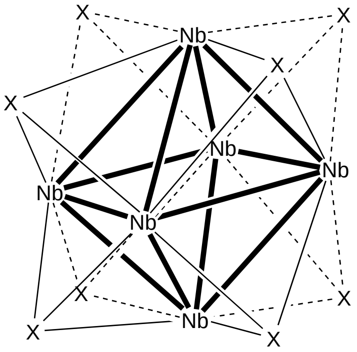


Figure 9 Octahedral clusters: (a) the $[M_6X_{12}]^{q+}$ core with additional centrifugal ligands L; (b) the $[M_6X_8]^{q+}$core

and oxygen; nitrogen or phosphorus donors complexes of the form $[(M_6X^i_{12})X^a_{6-x}L_x]^{(q-x)+}$ with X^i = Cl, Br, X^a = halide, CN, OSO_2CF_3, OH, BF_4, OMe, and L = H_2O, DMSO, DMF, $OPPh_3$, $OAsPh_3$, NH_3, MeCN, pyridine, PR_3. The stability of $[M_6X_{12}]^{q+}$ compounds toward hydrolysis decreases in the order Ta > Nb, Cl > Br, and with increasing oxidation states. Moisture- and oxygen-sensitive alkoxides of M_6 units have been obtained by substitution reactions; their hydrolysis offers a clean route to cluster hydroxides.[78]

The preparation of pure $[M_6X_{12}]^{2+}$ complexes from aqueous solutions is not easy, as oxidation to $[M_6X_{12}]^{3+}$ occurs with air. Oxidation is slow in neutral solution, but fast in acidic or basic media. The presence of $[M_6X_{12}]^{3+}$ may be detected by a band in the UV–vis spectra near 8000 cm^{-1}. Addition of reductants ($SnCl_2$ or Cd) to oxidized solutions allows a return of the green color of the $[M_6X_{12}]^{2+}$ clusters. In the solid state, $Ta_6Cl_{14}\cdot8H_2O$ undergoes reversible oxidation by *Topotactic* electron–proton transfer. While oxidation under mild conditions (iodine) leads to the paramagnetic yellow $[M_6X_{12}]^{3+}$ clusters, two or more moles of strong oxidants (H_2O_2, Ce^{IV}) led to the red–brown diamagnetic $[M_6X_{12}]^{4+}$

(X = Cl, Br) derivatives. Oxidation is faster for the chloride than for the bromide clusters. No redox chemistry has yet been reported for the fluoride or iodide clusters. Spontaneous reduction is observed for all $[M_6X_{12}]^{4+}$ clusters, except $[Ta_6Br_{12}]^{4+}$, upon redissolution. Examples of reduction by ligands appear limited to that of $Nb_6Cl_{15}\cdot 7H_2O$ by phosphines to give $(Nb_6Cl_{12})Cl_2(PR_3)_4$. Its cyclic voltammetry in nonaqueous media revealed three monoelectronic reductions (*see* ***Electrochemistry: Applications in Inorganic Chemistry***). The stabilizing effect of PR_3 leads to a redox chemistry that is more extensive than that in aqueous media. Indeed the monoanions $[(M_6Cl_{12})Cl_2(PR_3)_4]^-$ (**55**), formally derived from the previously unknown $[M_6X_{12}]^+$ core, are detected; attempts to synthesize them have failed so far. The average oxidation state of the metal in (**55**) remains higher than for $[Nb_6I_8]^{2+}$. The $[M_6X_{12}]^{q+}$ clusters displaying several oxidation states with small differences in redox potentials are attractive candidates for multielectron transfer reactions. In addition, the delocalization of the redox orbitals over the clusters might reduce their sensitivity to decomposition. Irradiation (*see* ***Photochemistry of Transition Metal Complexes***) of $[Ta_6Br_{12}]^{2+}$ in oxygen-free HCl solution led to $[Ta_6Br_{12}]^{3+}$ and H_2. An application of these clusters is their intercalation and subsequent oxidation to metal oxide aggregates in pillared clays such as montmorillonite[1] (*see* ***Intercalation Chemistry***).

$[M_6X_{12}]^{q+}$ clusters have been studied by X-ray diffraction, far-IR, UV–vis, XPS, and NQR.[1] The influence of the oxidation state on their structures can be evaluated from comparison of the X-ray data. The regular octahedral symmetry usually considered for the isolated clusters is an oversimplified view and five structural types can be distinguished. A contraction of the M–M bonds is observed upon increase of the number of valence electrons on the metal available for M–M bonding (valence electron count or VEC).[78] The Nb–Nb intracluster distances increase from 2.91, to 2.97, and 3.02 Å when the VEC decreases. The M–M stretching vibration in the IR has been located around 140 cm^{-1} or in the 60–110 cm^{-1} range. *DFT* calculations provide a better description of the relationships between the structural arrangement and the number of valence electron count (VEC) than extended hückel molecular orbital (EHMO) calculations. The observation that both the $[M_6X_{12}]^{2+}$ (16e) and $[M_6X_{12}]^{4+}$ (14e) clusters are diamagnetic and the values of the magnetic moments (*see* ***Magnetism of Transition Metal Ions***) found for the $[M_6X_{12}]^{3+}$ clusters show that the 15th and 16th electrons occupy a nondegenerate molecular orbital. A compilation of visible spectra on the solid state or in solution is available.[1]

A growing chemistry of niobium oxide clusters continues to emerge.[78] The reduced niobates and the NbO suboxide are also built up from condensation of M_6 units through shared vertices, namely, Nb_6O_{12}. Although the inner halides within the $[M_6X_{12}]^{q+}$ core are relatively inert to substitution, Nb_6 and Ta_6 oxohalides, such as $[Nb_6Cl_{12-m}O_m]^{n+}$ ($m = 1-4$) and even Nb_6 oxohydroxohalides, could be obtained by excision reactions.[80] Oxyhalide $A_xLnM_6X_{18-x}O_x$ compounds containing paramagnetic as well as nonparamagnetic lanthanide cations could also be prepared.

The $Rb_3[Nb_6SBr_{17}]$ salt is the first example of an isolated trigonal-primatic Nb_6 cluster. The Nb_6 units (distortion of structure of Figure 9(a)) enclosing an interstitial sulfide are linked through two terminal bromine.[78]

Nb_6I_{11} (**56**) and Nb_6I_9S are the lowest subhalides reported so far for niobium and tantalum. The structure of Nb_6I_{11} is atypical, since it is based on a $[Nb_6I_8]^{3+}$ unit and can be written as $[Nb_6I_8]I_{6/2}$. The $[Nb_6I_8]^{3+}$ moiety is paramagnetic and above 300 °C (**56**) absorbs H_2, giving diamagnetic $Nb_6I_{11}H$, where the hydrogen occupies the center of the Nb_6 cluster, as shown by neutron diffraction. A discrete complex possessing the $[Nb_6I_8]^0$ core, $Nb_6I_8(NH_2Me)_6$, was obtained by reacting (**56**) with the amine in ethanol.[1,78] Unlike Nb_6I_{11} and related compounds, it does not form an extended lattice. It represents the lowest oxidation state yet observed in a Nb_6 cluster.

6 MOLECULAR COMPOUNDS IN OXIDATION STATES II AND LOWER

The number of niobium and tantalum coordination compounds in oxidation states lower than II is limited, and they often are organometallic derivatives involving carbonyl, cyclopentadienyl, or alkenic ligands.

The first member of the series where the metal has a d^3 configuration, $TaCl_2(dmpe)_2$, was reported in 1977. Mononuclear paramagnetic halide adducts such as $MX_2(PMe_3)_4$ and $MCl_2(dmpe)_2$ have been isolated by reduction of monomeric M^Vor M^{IV} phosphine complexes. $TaCl_2(PMe_3)_4$ opens up access to Ta^{IV} and Ta^{III} chlorohydrides.[1] The niobium aryloxide (**57**), whose structure is related to that of $TaCl_2(dmpe)_2$, gives, by oxidation by the parent phenol, an ionic mixed-valence species (**58**) (equation 27). Monomeric t-$NbCl_2(py)_4$ is easily accessible by reduction of (**29**) (Scheme 7).[63] Reduction of $TaCl_5$ in similar condition gave a Ta^{III} species.

$$\underset{(\mathbf{57})}{2Nb(OAr)_2(dmpe)_2} + 2ArOH \xrightarrow[-H_2,\,-dmpe]{} \underset{(\mathbf{58})}{[Nb(OAr)_2(dmpe)_2][Nb(OAr)_6]} \quad (27)$$

$$Ar = 3,5\text{-}Me_2C_6H_3$$

Species with M≡M triple bonds are recent. Although dinuclear M^{II} species such as $Cp_2Nb_2L_4(\mu\text{-}Cl)_2$ (L = CO, RC≡CR′) were known, their Nb–Nb distance is that of a single bond. The synthesis of $TaCl_2(PMe_3)_4$ requires excess of PMe_3 in order to preclude the formation of the M=M bonded dimers $Ta_2Cl_6(PMe_3)_4$ that cannot be reduced by

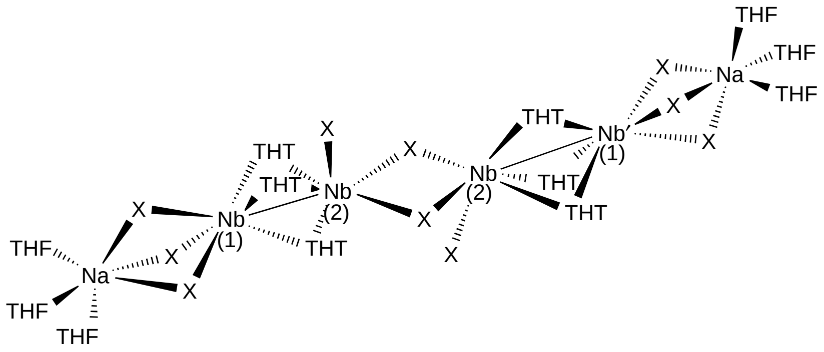

Figure 10 Structure of (**61**) with alternate M–M distances (2.6 Å) for the outer two pairs and more than 3.9 Å for the inner pair (Nb^2,Nb'^2)

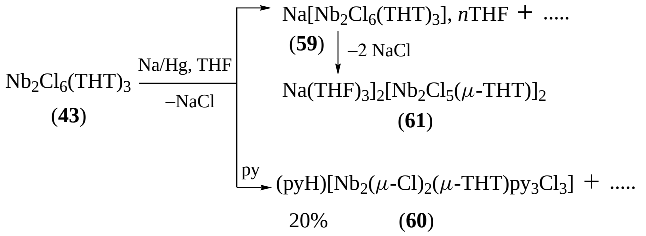
Na/Hg. By contrast, reduction of the M^{III} dimers based on THT (**43**) could be achieved by Na/Hg (equation 28). The metal–metal bond is retained with formation of ionic, diamagnetic, dimers $[M_2X_6(\mu\text{-THT})_3]^{2-}$ (**59**), $[Nb_2(\mu\text{-Cl})_2(\mu\text{-THT})Cl_3(py)_3]^-$ (**60**) or tetramers $[Nb_4X_{10}(\mu\text{-THT})_6]^{4-}$ (**61**; X = Cl, Br).[69] Their common structural unit is a confacial bioctahedral dimer analogous to that depicted in Figure 6(a). MO calculations have confirmed the presence of a M≡M triple bond for the short M–M distance of (**59**) (≈2.61 Å). (**59**) were the first dimers with Nb or Ta M≡M bonds. Unlike most M^{II} complexes, which are very reactive, they are unreactive to most donor ligands, and can even be recrystallized unchanged from degassed water. However, the unstability of their sodium salts in THF lead to an insoluble derivative, identified by X ray as a centrosymmetric tetramer (**61**) (Figure 10). It results from the junction of two dinuclear units (**59**) with extrusion of NaX. The X-ray data of (**61**) as well as MO calculations support a M≡M···M≡M bonding sequence.



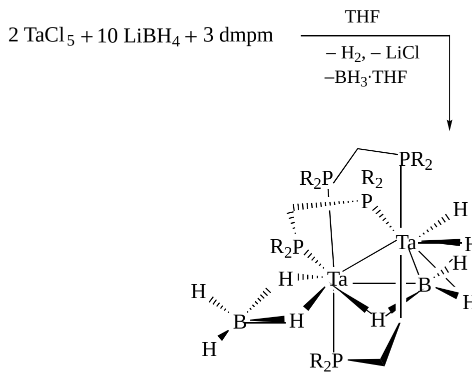
(28)

Triply bonded dimers where Nb has a $\sigma^2\pi^4$ configuration could also be stabilized with anionic ligands having N–C–N moieties such as 7-azaindolyl or hpp (1,3,4,6,7,8-hexahydropyrimido[1,2-a]pyrimidinate). The tetragonal lantern $Nb_2(hpp)_4$ compound (**50**) with a Nb–Nb distance of 2.035(9) Å represents the shortest triple bond reported so far for niobium.[81] This distance is much shorter than that found in the metal (2.85 Å). Attempts to reduce (**50**) with $NaBEt_3H$ afforded an adduct with a B–H···Na interaction. The diamagnetic $Nb_2Cl_5Li(tmeda)_3$ (**62**) cluster obtained by reacting $Nb_2Cl_6(tmeda)_2$ with Li diisopropylamide provides another example of a Nb≡Nb triple bond. Its formation was attributed to disproportionation of a Nb^{III} intermediate since Nb^{IV} species were isolated with other Li amides. The reaction of (**62**) with alkali 7-azaindolyl affords dia- or paramagnetic Nb^{II} dimers depending on the alkali metal.[82] Coordination of LiCl for the azaindolyl Nb^{II} species or of Na with the 'pseudo-allylic' units of hpp for (**50**) occurs at the expenses of the Nb≡Nb bond.

Other examples of M^{II} species are dialkylcarbamates $M(\eta^6\text{-}C_6Me_6)(O_2CNiPr_2)_2$[36] and the $Nb(TCNE)_x$ molecular magnets[83] grown as films by CVD (XPS accounts for Nb^{2+} species).

Compounds in oxidation state +1 generally derive from reduction (often reductive *Carbonylation*) of M^{II} complexes such as the seven-coordinate $M(CO)_3X(PMe_3)_3$ (X = Cl, Br) complexes or of M^{III} ones such as $Tp^*M(CO)_2(PhC{\equiv}CR)$ (Scheme 8). Complexes such as $NbX(CO)_2(dppe)_2$ (X=Cl, Br), $NbI(CO)_2(CNR)_2(dppe)$ and $TaH(CO)_4(dppe)$ have been reported.[22] The one-electron oxidation of bis-mesitylene Nb in the presence of ligands (L = CO, alkyne) giving the bent $[Nb(Mes)_2L]^+$ cation is another approach. Heating of the alkyne derivative results in total mesitylene displacement and formation of a neutral species with two η^6-aryl bonds of the BPh_4 original counterion (*see* ***Niobium & Tantalum: Organometallic Chemistry***). Well-characterized non-carbonyl compounds are $Ta[H_2Al(OC_2H_4OMe)_2(dmpe)_2]$, obtained through the reduction of $TaCl_2(dmpe)_2$ by vitride[1] or the $M(i\text{Pr}_2\text{-dad})_3^+$ cation.[84] Reduction of $TaCl_5$ with $LiBH_4$ in the presence of bis(dimethylphosphino)methane gave (**63**), the first structurally characterized metalloborane complex with a μ-BH_3 ligand (equation 29). Donation of d electrons from the Ta^I center to the electron-deficient μ-BH_3 provides the best explanation for the X-ray data. A Ta=Ta bond is consistent with the Ta–Ta distance (≈2.78 Å) and the diamagnetism.[67] Protonation of $[M(PF_3)_6]^-$ by H_2SO_4

afforded the $M(PF_3)_6H$ hydrides, the Nb one being quite unstable.[85]

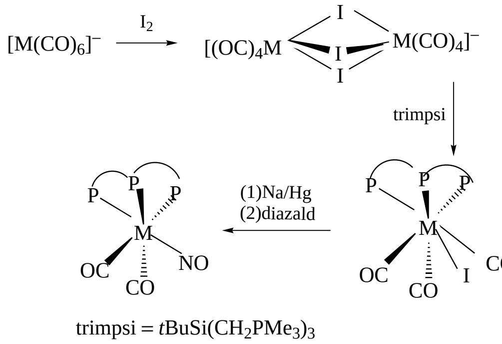


(29)

$Ta_2(\mu\text{-}BH_3)(\mu\text{-dmpm})_3(\eta^2\text{-}BH_4)_2$ (**63**)

Two-electron transfer processes applied to the hexacarbonyl $[M(CO)_6]^-$ (**38**) anions using reactants such as hydracids, nickel acetylacetonate, or metal halides offered $[M_2Cl_3(CO)_8]^-$, the first halocarbonyl complexes without ancillary ligands (*see Ancillary Ligand*), or the β-diketonate $Ta(acac)(CO)_4(THF)$.[1,22] The cothermolysis of $Cp''Ta(CO)_4$ ($Cp'' = 1,3\text{-}t Bu_2C_5H_3$) with As_4 or $(RAs)_n$ afforded polynuclear Ta derivatives with As_n moieties ($n = 3$, 6 or 8) as ligands. The phosphido-phosphinidene coordination mode of a P_2 ligand has been realized in the trinuclear complex $(Cp''Ta)_3(P_4)(P_2)$ obtained by thermolysis of $Cp''Ta(CO)_4$ and P_4.[86]

Metal vapor synthesis techniques (*see* ***Metal Vapor Synthesis of Transition Metal Compounds***) are the most convenient access to M^0 derivatives, solution routes being limited to the synthesis $Nb(Mes)_2$.[5] Highly air-sensitive, paramagnetic but crystalline $M(dmpe)_3$ with a distorted octahedral geometry were isolated in good yields. The formally zerovalent 17e $M(i Pr_2\text{-dab})_3$ species were shown by *DFT calculations* to be actually $[Ta]^+ [(i Pr_2dad)_3]^-$ rather than Ta^0 species.[84] The 17e species, $Ta(CO)_4(dppe)$, has been the first Ta^0 carbonyl isolated. The first nitrosyl complexes of Nb and Ta were reported in 1998.[87] They were obtained in high yields according to equation (30). Diazald (N-methyl-N-nitroso-p-toluenesulfonamide) was the source of the nitrosyl. The M–N bond distances suggest multiple M–N bonding due to M → NO back bonding.



(30)

trimpsi = $t BuSi(CH_2PMe_3)_3$

$[Nb(CO)_6]^-$ (**38**) has become accessible in high yield by reduction of $NbCl_4(THF)_2$ at atmospheric pressure (Scheme 7).[85] $[Nb(PF_3)_6]^-$ is accessible either by photolysis (*see* ***Photosynthesis***) of $[Nb(CO)_6]^-$ under PF_3 or by a reductive route similar to that of (**38**). The ^{93}Nb NMR chemical shifts suggest weaker Nb–PF_3 bonds than Nb–CO ones.[1]

No derivative in which niobium or tantalum displays an oxidation state of −II has been reported so far, while carbonyl complexes derived from $[M(CO)_5]^{3-}$ represent the only coordination compounds for these metals in oxidation state −III.

1 INTRODUCTION

Organometallic chemistry of niobium and tantalum has developed rapidly over the past ten years, as judged by the number of papers published in the field. This review covers the literature between 1993 to early 2003. *SciFinder* (*Chemical Abstracts*) searches were conducted on ‘‘niobium (Nb) or tantalum (Ta)’’ between 1993 and early 2003. The hits were then sorted so that those in Section 29 (Organometallic and Organometalloidal Compounds) were selected. In addition, hits in Sections 78 (Inorganic Chemicals and Reactions) and 67 (Catalysis, Reaction Kinetics, and Inorganic Reaction Mechanisms) were also reviewed. This paper is primarily based on the literature from these searches. Because of the limit of space, the current paper highlights leading literature during this period. General references for niobium and tantalum organometallic chemistry include the chapter by Wigley and Gray in *Comprehensive Organometallic Chemistry II*, which reviews the literature through 1993.[1] M refers to Nb and Ta throughout this chapter.

2 CARBONYLS, ISOCYANIDES, PHOSPHAALKYNES, AND AZIDES

2.1 Carbonyls and Substituted Carbonyls

2.1.1 Carbonyl Complexes without Cyclopentadienyl Ligands

Unlike stable $V(CO)_6$, neutral $M(CO)_6$ (M = Ta, Nb) have not been characterized (except in matrix-isolation experiments,[2] *see Matrix Isolation*). Neutral mixed-ligand complexes were unknown until 1996. The first Ta(0) carbonyl complex $Ta(CO)_4(dppe)$ was synthesized by the reaction of hydride $TaH(CO)_4(dppe)$ with the $(p\text{-}Bu^tC_6H_4)_3C\bullet$ radical.[3] This complex exists as a CO-bridged dimer in solid and, in solution, as an equilibrium mixture of the monomer and dimer.[4]

Density functional theory calculations of 17-electron (*see Seventeen Electron Configuration*), metal-centered radical $Ta(CO)_6$ and its dimer $[Ta(CO)_6]_2$ show that the dimer is energetically bound with respect to the monomer. The bidentate phosphine ligand in $Ta(CO)_4(H_2PCH_2CH_2PH_2)$ leads to several energetically competitive chelated dimers. In these dimers, linear semibridging carbonyls (*see Semibridging Carbonyl Ligand*) support a weak, delocalized Ta−Ta interaction.[5]

A recent review gives a chronological survey of the syntheses and characterizations of homoleptic mononuclear metal-carbonyl (*see* ***Carbonyl Complexes of the Transition Metals***) anions.[6] $[M(CO)_6]^-$ is a key precursor to niobium and tantalum carbonyls. More reliable synthesis of $[Ta(CO)_6]^{-}$[7]

and a higher yield route to $[Nb(CO)_6]^{-}$[8] are now available. Reduction of $[Nb(CO)_6]^-$ by sodium in liquid ammonia affords $[Nb(CO)_5]^{3-}$, the only known Nb^{3-} species.[8] Treatment of $[Et_4N][M(CO)_6]$ with I_2 produces $[M_2(\mu\text{-}I)_3(CO)_8]^-$. Addition of trimpsi [trimpsi = $Bu^tSi(CH_2PMe_2)_3$] to $[M_2(\mu\text{-}I)_3(CO)_8]^-$ affords (trimpsi)$M(CO)_3I$ (**1**). Treatment of (**1**) with Na/Hg followed by diazald results in the formation of (trimpsi)$M(CO)_2(NO)$, the first nitrosyl complexes of niobium and tantalum.[9]

Vibronic structure and coupling (*see Vibronic Coupling*) in the electronic spectra of $[Ph_4P][Ta(CO)_6]$ have been studied. The emission spectrum originates from a ligand field transition. There is an apparent energy gap between the red and the blue regions of the spectrum, and this is interpreted in terms of Herzberg–Teller coupling of the ligand field state, with an allowed Ta-to-CO charge-transfer (*see Charge Transfer*) excited state.[10]

2.1.2 Cyclopentadienyl Carbonyl Complexes

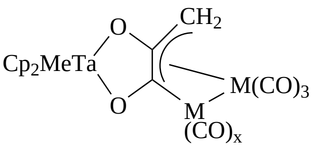
The cyclopentadienyl carbonyl derivatives $(C_5R_5)M(CO)_4$ are easily prepared by reductive carbonylation (*see Reductive Carbonylation*) of $(C_5R_5)MCl_4$ under CO. $[M_2(\mu\text{-}Cl)_3(CO)_8]^-$ readily reacts with NaC_5H_4R to give $(C_5H_4R)M(CO)_4$.[11] Reduction of the borollide complex $Cp^*[C_4H_4B\text{-}NPr^i{}_2]TaCl_2$ with Mg under CO gives $Cp^*[C_4H_4B\text{-}NPr^i{}_2]Ta(CO)_2$.[12] Carbonylation of $CpTa(\eta^4\text{-butadiene})(\eta^2\text{-}C_2H_4)(PMe_3)$ afforded monocarbonyl $CpTa(\eta^4\text{-butadiene})(CO)(PMe_3)$ and dicarbonyl $CpTa(\eta^4\text{-butadiene})(CO)_2$.[13]

Gas-phase photoelectron spectroscopy has been used to study the bonding in $CpM(CO)_4$, $Cp'M(CO)_4$, and $(\eta^5\text{-}C_5H_4COMe)Nb(CO)_4$. The character of two overlapping ionizations in the lowest ionization energy region is dominated by the carbonyls rather than by the metals. The second group of ionizations corresponds to orbitals with predominantly cyclopentadienyl π character that donate to empty metal d orbitals. A much larger shift of these ionizations is observed upon cyclopentadienyl substitution.[14]

μ-Phosphido complex $Cp''CpTa(\mu\text{-}CO)(\mu\text{-}PMe_2)W(CO)_4$ ($Cp'' = 1\text{-}Bu^t\text{-}3,4\text{-}Me_2\text{-}C_5H_2$) reacts with an optically active phosphine (PRR′R″) to give a pair of optically active diastereoisomers $Cp''CpTa(CO)(\mu\text{-}PMe_2)W(CO)_4(PRR'R'')$. X-ray structure determinations of these diastereoisomers lead to the assignment of absolute configurations of the Ta chiral centers.[15]

2.2 CO Reductive Coupling

The reductive coupling (*see Reductive Coupling*) of CO ligands in $M(CO)_2(dmpe)_2Cl$ (M = V, Nb, or Ta) to form $M(R_3SiOC{\equiv}COSiR_3)(dmpe)_2X$ occurs via sequential formation of $Na[M(CO)_2(dmpe)_2]$ and $M({\equiv}COSiR_3)(CO)(dmpe)_2$ complexes. Reactions of siloxycarbynes (*see Carbyne Complexes*) $M({\equiv}COSiR_3)(CO)(dmpe)_2$ ($R_3 = Pr^i{}_3$, **2a**; Bu^tPh_2, **2b**; Ph_3, **2c**) with, for example, Me_3SiCl afford CO reductive coupling products $Ta(R_3SiOC{\equiv}COSiMe_3)(dmpe)_2Cl$. Kinetic studies of carbyne/CO coupling in the reaction of $Ta({\equiv}COSiPr^i{}_3)(CO)(dmpe)_2$ with Me_3SiCl to form $Ta(Me_3SiOC{\equiv}COSiPr^i{}_3)(dmpe)_2Cl$ show that the reaction is first order in both the Ta complex and Me_3SiCl in the presence of excess $Bu^n{}_4NBPh_4$, suggesting that initial electrophilic attack of the silyl reagent occurs at the O atom of the carbonyl ligand.[16,17] Reactions of carbon-based electrophiles (e.g. AcCl) with the siloxycarbynes such as (**2b**) and $M(COSiBu^tPh_2)(CO)(depe)_2$ give mixed siloxy/alkoxyacetylene complexes $M(Ph_2Bu^tSiOC{\equiv}COAc)(P_2)_2Cl$ (P_2 = dmpe, depe).[18] Similarly, AcCl reacts with $Na[Ta(CO)_2(P_2)_2]$ to yield $Ta(AcOC{\equiv}COAc)(P_2)_2Cl$ through direct alkylation at the terminal CO ligands.[18] Treatment of methylene $Cp_2Ta({=}CH_2)Me$ with carbonyls $Co_2(CO)_8$ and $Fe_2(CO)_9$ results in CO coupling reactions to yield trinuclear complexes (**3**).[19,20]



(**3**) M = Co, x = 3
M = Fe, x = 4

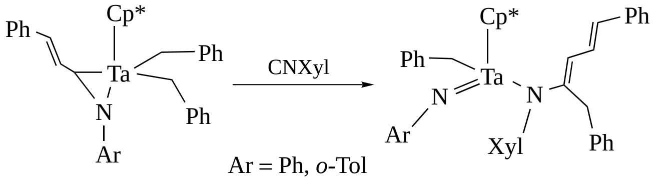
Reaction of $Cp^*TaMe_2({=}NXyl)$ with CO gives an ene diolate $[Cp^*Ta({=}NXyl)Me]_2\{\mu\text{-}\eta^2\text{-}OC(Me){=}C(Me)O\}$ via intermolecular coupling between acyls of an intermediate $Cp^*TaMe\{{=}NXyl\}\{\eta^2\text{-}C(Me){=}O\}$ (**4**).[21,22] In comparison, the reaction of the chloro analog $Cp^*TaMeCl({=}NXyl)$ with CO yields an unexpected oxo η^2-iminoacyl complex $Cp^*TaCl(O)[\eta^2\text{-}C(Me){=}NXyl]$ through an intermediate $Cp^*TaCl({=}NXyl)[\eta^2\text{-}C(Me){=}O]$.[21]

Similar coupling reactions were observed when $[Ta(OEP)Me_2](BPh_4)$ (OEP = octaethylporphyrin) and a bis (amidinate) complex $[PhC(NSiMe_3)_2]_2TaMe_3$ were added CO to give $\{Ta(OEP)[OC(Me){=}CMe(O)]\}(BPh_4)$,[23] and $[PhC(NSiMe_3)_2]_2Ta[OC(Me){=}C(Me)O]Me$,[24] respectively.

2.3 Complexes of Isocyanides, Phosphaalkynes, Azides, and the Reductive Coupling of the Ligands

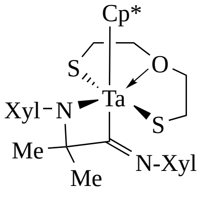
The interests in homoleptic (*see Homoleptic Compound*) isocyanide ('isonitrile,' *see Isocyanide Ligands*) complexes of transition metals have largely been associated with their similarities to metal carbonyls. The greater versatility of isocyanide ligands in comparison to CO makes isocyanide complexes potentially valuable reagents in synthetic chemistry and catalysis. The dication $[V(CNBu^t)_6]^{2+}$ reported in 1980 remained the sole example of a homoleptic group 5 metal isocyanide until 1999, when the first binary

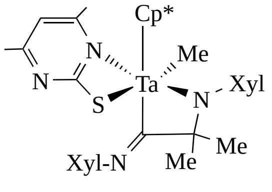
Nb and Ta isocyanides were isolated.[25] Two-electron oxidation of anions $[M(CO)_6]^-$ by $AgBF_4$ in the presence of CNXyl and a mixture of CNXyl and I_2 yields $[M(CNXyl)_7](BF_4)$ and $MI(CNXyl)_6$, respectively.[25] Direct reactions of $[M(CO)_6]^-$ with CNR and X_2 also yield halo isocyanide complexes such as $[I_2M^{III}(CNBu^t)_6]I$ and $ITa(CO)_3(CNBu^t)_3$. In the presence of a small amount of water, the reaction of $[Nb(CO)_6]^-$ gives aminoalkyne complexes $[X_2Nb(CNBu^t)_4(Bu^tHNC{\equiv}CNHBu^t)]X$ (X = I, Br), suggesting successive protonation and intramolecular reductive isocyanide coupling (*see Reductive Coupling*) mediated by a Nb^I center.[26] Direct nitrosylation of $[M(CO)_6]^-$ with $(NO)^+$ in the presence of CNXyl yields *cis*-$[M(NO)_2(CNXyl)_4]^+$, the first dinitrosyls of niobium and tantalum.[27]



(5) (6)

In the reactions of dibenzyl 1-aza-1,3-butadiene complexes (**5**) with CNXyl, alkyl-insertion followed by coupling with the 1-aza-1,3-butadiene ligand affords amido-imido complexes (**6**).[28] The reaction of $Cp^*TaMe_2(SCH_2CH_2)_2O$ with CNXyl yields $Cp^*Ta(\eta^2\text{-}XylNCMe_2)(SCH_2CH_2)_2O$, which undergoes a second isocyanide insertion to yield (**7**).[29] A similar reaction of $Cp^*TaMe_3(SC_6H_7N_2)$ with CNXyl gives (**8**).[30]



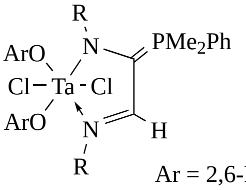


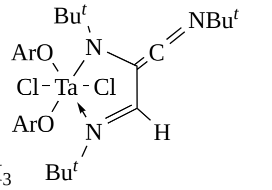
(7) (8)

The Ta hydride compound $Ta(OAr)_2Cl_2(H)(PMe_2Ph)_2$ (Ar = 2,6-$Pr^i{}_2$-C_6H_3, **9**) reacts with RNC (R = Xyl, 2,6-$Pr^i{}_2$-C_6H_3) to yield the ylide (*see Ylide*) derivatives (**10a**). The reaction of (**9**) with Bu^tNC gives the keteneimine complex (**10b**).[31]

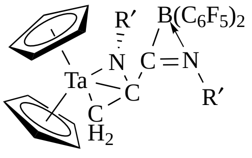
$Cp_2Ta({=}CH_2)Me$ reacts with 1 and 2 equiv of $HB(C_6F_5)_2$ to give $Cp_2Ta[CH_2B(C_6F_5)_2](\mu\text{-}H)Me$ (**11**) and $Cp_2Ta[CH_2B(C_6F_5)_2](\mu\text{-}H)(H)$, respectively. Reductive elimination (*see Reductive Elimination*) of CH_4 from (**11**) in the presence of Bu^tNC (or CO) and R′NC (R′ = Cy, $PhCH_2$) leads to the formation of $Cp_2Ta^{III}[\eta^2\text{-}CH_2B(C_6F_5)_2](L)$ (L = Bu^tNC, CO),[32] and unusual η^3-1-azaallyl Ta^{III} complexes (**12**).[33]

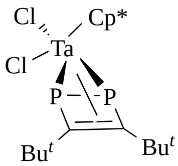
Substitution of CO ligands in $Cp^*TaCl_2(CO)_2(THF)$ with phosphaalkynes RC≡P (R = Bu^t, adamantyl) gives η^2(4e)-bonded $Cp^*TaCl_2(P{\equiv}CR)$. Treating $Cp^*TaCl_2(P{\equiv}CBu^t)$ with additional P≡CBu^t gives the 1,2-diphosphacyclobutadiene complex (**13**).[34]





Ar = 2,6-$Pr^i{}_2$-C_6H_3
(**10a**) R = Xyl, Ar (**10b**)





(**12**) (R′ = Cy, CH_2Ph) (**13**)

Aryl azides ArN_3 (Ar = Ph, *p*-$CF_3C_6H_4$, *p*-$Me_2NC_6H_4$) replace PMe_3 in $Cp_2TaMe(PMe_3)$, affording rare examples of terminal phenylazido complexes $Cp_2TaMe(N_3Ar)$, which under heating or UV irradiation give imides $Cp_2TaMe({=}NAr)$ and N_2. Thermolysis of Cp_2TaMe-$(NN^{15}NPh)$ yields $Cp_2TaMe(^{15}NPh)$. Crossover (*see Crossover Experiment*) and kinetic studies reveal that this is a unimolecular decomposition.[35]

3 η^1-COMPLEXES

3.1 Alkyls, Aryls, Silyl, and Related σ-Complexes

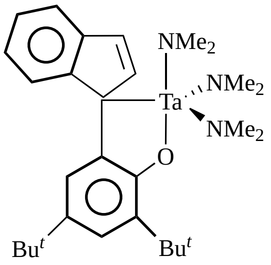
3.1.1 Synthesis and Complexes

Metathesis reactions (*see Metathesis*) of Nb and Ta halide complexes with main group alkyls or milder alkylating reagents such as organozinc, -tin and -aluminum compounds (*see* ***Zinc: Organometallic Chemistry***; ***Tin: Organometallic Chemistry***, and ***Aluminum: Organometallic Chemistry***), continue to be the most common approach to the formation of Nb– and Ta–C bonds. NaCp was used, for example, to give the η^1-C_5H_5 ligands in $Cp_2Nb(\eta^1\text{-}C_5H_5)_2$[36] and $Cp_2M({=}NSiMe_3)(\eta^1\text{-}C_5H_5)$.[37]

Migratory insertions (*see Migratory Insertion*) of alkenes or alkynenes into M–H bonds are also a common method

to form the Nb and Ta alkyls. Such reactions with activated alkynes lead to the formation of $Cp'_2Nb(CNR)(\eta^1$-$CR'{=}CHR')$ and $Cp'_2Nb(CO)(\eta^1$-$CR'{=}CHR')$ (R = Xyl, Cy, Bu^t; $R' = CO_2Me$, CO_2Bu^t) from $Cp'_2Nb(H)(CNR)$ and $Cp'_2Nb(H)(CO)$, respectively.[38]

A less common method to give η^1-alkyl or aryl complexes is the C–H bond activation reactions. Elimination of $HNMe_2$ from Ta(O-2-Ind-4,6-Bu^t_2-C_6H_3)$(NMe_2)_4$ yields (**14**).[39] Activation of a C–H bond in a Ta ← NMe_2 group led to the formation of the Ta ← NMe-CH_2 moiety, as discussed in Section 9.1.[40,41]



(**14**)

Reactions of $TaMe_5$ with triamines $(Me_3SiNHCH_2CH_2)_2$-NH and $(Me_3SiNH$-o-$C_6H_4)_2NH$ yield $[(Me_3SiNCH_2CH_2)_2N]TaMe_2$ and $[(Me_3SiN$-o-$C_6H_4)_2N]TaMe_2$, respectively. $(C_6F_5NHCH_2CH_2)_2NH$ reacts with $TaMe_5$, yielding first $[(C_6F_5NCH_2CH_2)_2NH]TaMe_3$, which then decomposes to $[(C_6F_5NCH_2CH_2)_2N]TaMe_2$.[42]

A review by Eisen summarizes chemistry of transition metal silyl chemistry between 1992 and mid-1996.[43] Earlier general references in this field include the reviews by Tilley and Schubert for the literature before 1992.[44] Nb silyl complexes $Cp'_2NbH_2(SiR_3)$ ($SiR_3 = SiMe_2Ph$, $SiMePh_2$, $SiPhH_2$, $SiPh_2H$, $SiPh_3$) have been prepared from the reactions of Cp'_2NbH_3 with silanes $HSiR_3$.[45] In these silyl complexes, the silyl ligands occupy the central equatorial position. Reactions of Cp_2NbH_3 or Cp_2NbBH_4 with $HSiR_3$ [R_3=, for example, Me_2Cl, $(OEt)_3$] yield $Cp_2Nb(SiR_3)H_2$.[46] Disilyl hydrides $Cp_2NbH(SiMe_2X)_2$ are obtained by reactions of $Cp_2NbH(CH_2{=}CHPh)$ with $HSiMe_2X$ (X = Cl, Ph),[47] or reactions of $NbCp_2(SiMe_2Cl)_2H$ with $XSiMe_3$ (X = Br, I).[48] Similar reactions of Ph_3EH (E = Ge, Sn) with Cp'_2NbH_3 lead to the formation of $Cp'_2NbH_2(EPh_3)$ (E = Ge, Sn).[49]

$(RCH_2)_3TaCl_2$ ($R = Bu^t$, Me_3Si) react with LiSi-$(SiMe_3)_3$, affording Cp-free silyl alkylidene (*see Alkylidene*) complexes $(RCH_2)_2Ta({=}CHR)Si(SiMe_3)_3$ ($R = Bu^t$, Me_3Si).[50,51] Mechanistic studies (*see* ***Mechanisms of Reaction of Organometallic Complexes***) of the formation of $(Me_3SiCH_2)_2Ta({=}CHSiMe_3)Si(SiMe_3)_3$ suggest that the intermediate $(Me_3SiCH_2)_3Ta[Si(SiMe_3)_3]Cl$ undergoes α-H abstraction (*see α-Elimination*) with the elimination of $HSi(SiMe_3)_3$ to give '$(Me_3SiCH_2)_2Ta({=}CHSiMe_3)Cl$.'[51,52] Subsequent chloride replacement by the second equiv of $Si(SiMe_3)_3^-$ gives the silyl alkylidene complex.

3.1.2 Reactions

Alkyl ligands in niobium and tantalum complexes are susceptible to attack by electrophiles (*see Electrophilic Reaction*). Hydrogenation (*see Hydrogenation*) of niobium or tantalum M–R bonds to provide the metal hydrides is an important reaction of synthetic utility. Insertion reactions of unsaturated reagents into Nb– or Ta–C bonds are common. The unsaturated reagents include alkenes, alkynes, CO, NO, RN=C=NR, CNR, and others.

Photolysis of Ta(O-2,6-Ph_2-3,5-R_2-$C_6H)_2(CH_2SiMe_3)_3$ and $^{Ph}[P_2N_2]TaMe_3$ yields alkylidenes Ta(O-2,6-Ph_2-3,5-R_2-$C_6H)_2({=}CHSiMe_3)(CH_2SiMe_3)$[53] and $^{Ph}[P_2N_2]Ta({=}CH_2)(Me)$,[54] respectively. In the presence of ethylene, $^{Ph}[P_2N_2]Ta({=}CH_2)(Me)$ is slowly converted to $^{Ph}[P_2N_2]Ta(C_2H_4)Et$ and $^{Ph}[P_2N_2]Ta(C_2H_4)Me$.[54]

Transition structures of CH_4 elimination in MMe_5 have been investigated in detail with *ab initio* (*see Ab Initio Calculations*) quantum mechanics calculations. The most favorable transition structure for the elimination is close to a trigonal-bipyramidal geometry. A dimeric mechanism through intermolecular hydrogen abstraction is found to be much lower in activation free energy than the unimolecular mechanism. The dimeric transition structure is mainly stabilized by an M–CH_2–M bridge.[55]

Reactions of the silyl complex $Cp_2Ta^{III}(PMe_3)(SiBu^t_2H)$ with L→BH_3 (L = NEt_3, N-methylmorpholine) give Cp_2-$Ta(\mu$-$H)_2B(SiBu^t_2H)H$ containing a B–Si bond.[56]

3.2 Hydride Complexes

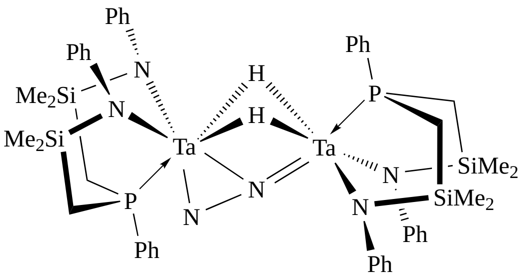
Transition metal hydride (*see Hydrides*) derivatives are thought to be responsible for a plethora of organic transformations and catalytic cycles. The chemistry of Nb and Ta hydrides has developed rapidly in the past ten years. This part will focus on the synthetic and reactivity studies of these hydride complexes. A recent review surveyed the synthesis and reactivity of early metal hydride complexes.[57]

3.2.1 Cyclopentadienyl-free Hydride Complexes

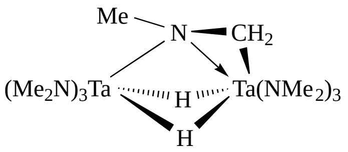
Phosphines and alkoxides constitute common ancillary ligands in Cp-free hydride complexes. A Ta^{IV} penta-hydride $[TaH_5(dmpe)_2](LiHBEt_3)$ has been reported.[58] Hydrogenation of arenes is catalyzed by Nb and Ta hydrides with ancillary aryloxide ligation.[59] Reactions of alkynes and olefins with hydrides such as Ta(O-2,6-Ph_2-$C_6H_3)_2(H)_2Cl(PMe_3)_2$ were studied to explore the mechanistic pathways.[60] Reaction of $[(silox)_2TaH_2]_2$ with ethylene gives $[(silox)_2HTaEt]_2$ and $[(silox)_2EtTa](\mu$-$CHCH_2)(\mu$-$H)_2[Ta(silox)_2]$.[61]

Hydrogenation of $[NPN]TaMe_3$ {$[NPN] = PhP(CH_2$-$SiMe_2NPh)_2$} yields an interesting series of hydride-bridged dimers such as $\{[NPN]Ta\}_2(\mu$-$H)_4$.[62] This Ta^{IV} complex, upon exposure to N_2, loses H_2 to give a dinitrogen complex

$\{[NPN]Ta(\mu\text{-}H)\}_2(\mu\text{-}\eta^1{:}\eta^2\text{-}N_2)$ (**15**).[63] Reactions of silanes with the amido complex $Ta(NMe_2)_5$ have been reported to give the dihydride η^2-imine complex (**16**).[64]



(**15**)



(**16**)

The niobaziridine-hydride $Nb(H)[\eta^2\text{-}Bu^t(H)C{=}NAr]\text{-}[N(Np)Ar]_2$ ($Ar = 3,5\text{-}Me_2\text{-}C_6H_3$), acting as a reactive synthon for its tautomer, the three-coordinate, trisamide $Nb[N(Np)Ar]_3$, reveals divergent reactivity for 2-electron reduction chemistry. It reacts with P_4, forming bridging diphosphide complex $(\mu_2{:}\eta^2,\eta^2\text{-}P_2)\{Nb[N(Np)Ar]_3\}_2$. In demonstrations of dual pathways of reactivity, nitriles and aldehydes insert into the Nb–H bond, leaving the niobaziridine ring intact.[65]

3.2.2 Cyclopentadienyl Hydrides

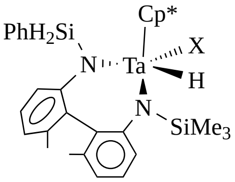
Important references of cyclopentadienyl hydrides include a review by Otero and coworkers, which covered the literature till mid-1998.[66]

$(\eta^5\text{-}C_5R_5)_2MH_3$ are useful stating hydrides of these two elements. Preparation of Nb silyl complexes from Nb hydrides is discussed in Section 3.1.1. In the studies of hydridosilyl complexes $Cp(ArN{=})Ta(PMe_3)(H)(SiCl_nR_{3-n})$ [$Ar = 2,6\text{-}Pr^i{}_2\text{-}C_6H_3$, $SiCl_nR_{3-n} = SiHMePh$, (**17a**); $SiClMe_2$, (**17b**); $SiCl_2Me$, (**17c**); $SiCl_3$, (**17d**)], an unprecedented increase of the $J_{Si\text{–}H}$ coupling constants between the hydride and silyl ligands from 14 Hz for (**17a**) to 50 Hz in (**17d**) was observed. This work shows that the increase in the magnitude of $J_{Si\text{–}H}$ does not necessarily correspond to stronger bonding interaction between these two ligands.[67] The nature of possible $H\cdots SiR_3$ interligand interactions in the complexes $Cp_2MXH(SiR_3)$ ($X = SiR_3$, Cl, H, Me) has been studied by *ab initio* calculations at the MP2 level. These theoretical studies indicate that the presence of a Si–Cl bond trans to hydride is crucial to developing shortened $H\cdots Si$ contacts and gives a concomitant lengthening of the Si–Cl bond.[68]

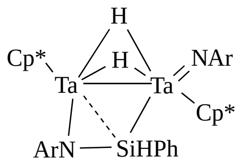
cis-$[Cp'_2Nb(HD)(PMe_2Ph)](CF_3CO_2)$ exhibits hindered rotation of the coordinated H-D. At 203 K, the *endo* H and *exo* H rotamers are observed, and they interconvert by rotation of the HD ligand reaching the coalescence at 233 K. This is the first observation of a freezing of H-D rotation on a transition metal complex.[69]

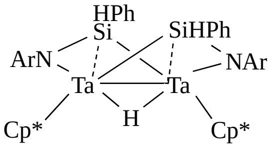
Insertion of $ClPPh_2$ into M–H bonds in Cp_2MH_3 and Cp'_2NbH gives phosphines $[Cp_2MH_2(PHPh_2)]Cl$ (M = Nb,[70] Ta[71]) and $[Cp'_2NbH_2(PHPh_2)]Cl$,[72] which undergo deprotonation to yield $Cp_2Nb^{III}H(PHPh_2)$, $Cp_2Ta^{V}H_2(PPh_2)$, and $Cp'_2NbH(PHPh_2)$, respectively. Similar reactions give $Cp_2NbH_2AsR_2$,[73] $Cp_2NbH_2SbPh_2$,[74] $Cp_2NbH_2PbMe_3$,[75] $Cp_2NbH_2BiPh_2$,[76] and $Cp_2NbH_2GeR_3$.[77] Protonation of $Cp'_2NbH(L)$ ($L = PHPh_2$, CNXyl) with CF_3COOH gives dihydrogen complexes $[Cp'_2Nb(\eta^2\text{-}H_2)(L)](CF_3CO_2)$.[72,78] Upon heating, $[Cp'_2Nb(\eta^2\text{-}H_2)(PHPh_2)](CF_3CO_2)$ is converted to its transoiddihydride isomer. Reactions of $(C_5H_4R)_2MH_3$ ($R = H$, $SiMe_3$) with PH_2R' afford $(C_5H_4R)_2MH[(PR')_2]$ ($R' = Ph$, Cy) with a MP_2 ring, while the reaction of Cp_2TaH_3 with white phosphorus gives $Cp_2TaH[(PH)_2]$.[79]

Reactions of silanes with cyclopentadienyl Ta imides are a new method to yield hydrides. Addition of the Si–H bond in $PhSiH_3$ across the Ta=N double bond in $Cp^*Ta[{=}N(C_6H_3Me)_2NSiMe_3]X$ (X = Cl, Me) yields hydrides (**18**).[80] The reaction of $Cp^*Ta({=}N\text{-}Ar)[Si(SiMe_3)_3]H$ ($Ar = 2,6\text{-}Pr^i{}_2\text{-}C_6H_3$) with $PhSiH_3$ gives a mixture of hydrides $[Cp^*(ArN{=})TaH(\mu\text{-}H)]_2$, (**19**), and (**20**).[81]



X = Cl, Me (**18**)





Ar = 2,6-$Pr^i{}_2$-C_6H_3

(**19**) (**20**)

$(Bu^tC_5H_4)_2NbBH_4$ or $(Bu^tC_5H_4)_2TaH_3$ reacts with Se to afford $(Bu^tC_5H_4)_2Nb(\eta^2\text{-}SeSeH)$ and $(Bu^tC_5H_4)_2Ta(\eta^2\text{-}Se_2)H$.[82] Similar reactions of $(Bu^tC_5H_4)_2NbH_3$ and $Cp^*{}_2TaH_3$

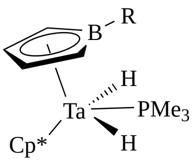
with Te give $(Bu^tC_5H_4)_2Nb(\eta^2\text{-}Te_2)H$[83] and $Cp^*_2Ta(\eta^2\text{-}Te_2)H$.[84] The telluroformaldehyde complex $Cp^*_2Ta(\eta^2\text{-}TeCH_2)H$ has been prepared by the PMe_3-catalyzed addition of Te to the $Ta{=}CH_2$ bond in $Cp^*_2Ta({=}CH_2)H$.[84]

Insertion of alkynes $RC{\equiv}CR'$ bearing electron-withdrawing substituents into Nb–H bonds in $Cp'_2NbH(L)$ (L = CO, isocyanide) and Cp'_2NbH_3 were found to give alkenyl complexes $Cp'_2Nb(CR{=}CHR')L$ and hydride olefin derivatives $Cp'_2Nb(CHR{=}CHR')(H)$.[38] The formation of the latter is believed to occur via initial stereospecific *trans*-insertion, followed by intramolecular rearrangement. Reactions of olefins $RCH{=}CH_2$ with Cp'_2NbH_3 yield $Cp'_2Nb(H)(\eta^2\text{-}RCH{=}CH_2)$.[85] Such olefin hydrides are also prepared from the alkylation of $(Cp'_2NbCl)_2$ with Grignard reagents RMgX (R = Et, CH_2CH_2Ph), followed by β-hydrogen elimination (*see β-Elimination*).[86]

Recent studies of the rates of H-exchange following intramolecular ethylene insertion into the M–H bond in *ansa*-metallocene (*see Metallocene Complexes*) complexes, $[Me_2Si(\eta^5\text{-}C_5H_4)(\eta^5\text{-}3\text{-}R\text{-}C_5H_3)]Nb(CH_2CH_2)H$ (R = Pr^i, Bu^t), *rac*- and *meso*-$[Me_2Si(\eta^5\text{-}3\text{-}Bu^t\text{-}C_5H_3)_2]Nb(CH_2CH_2)H$, and $[(1,2\text{-}SiMe_2)_2(\eta^5\text{-}3,5\text{-}Pr^i{}_2\text{-}C_5H)(\eta^5\text{-}4\text{-}Bu^t\text{-}C_5H_2)]Ta(CH_2CH_2)H$, show that the singly bridged *ansa*-niobocenes exchange up to three orders of magnitude faster than unbridged complexes. The doubly bridged *ansa*-tantalocene complex exchanges at a rate comparable to that previously reported for $Cp^*_2Ta(CH_2CH_2)H$ and much slower than the singly bridged complex $[Me_2Si(\eta^5\text{-}C_5Me_4)_2]Ta(CH_2CH_2)H$. DFT calculations on model complexes indicate the presence of an agostic (*see Agostic Bonding*) ethyl intermediate in the computed exchange pathway.[87]

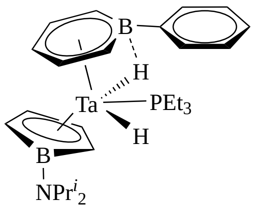
Reactions of Cp_2NbH_3 with catecholborane or 9-borabicyclononane HBR_2 yield disubstituted hydridoborates $Cp_2Nb(H_2BR_2)$ via loss of H_2.[88] Ta boryl complexes *endo*- and *exo*-$Cp_2Ta(H)_2(BO_2C_6H_4)$ are prepared from the reaction of chlorocatecholborane with $(Cp_2TaH_2Li)_x$.[89] *ansa*-Niobiocene tetrahydroborate complexes $[(C_5H_4)X(C_5H_4)]Nb(\eta^2\text{-}BH_4)$ (X = *ansa*-bridging unit) are prepared as well,[90] and the barrier to bridge-terminal hydrogen exchange is considerably reduced when the bridging unit imposes significant structural changes in the metallocene (*see Metallocene Complexes*). Theoretical studies of catecholborane adducts of hydride complexes $Cp_2M(H)$ that are obtained from $Cp_2M(H)(\eta^2\text{-}CH_2{=}CH_2)$ show that there are structural isomers of the *O*- and *N*-substituted borane adducts including boryl, hydridoborate, and σ-complex structures. These structures are related to how the electron-deficient (*see Electron Deficient Compound*) B atom is electronically saturated.[91]

Dianionic borollide complexes $Cp^*(C_4H_4B\text{-}R)TaMe_2$ have been prepared and found to undergo hydrogenolysis in the presence of PMe_3 to give $Cp^*(C_4H_4B\text{-}R)Ta(H)_2(PMe_3)$ (**21a**).[92,93] $[C_4H_4BNPr^i{}_2](C_5H_5BPh)Ta(H)_2PEt_3$ (**21b**) is similarly prepared.[12]



R = $NPr^i{}_2$, Me

(**21a**)

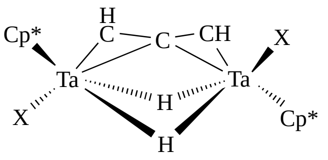


(**21b**)

Treatment of the imide hydride $Cp^*_2Ta({=}NBu^t)H$ with $[Ph_3C][B(C_6F_5)_4]$ yields the cationic imide $[Cp^*_2Ta({=}NBu^t)(THF)][B(C_6F_5)_4]$ (**22**). (**22**) reacts cleanly with H_2 to yield $[Cp^*_2Ta(NHBu^t)H][B(C_6F_5)_4]$, and undergoes C–H bond activation reactions with propyne or phenylacetylene to afford $[Cp^*_2Ta(NHBu^t)(C{\equiv}CR)][B(C_6F_5)_4]$ (R = Me, Ph). The heterolytic cleavage reactions of (**22**) may be the result of the presence of both electrophilic and nucleophilic sites of reactivity in the same molecule. Intramolecular activation of a C–H bond of a Cp^* ligand yields $[Cp^*Ta(\eta^5\text{-}C_5Me_4CH_2NBu^t)H][B(C_6F_5)_4]$ with the methylene group attached to the N rather than the Ta atom. Dealkylation of the imido group is observed in an unusual reaction of (**22**) with CO_2 giving isobutylene and the isocyanate complex $[Cp^*_2Ta(OH)(NCO)][B(C_6F_5)_4]$.[94]

Reactions of $(C_5H_4Bu^t)_2Ta({=}S)H$ with PhNCS and HCl exhibit a surprisingly low hydride reactivity. The Ta=S bond is involved either in a [2 + 2] cycloaddition giving $(C_5H_4Bu^t)_2Ta(H)[S\text{-}C({=}S)\text{-}NPh]$ or in a protonation yielding $(C_5H_4Bu^t)_2Ta(H)Cl_2$.[95]

Reduction of the allene complex $Cp^*_2Ta_2(\mu\text{-}X)X_3(\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4)$ (X = Cl, Br) with Na/Hg gives $Cp^*_2Ta_2(\mu\text{-}H)_2X_2(\mu\text{-}HCCCH)$ (**23**). The reactions proceed via a double 1,3-C-H activation, with C_3H_2 and two μ-hydride ligands instead of an allenyl hydride.[96]



(**23**)

Selective conversion of an ethylene to an ethylidene ligand in reactions of a $Cp_2Ta(C_2H_4)H$ with iodofluorocarbons has been reported. Reactions of $Cp_2Ta(C_2H_4)H$ with perfluorobutyl iodide or perfluorobenzyl iodide, and perfluoro-*iso*-Pr iodide or pentafluorophenyl iodide are found to yield the ethylene complex $Cp_2Ta(C_2H_4)I$ and the ethylidene complex $Cp_2Ta(CHMe)I$, respectively. No interconversion of these two isomers is observed under these reaction conditions, indicating that each is formed under conditions of kinetic control.[97]

Thermodynamic studies of hydride transfer from $Cp_2M(H)L$, $Cp^*_2M(H)L$, $Cp'_2M(H)L$ [L = CO, PEt_3, $(H)_2$, $PhC{\equiv}CPh$, $CH_2{=}O$, $=O$], and $Cp'_2Nb(Cl)(L')$ (L' =

O=C=CEtPh, O=C=CEt$_2$) to Ar_3C^+ indicate that the free energies of hydride transfer are heavily influenced by coligands, but less so by 4d versus 5d effects in isostructural Nb or Ta complexes.[98]

3.2.3 Heterobimetallic Complexes

Hydride complexes discussed here include both μ-hydride heterobimetallic complexes, and bimetallic complexes with Nb–H or Ta–H ligands.

Reduction of $Cp_2Nb(SiMe_2Cl)H_2$ with $LiAlH_4$ gives $[Cp_2Nb(\mu\text{-}H)_2AlH(\mu\text{-}H)]_2$.[48] Reactions of Cp_2TaH_3 with $M(CO)_6$ also give μ-hydride heterobimetallic complexes $Cp_2TaH_2(\mu\text{-}H)M(CO)_5$ (M = Cr, Mo, W).[99] $[(Cp'_2NbH_3)_2M](PF_6)$ (M = Cu, Ag, Au) are prepared via the reactions of Cp'_2NbH_3 with $[Cu(MeCN)_4]PF_6$, $AgBF_4$, or '$Au(THT)PF_6$'.[100] Tantalum analogues $[(C_5H_4Bu^t)_2TaH_3\text{-}MPPh_3](PF_6)$ (M = Cu, Au) have also been prepared from the reactions of $(C_5H_4Bu^t)_2TaH_3$ with $(MPPh_3)(PF_6)$.[101] NMR studies are consistent with two bridging hydride ligands between the disparate metals centers. $Cp'_2NbH(CO)$ reacts with $[Cu(MeCN)_4]BF_4$, $CuPPh_3Cl/TlPF_6$, $AgBF_4$, $AgPPh_3Cl/TlPF_6$, and $Au(THT)Cl/TlPF_6$, giving $[\{Cp'_2Nb(CO)\}_2(\mu\text{-}H)_2M]^+$ (M = Cu, Ag, Au), whereas the reaction with $[Au(PPh_3)]^+$ leads to $[\{Cp'_2Nb(CO)\}(\mu\text{-}H)Au]PF_6$.[102]

Electrophilic addition of the Lewis acid $B(C_6F_5)_3$ to Cp_2TaH_3 yields $Cp_2TaH_2[\eta^1\text{-}HB(C_6F_5)_3]$.[103] Protonation of $Cp_2TaH(CO)$ by $HBF_4{\cdot}Et_2O$ gives a dihydrogen complex $Cp_2TaH_2(CO)^+BF_4^-$. This complex exists as two isomers. The minor isomer is a *trans*-dihydride, and the major isomer is $[Cp_2Ta(\eta^2\text{-}H_2)(CO)]BF_4$, the first thermally stable group 5 dihydrogen complex. Protonation of the silyl hydride $Cp_2TaH_2(SiMe_2Ph)$ gives a dinuclear complex $[(Cp_2TaH_2)_2(\mu\text{-}H)]\{B[3,5\text{-}(CF_3)_2\text{-}C_6H_3]_4\}$.[104] Organocyclichydroborate complexes of niobiocenes $Cp_2Nb^{III}(\mu\text{-}H)_2BR_2$, where R_2 is, for example, *cyclic*-$(CH_2)_n$- ($n = 4$, 5), are prepared from the reductions of $Cp_2Nb^{IV}Cl_2$ with the hydroborate salts.[105] Reactions of $Cp_2Nb^{III}(\mu\text{-}H)_2B(C_5H_{10})$ with $B(C_6F_5)_3$ are solvent-dependant, yielding cationic $[Cp_2Nb(\mu\text{-}H)(\eta^5,\eta^1\text{-}C_5H_4)Nb(\eta^5,\eta^1\text{-}C_5H_4)_2Nb\{(\mu\text{-}H)(\eta^5\text{-}C_5H_4B(C_6F_5)_2)\}]^+$ in toluene and neutral $CpNb(C_6F_5)\{(\mu\text{-}H)[\eta^5\text{-}C_5H_4B(C_6F_5)_2]\}$ in diethyl ether.[106]

4 ALKYLIDENES AND ALKYLIDYNES

4.1 Synthesis and Complexes

A recent paper by Schrock reviewed chemistry of complexes with high-oxidation-state metal-carbon multiple bonds.[107]

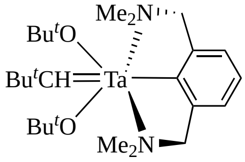
The most common approach to alkylidene (*see Alkylidene*) and alkylidyne (*see Alkylidyne*) complexes involves α-hydrogen abstraction from bis(alkyl) and alkyl-alkylidene complexes to give alkylidenes and alkylidynes, respectively. Short-lived $TaNp_5$ is directly observed as an intermediate in the formation of the first alkylidene $Np_3Ta{=}CHBu^t$ from the alkylation of $TaNp_4Cl$.[108] $Ta(CH_2SiMe_3)_5$, which is less bulky and thus more stable than $TaNp_5$, is isolated. It converts to alkylidene $(Me_3SiCH_2)_3Ta{=}CHSiMe_3$ and then to bridging alkylidyne $(Me_3SiCH_2)_4Ta_2(\mu\text{-}CSiMe_3)_2$. The first and second conversions follow first-order [$\Delta H_1 = 21.6(1.4)\ \text{kcal mol}^{-1}$ and $\Delta S_1 = -5(5)$ e.u.] and second-order kinetics [$\Delta H_2 = 6.2(0.3)\ \text{kcal mol}^{-1}$ and $\Delta S_2 = -61.6(0.8)$ e.u.], respectively.[108] Dialkylation of $[N_3N]TaCl_2$ and $[N_3N^*]TaCl_2$ with RCH_2Li or RCH_2MgCl (R = for example, Et, Pr^n,and Bu^i) yields $[N_3N]Ta{=}CHR$ and $[N_3N^*]Ta{=}CHR$, respectively. Alkylation of $[N_3N]TaCl_2$ and $[N_3N^*]TaCl_2$ with EtMgCl gives ethylene complexes $[N_3N]Ta(C_2H_4)$ and $[N_3N^*]Ta(C_2H_4)$.[109–111] Reactions of $Cp^*Ta(N{=}PR_3)Cl_3$ (R = Bu^t, Pr^i) with $PhCH_2MgCl$ similarly afford $Cp^*Ta(N{=}PR_3)({=}CHPh)(CH_2Ph)$.[112]

Reactions of phenols (ArOH) with $(RCH_2)_4Ta_2(\mu\text{-}CR)_2$ (R = $SiMe_3$) lead to the substitution of an alkyl ligand to give $(ArO)(RCH_2)_3Ta_2(\mu\text{-}CR)_2$. Such a reaction follows second-order kinetics with a strong kinetic isotope effect (k_H/k_D), and the rates strongly depend on the nature of the phenol substituents.[113]

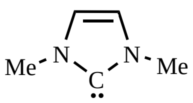
The alkylidenes or alkylidynes can also be prepared by the intermolecular deprotonation reactions. Reaction of $[PhC(NSiMe_3)_2]TaCl(CH_2Ph)_3$ with $LiN(SiMe_3)_2$ affords $[PhC(NSiMe_3)_2]Ta({=}CHPh)(CH_2Ph)_2$.[24] An unusual alkylidene complex $CpTa(NEt_2)_2({=}C_5H_4)$ was prepared from the reaction of $CpTa(NEt_2)_2Cl_2$ with MeLi.[114]

Phosphorus ylides (*see Ylide*) are useful reagents to introduce alkylidene groups to Nb or Ta complexes. $Ph_3P{=}CH_2$ reacts with $Cp_2M({=}NBu^t)Cl_2$ (M = Ta, Nb) yielding $Cp_2M({=}NBu^t)(CHPPh_3)Cl$. Treatment of the Nb complex with an excess of $Ph_3P{=}CH_2$ leads to $Cp_2Nb({=}NBu^t)(CHPPh_3)_2$.[115]

Alkene metathesis (*see Alkene Metathesis*) reactions have also been used to give isolable alkylidenes. Reactions of $Ta({=}CHBu^t)[NCN](OBu^t)X$ (X = Cl, **24a**; OBu^t; **24b**) with $Me_3SiCH{=}CH_2$ afford $Ta({=}CHSiMe_3)[NCN](OBu^t)X$ stabilized by *ortho*-chelating arylamine ligands.[116]



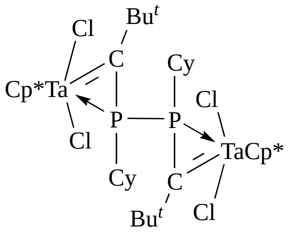
(**24b**)



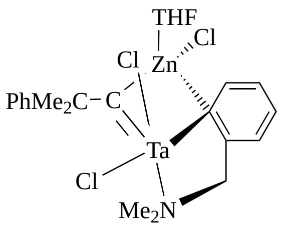
(**25**)

Several other approaches have led to the formation of alkylidene and carbene complexes. Substitution of pyridine ligands in $MCl_4(py)_2$ by nucleophilic cyclocarbene 1,3-dimethylimidaxolin-2-ylidene (**25**) gives MCl_4L_2.[117]

Rearrangement of the ethylene ligand in $[N_3N]Ta(H_2C{=}CH_2)$ affords $[N_3N]Ta{=}CHMe$, and this reaction is catalyzed by $PhPH_2$.[109,110] Reaction of Cp^*TaCl_4 with phosphavinyl Grignard reagent (*Z*)-MgCl{C(Bu^t)=PCy} gives a novel bis(phosphinoalkylidene) complex {Cp*TaCl$_2$-[=C(Bu^t)-P(Cy)-]}$_2$ (**26**).[118]

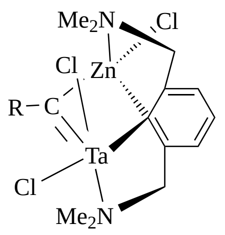


(**26**)



(**27**)

Bimetallic complexes containing bridging alkylidene and alkylidyne ligands have been prepared using alkylating reagents. Ta–Zn neophylidyne {[TaCl$_2$(μ-CCMe$_2$Ph)(μ-Cl)(THF)$_2$][Zn(μ-Cl)]}$_2$ is a good starting material for the synthesis of alkylidynes such as the Ta–Zn neophylidynes (**27**) and (**28a**), where the alkylidyne functionality and the aryl ipso-carbon bridge between the Zn and Ta centers. The reaction of TaCl$_2$[NCN](=CHBu^t) with NpZnCl affords (**28b**), an analog of (**28a**).[41] (**28a-b**) react with TMEDA leading to C–H activation of the methyl group in –NMe$_2$, a subject discussed in Section 9.1.[119]



(R = CMe$_2$Ph, **28a**; Bu^t, **28b**)

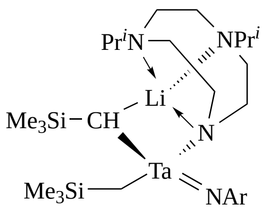
4.2 Reactions

The reactions of alkylidenes (*see Alkylidene*) and alkylidynes (*see Alkylidyne*) of niobium and tantalum are typically characterized by nucleophilic alkylidene and alkylidyne ligands. Cp*Ta(CH$_2$SiMe$_3$)$_2$(=CHSiMe$_3$) reacts with PhOH to give alkyl phenoxo Cp*Ta(CH$_2$SiMe$_3$)$_3$(OPh), and is hydrolyzed in the presence of a trace amount of H_2O to give the oxo dialkyl derivative [Cp*Ta(CH$_2$SiMe$_3$)$_2$O]$_n$.[120]

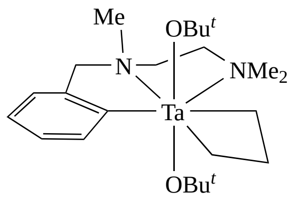
Nb and Ta alkylidenes readily undergo metathesis reactions (*see Alkene Metathesis*) with carbonyl functionalities or imines to form alkene and M=O or M=NR bonds. Reactions of (Me$_3$SiCH$_2$)(ArN=)Ta(μ-CHSiMe$_3$)(μ-η^1:η^3-Pr$^i{}_2$-tacn)Li (Pr$^i{}_2$-tacn$^-$ = anionic triazacyclononane, **29**) with Ph$_2$C=O give [(Me$_3$SiCH$_2$)(RN=)Ta(μ-O)(μ-η^1:η^3-Pr$^i{}_2$-tacn)Li]$_2$.[121]

In some cases, hydrogenation of the alkylidenes and alkylidynes reduces the metal-carbon multiple bonds to single bonds. The alkylidene ligand in (**29**) is converted to an alkyl group when exposed to H_2, leading to the formation of an interesting tantalum–lithium bridging hydride complex.[122]

The reactions of alkylidene with alkenes typically afford metallacyclic complexes (*see Metallacycle*), a subject discussed in Section 6.1. Ta(=CHR)[CNN](OBu^t)$_2$ (R = Bu^t, **30a**; CMe$_2$Ph, **30b**) reacts with ethene to afford the tantalacyclobutane complex Ta[(CH$_2$)$_3$-1,3][CNN](OBu^t)$_2$ (**31a**) at room temperature. Under heating, (**30b**) reacted with ethene to give Ta[CNN](OBu^t)$_2$(H$_2$C=CH$_2$).[123]



(**29**) Ar = 2,6-Pr$^i{}_2$-C$_6$H$_3$



(**31a**)

Reactions of [TolC(NSiMe$_3$)$_2$]$_2$Ta(=CH$_2$)Me with pyridine N-oxides proceed via regioselective methylene transfer to afford 2-methylpyridines and [TolC(NSiMe$_3$)$_2$]$_2$-Ta(=O)CH$_3$, while the reaction with the nitrone PhCH=N($\rightarrow$O)Bu^t leads to [TolC(NSiMe$_3$)$_2$]$_2$Ta(=O)(NMeBu^t) and PhCH=CH$_2$.[124]

The mechanism of H_2 addition to Cp*$_2$Ta(=CH$_2$)H has been studied using parahydrogen-induced polarization (PHIP), ^{13}C labeling, and comparison to the related complex Cp*$_2$Ta(=CH$_2$)Me. The reaction of *para*-enriched H_2 with labeled Cp*$_2$Ta(=^{13}CH$_2$)H leads to polarized resonances for both Cp*$_2$TaH$_3$ and Cp*$_2$Ta(CH$_3$)H$_2$, where the polarized resonances correspond to the two hydride ligands. The results thus support a pathway of H_2 addition to a Ta(III) intermediate Cp*$_2$TaCH$_3$, rather than addition directly across the Ta=C bond.[125]

Surface chemistry of the alkyl/alkylidene complexes has been studied by ^{13}C CPMAS NMR spectroscopy. Cp$_2$Ta(=^{13}CH$_2$)(^{13}CH$_3$) is converted predominantly to a stable cation-like Cp$_2$Ta(^{13}CH$_3$)$_2{}^+$ species on partially dehydroxylated SiO_2 (PDS) presumably via electrophilic addition of a proton from the PDS surface. The formation of cation-like Cp$_2$Ta(^{13}CH$_3$)$_2{}^+$ and CpTa(^{13}CH$_3$)$_3{}^+$ is observed when Cp$_2$Ta(^{13}CH$_3$)$_3$ and CpTa(^{13}CH$_3$)$_4$ are chemisorbed on PDS and dehydroxylated SiO_2 (DS),

and on dehydroxylated γ-alumina, respectively. In comparison, $(Bu^t{}^{13}CH_2)_3Ta{=}^{13}CHBu^t$ forms predominantly a $Ta(^{13}CHBu^t)(^{13}CH_2Bu^t)_2O$-Si, μ-oxo-alkylidene species on PDS.[126]

The conversion of NH_3 and pentamer $[Np_2TaN]_5$, which had been prepared from $Np_3Ta{=}CHBu^t$ and NH_3, to cubic $TaN_{0.8}$ is found to proceed via precipitate $1/n[TaC_{1.41}H_{3.90}N_{1.90}]_n$ at 80 °C and amorphous TaN at 400 °C. The latter was then converted to cubic $TaN_{0.8}$ at 820 °C.[127]

5 η^2-COMPLEXES

5.1 Alkene Complexes

Alkene complexes of niobium and tantalum are of great interest in large part because they are implicated in polymerization, metathesis, and dimerization reactions of alkenes (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis*** and ***Metathesis Polymerization Processes by Homogeneous Catalysis***). Nb and Ta alkene complexes are usually prepared from: (i) direct alkene coordination to metal centers. Substitution of the 4-picoline ligand in $(silox)_3Nb(\eta\text{-}C,N$-4-picoline) by COT, followed by dehydrogenation, gives the cyclooctatrieneyne complex $\{(silox)_3Nb\}_2(\eta$-1,2;η-5,6-$C_8H_6)$. Treatment of this complex with H_2 leads to a rearrangement to the alkylidene-yne $\{(silox)_3Nb\}_2(\eta^1;\eta^2$-4,5-$C_8H_6)$.[128] (ii) β-Hydrogen abstraction (*see α-Elimination*) in dialkyl complexes. One such example is the reaction of $[N_3N]TaCl_2$ with 2 equiv of EtMgCl to give $[N_3N]Ta(H_2C{=}CH_2)$.[109,110] The presence of a catalytic amount of $PhPH_2$ leads to the conversion of $[N_3N]Ta(H_2C{=}CH_2)$ to the ethylidene complex $[N_3N]Ta{=}CHMe$.[110] Alkylation of $Cp^*Ta(NPR_3)Cl_3$ ($R = Bu^t$, Pr^i) with 2 equiv of EtMgCl results in formation of $Cp^*Ta(NPR_3)(\eta^2\text{-}C_2H_4)Cl$. Substitution of the remaining chloride by EtMgCl affords $Cp^*Ta({=}NPBu^t{}_3)(\eta^2\text{-}C_2H_4)(Et)$.[112] (iii) β-Hydride elimination in unsaturated d^3 complexes. The olefin-hydride complexes *endo*-$Cp'_2Nb(H)$-$(\eta^2\text{-}RHC{=}CH_2)$ (R = H, Ph) are prepared by alkylation of $(Cp'_2NbCl)_2$ with RCH_2CH_2MgX followed by a stereoselective β-H elimination from $Cp'_2Nb(CH_2CH_2R)$. In comparison, reactions of Cp'_2NbH_3 with styrene or other olefins give a mixture of *endo*- and *exo*-isomers.[85,86] Similarly, $Cp'_2NbR'[\eta^2\text{-}(C,Z)$-ZCCRPh] (Z = NPh, R = Ph, Me, Et, H; Z = O, R = Ph; R′ = H, Me, Et), prepared from $Cp'_2NbCl[\eta^2\text{-}(C,Z)$-ZCCRPh] and R′MgI or R'_2Mg, readily undergo the loss of the ketene ligand and subsequent β-hydride elimination to form $Cp'_2NbH(\eta^2\text{-}CH_2{=}CH_2)$.[129] (iv) Reductive addition of alkynes to the hydride complexes. $Cp'_2Nb(H)[\eta^2\text{-}RO_2C(H){=}C(H)CO_2R]$ ($R = Me$, Bu^t) and $Cp'_2Nb(H)(\eta^2\text{-}MeO_2CH{=}CH_2)$ are prepared from Cp'_2NbH_3 and active alkynes $RO_2CC{\equiv}CCO_2R$ or $MeO_2CC{\equiv}CH$.[38]

Substitution of two chloride ligands in $[\eta^5\text{-}C_4H_4BN(CHMe_2)_2]TaCl_3$ by methylcyclopentadienyl $MeC_5H_4^-$ affords η^2 borollide $(MeC_5H_4)_2[\eta^2\text{-}C_4H_4BN(CHMe_2)_2]TaCl$.[12]

5.2 Alkyne and Benzyne Complexes

Nb and Ta alkyne complexes are of interest in part because they have found use in organic synthesis and cyclooligermerization (*see Cyclodimerization & -trimerization Reactions*) of alkynes.

5.2.1 Alkyne Complexes without Cyclopentadiene Ligands

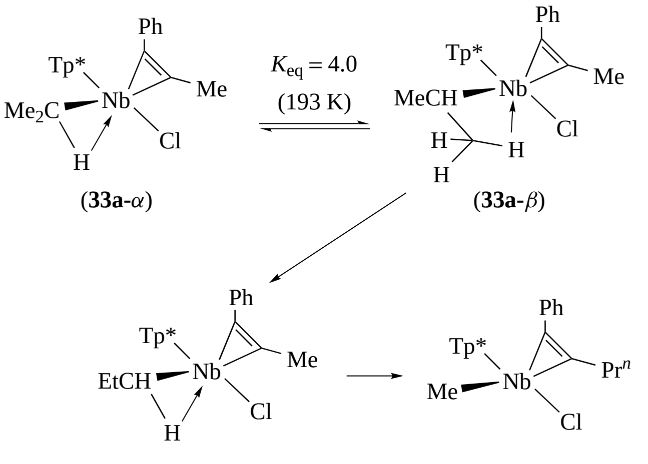
Reactions of low-valent Nb and Ta complexes with alkynes are one of the simplest methods to prepare the alkyne complexes. Substitution of a CO and PR_3 ligand in $INb(CO)_3(PR_3)_3$ by diynes gives $INb(CO)_2(PR_3)_2$(diyne) ($PR_3 = PEt_3$; diyne = 2,4-hexadiyne, 1,5-hexadiyne; $PR_3 = PMe_2Ph$, diyne = 2,6-octadiyne). When $Ph_2PCCPPh_2$ is used, its reaction with $INb(CO)_3(PMe_2Ph)_3$ affords $INb(CO)_2(PMe_2Ph)_2(Ph_2PC{\equiv}CPPh_2)$.[130] $[Nb(\eta^2\text{-}F_3CC{\equiv}CCF_3)(py)Br_4]^-$ is obtained from the reaction of $[Nb(CO)_6]^-$, $F_3CC{\equiv}CCF_3$, and [Hpy]Br.[131] Treatment of alkynes with low-valent Ta species derived from the reduction of $TaCl_5$ with Zn yields $TaCl_3(R^1C{\equiv}CR^2)$(dme) (R^1 = Et, $n\text{-}C_5H_{11}$, Ph; R^2 = Et, $n\text{-}C_5H_{11}$, Me, Ph).[132] Tp^*NbCl_2(alkyne) (alkyne = $PhC{\equiv}CMe$, $PhC{\equiv}CEt$, $PhC{\equiv}CPr^n$, $MeC{\equiv}CMe$, $PhC{\equiv}CPh$) have been prepared from the high-yield, one-pot reaction of $NbCl_3$(DME) first with an alkyne and then with KTp^*.[133,134] Alkyne adducts $Tp^*Nb(CO)(PhC{\equiv}CMe)(L)$ (L = RCN, PMe_2Ph) have also been prepared by ligand exchanging reactions. $PhC{\equiv}N$ is thermally displaced from $Tp^*Nb(CO)(PhC{\equiv}CMe)(PhC{\equiv}N)$ by $PhC{\equiv}CMe$ to give $Tp^*Nb(CO)(PhC{\equiv}CMe)_2$.[135]

β-Hydrogen abstraction from η^1-alkene ligands is another method to yield alkyne complexes. $[N_3N]Ta(C_2H_2)$ is obtained, for example, from the reaction of $[N_3N]TaCl_2$ with 2 equiv of $CH_2{=}CHMgBr$.[110]

Unique reversible migratory insertion/β-alkyl elimination (*see Migratory Insertion*) in Nb alkyl alkyne complexes has been reported. $Tp^*Nb(Cl)(CH_2R)(PhC{\equiv}CMe)$ (R = Me, **32a**; Et, **32b**; $SiMe_3$, **32c**) undergo a thermally induced, first-order rearrangement, yielding methyl complexes $Tp^*Nb(Cl)(Me)(PhC{\equiv}CCH_2R)$ (**32d-f**), respectively. $Tp^*Nb(Cl)(Pr^n)(PhC{\equiv}CEt)$ is in a 1:1 equilibrium with $Tp^*Nb(Cl)(Et)(PhC{\equiv}CPr^n)$. $Tp^*Nb(Cl)(Et)(PhC{\equiv}CEt)$ reacts with $PhC{\equiv}CMe$ yielding $Tp^*Nb(Cl)(\eta^1\text{-}CPh{=}CEt_2)(PhC{\equiv}CMe)$, demonstrating that alkyl migration is a key step of the rearrangement. Kinetic and trapping studies indicate that the migratory insertion of the alkyl group onto the alkyne is the rate-determining step of the reactions.[136]

The *iso*-propyl complex $Tp^*Nb(Cl)(Pr^i)(PhC{\equiv}CMe)$ (**33a**) exhibits an unusual equilibrium between its β- (**33a**-β)

and minor α-agostic (*see Agostic Bonding*) rotamer (**33a**-α) in solution ($\Delta G^{\neq}{}_{193\,K} = 11.4 \pm 0.6\,kcal\,mol^{-1}$; $\Delta G^{\circ}{}_{193\,K} = -0.53\,kcal\,mol^{-1}$) as the result of the restricted rotation about the Nb–C bond. This is a case that steric factors overcome the intrinsic electronic preference for the β-agostic structure. In solid state, the β-agostic isomer (**33a**-β) is observed. This secondary alkyl complex thermally rearranges via a first-order reaction ($\Delta G^{\neq}{}_{323\,K} \approx 25.8\,kcal\,mol^{-1}$) to the linear, α-agostic n-propyl isomer Tp*Nb(Cl)(Pr^n)(PhC≡CMe) (**33b**), which undergoes another first-order isomerization ($\Delta G^{\neq} = 27.0\,kcal\,mol^{-1}$) to methyl complex (**33e**).[137] In the cyclopropyl complex Tp*Nb(Cl)(*cyclo*-C_3H_5)(MeC≡CMe), an unprecedented α-C–C agostic interaction is observed to be preferred over both α- and β-C–H agostic alternatives.[138]



(**33a**-α) (**33a**-β) (**33b**) (**33e**)

5.2.2 *Cyclopentadienyl Alkyne Complexes*

Reduction of niobocene dichlorides in the presence of RC≡CR is one common path to niobocene alkyne complexes such as Cp_2Nb^V(RC≡CR)Cl,[139–141] and Cp'_2Nb^{IV}(η^2-RC≡CR).[142] Direct reactions of $Cp'_2Nb^{III}Cl$ with the diynes or alkyne-alkenes give, for example, $Cp'_2NbCl[\eta^2(C,C)$-PhC≡$CCH_2CH{=}CH_2$]. Hydrogenation of the enyne-containing products occurs at the C=C bond using Pd/C as catalyst to give the alkyne complexes such as $Cp'_2NbCl[\eta^2(C,C)$-PhC≡$CCH_2CH_2CH_3$].[143]

The deprotonation with BuLi at the propargylic site of the coordinated alkyne in Tp′Nb(Cl)(X)(PhC≡CMe) (X = Cl, OMe) followed by the reaction with MeI or $PhCH_2Br$ affords the alkylated alkyne complexes Tp′Nb(Cl)(X)(PhC≡CCH_2R) (R = Me, CH_2Ph). Adding $PhCH_2Br$ and MeI to the deprotonated Tp′Nb(Cl)-(OMe)(PhC≡CCH_2Me) and Tp′Nb(Cl)(OMe)(PhC≡CCH_2CH_2Ph), respectively, gives 4:1 and 1:6 diastereomeric mixtures of Tp′Nb(Cl)(OMe)[PhC≡CCHMe(CH_2Ph)].[144]

5.2.3 *Benzyne Complexes*

Benzyne complexes contain η^2-benzyne, a moiety not stable in its free state, and are relatives of the alkyne complexes. Several methods have been used to prepare these complexes. Refluxing $[N_3N]TaCl_2$ with PhLi affords $[N_3N]Ta(C_6H_4)$.[110] Thermolysis of the methyl phenyl complex Cp*TaMe(Ph)(η^4-butadiene) gives the benzyne complex Cp*Ta(η^4-butadiene)(η^2-C_6H_4), the first example of the parent benzyne complex bearing a metallocene-like MCp(diene) fragment.[145] The η^2-benzyne complex CpTa(η^2-C_6H_4)(PMe_3)($Et_2C_2B_4H_4$) (**34**), an analogue of tantalocenes, is prepared from $CpTaPh_2(Et_2C_2B_4H_4)$ and excess PMe_3. In a striking demonstration of the electronic influence of the carborane ligand, the properties of (**34**) contrast dramatically with those of normal metal (η^2-benzyne) complexes. (**34**) is air-stable, does not undergo coupling with unsaturated substrates such as acetone, and is not protonated by MeOH.[146]

The mechanism of H_2 addition to benzyne complex $Cp^*{}_2Ta(\eta^2$-$C_6H_4)H$ has been investigated by parahydrogen-induced polarization (PHIP). This hydrogenation (*see Hydrogenation*) gives $Cp^*{}_2Ta(Ph)H_2$, which then adds another equiv of H_2 to give Cp^*TaH_3. Addition of *para*-H_2 leads to strong polarization in the hydride resonances of $Cp^*{}_2Ta(Ph)H_2$, providing evidence for a 16-electron intermediate in the reaction. In the formation of Cp^*TaH_3 with *para*-H_2, polarization of the hydride resonances is observed. D-labeling studies also indicate H_2 addition to the 16-electron monohydride '$Cp^*{}_2TaH$' intermediate. This work provides definitive evidence of pairwise, concerted H_2 oxidative addition to two Ta^{III} complexes in the hydrogenation reactions.[147]

5.3 η^2-Acyls, η^2-Iminoacryls, and Related Complexes

The η^2-acyls, η^2-iminoacryls and related complexes originate from the migratory insertion (*see Migratory Insertion*) of C≡O or isocyanides C≡NR into a metal–alkyl bond. These complexes are of interest mainly because of their relevance to catalytic CO reduction and the C–C bond formation in Fischer–Tropsch (*see Fischer–Tropsch Process*) reactions.

A large number of η^2-iminoacyl complexes have been reported. A series of η^2-iminoacyl derivatives CpMX(NXyl)[η^2-C(R)=NXyl] (X = Cl, R) are prepared by reactions of chloro alkyl or dialkyl imides CpMX(R)(NXyl) with 1 equiv of CNXyl. Reaction of Cp*TaRMe(NXyl) with CNXyl involves the migration of alkyl or Me group, giving a mixture of Cp*TaMe(NXyl)[η^2-C(R)=NXyl] and Cp*TaR(NXyl)[η^2-C(Me)=NXyl].[22] The following complexes are prepared similarly: Cp*Ta(CH_2SiMe_3)($CHSiMe_3$)-[η^2-C(CH_2SiMe_3)=NXyl],[120] Cp*Ta(η^2-MeCNR)(η^2-PhCCPh)Me (R = Bu^t, Me),[148] Cp*TaR(η^2-CR=NXyl)-(NXyl) (R = Et, Pr^n),[149] and $Cp'_2Ta[\eta^2$-Bu^{t}N=$CCH_2B(C_6F_5)_3$].[150]

The carborane (*see Carborane*) complex $(Et_2C_2B_4H_4)$-$CpTaMe_2$ is found to undergo insertion reactions with isocyanides under UV-visible irradiation to afford both isomers of $(Et_2C_2B_4H_4)CpTaMe[\eta^2\text{-}C,N\text{-}C(=NR)Me]$ (R = Bu^t, Xyl). The isomers interconvert under heat. The diphenyl complex $(Et_2C_2B_4H_4)CpTaPh_2$ generally reacts at elevated temperatures to give only one isomer of $(Et_2C_2B_4H_4)CpTaPh[\eta^2\text{-}C,N\text{-}C(=NXyl)Ph]$.[151]

Reactions of $Cp^*TaMe_2X_2$ [$X_2 = Cl_2$, $(SCH_2CH_2)_2O$] with 1 equiv of isocyanides occur with double migration of Me, giving imine complexes $Cp^*TaX_2(\eta^2\text{-}Me_2CNR)$ [R = Xyl, 2,4,6-Me_3-C_6H_2, $X_2 = Cl_2$;[152,153] R = Xyl, $X_2 = (SCH_2CH_2)_2O$].[29] Mono- and dimethylated imines $Cp^*TaCl_nMe_{2-n}(\eta^2\text{-}XylN{=}CMe_2)$ were similarly prepared. They react with second equiv of isocyanide to give imido alkenylamido species $Cp^*TaX(=NXyl)(NR'CMe{=}CMe_2)$ (X = Cl, Me; R′ = Xyl, 2,4,6-$Me_3C_6H_2$, **35**). Reactions of (**35**) with third equiv of R″NC (R″ = Xyl, 2,4,6-$Me_3C_6H_2$, Bu^t) afford η^2-imino acyl compounds $Cp^*TaX(=NXyl)(\eta^2\text{-}NR''{=}CCMe_2CMe{=}NR')$.[154] It is interesting to note that insertion of CNXyl into the Ta–Me bond in $Cp^*Ta(=NBu^t)Me(NR_2)$ (R = Ph, $SiMe_3$) gives $Cp^*Ta(=NBu^t)(NR_2)[\eta^1\text{-}C(Me){=}NXyl]$, and CNXyl inserts into the Ta–N bond in $Cp^*Ta(=NBu^t)Me(NMeR)$ (R = H, Me) to give $Cp^*Ta(=NBu^t)Me[\eta^2\text{-}C(NRMe){=}NXyl]$.[155] When the reaction of $Cp^*TaMe_2Cl_2$ with CNXyl is carried out in the presence of a trace amount of H_2O, a cyclic η^2-amido-carbene species $Cp^*TaCl_3[\eta^2\text{-}N(Xyl)CMe_2CNHR]$ was produced.[154] η^2-Iminoacyl complexes $Cp^*Ta(NBu^t)(NHBu^t)\{\eta^2\text{-}C(Me){=}NR\}$ react with one equiv of CNXyl to give the double insertion imine-η^2-iminoacyl complexes $Cp^*Ta(NBu^t)(NHBu^t)\{\eta^2\text{-}C[C(Me){=}NR]{=}NR\}$, which when heated undergo an intramolecular H migration to yield η^2-diamidoalkenes $Cp^*Ta(NBu^t)\{\eta\text{-}NBu^t\text{-}C(NHR){=}C(Me)\text{-}\eta\text{-}NR\}$.[156]

In the reactions of $(Me_2S)_2Cl_4Ta_2(\mu\text{-}Me_2S)(\mu\text{-}Cl)_2$ with formamidinate anions, $[ArNC(H)NAr]^-$, C–N bond cleavage is observed. The reaction of $[PhNC(H)NPh]^-$ ($DPhF^-$) with $(Me_2S)_2Cl_4Ta_2(\mu\text{-}Me_2S)(\mu\text{-}Cl)_2$ and Zn yields the CNPh-containing compound $(\eta^2\text{-}DPhF)_2Ta(\mu\text{-}NPh)(\mu\text{-}\eta^2\text{-}CNPh)Ta(\eta^2\text{-}DPhF)_2$. When $[TolNC(H)NTol]^-$ ($DTolF^-$) and Na/Hg are used, the isolated product is $(\eta^2\text{-}DTolF)Ta(\mu\text{-}NTol)(\mu\text{-}\eta^2\text{-}CNTol)(\mu\text{-}DTolF)_2Ta(\eta^2\text{-}DTolF)$. In the absence of a reducing agent, the reaction with LiDTolF produces $Cl_2(\eta^2\text{-}DTolF)Ta(\mu\text{-}NTol)(\mu\text{-}\eta^2,\eta^2\text{-}HCNTol)Ta(\eta^2\text{-}DTolF)_2$ in which a tolylformimidoyl fragment ($HCNTol^{3-}$) binds to the Ta atoms through both C and N atoms in an η^2,η^2 mode.[157]

5.4 CO_2, Isocyanate, and Related Complexes

Olefin-hydride complexes such as $Cp'_2Nb(H)(\eta^2\text{-}H_2C{=}CH_2)$ react with CO_2 to afford, for example, $Cp'_2Nb(Et)(\eta^2\text{-}CO_2)$ (**36**). When $B(C_6F_5)_3$ is added to (**36**), the adduct $Cp'_2Nb(Et)[\eta^2\text{-}CO_2\text{-}B(C_6F_5)_3]$ is yielded in the first step, which subsequently evolves to give the oxo-alkyl complexes $Cp'_2Nb(Et)[O\text{-}B(C_6F_5)_3]$ with the loss of CO.[86] Upon heating, the coordinated CO_2 ligand in $(MeC_5H_4)_2Nb(\eta^2\text{-}CO_2)(CH_2R)$ (R = $SiMe_3$, Bu^t, Ph, H) splits, giving $(MeC_5H_4)_2Nb(=O)(CH_2R)$ and CO.[158] As in the formation of (**36**), reactions of CS_2 with $Cp'_2Nb(H)(\eta^2\text{-}RHC{=}CH_2)$ (R = H, Ph) afford $Cp'_2Nb(\eta^2\text{-}CS_2)(CH_2CH_2R)$. Interaction of $Cp'_2NbX(\eta^2\text{-}CS_2)$ (X = Cl, carboxylate) with alkynes $R'C{\equiv}CR'$ bearing electron-withdrawing groups gives 1,3-dithiol-2-ylidene complexes $Cp'_2NbX[=CS(R')C{=}C(R')S]$.[159]

Nb and Ta complexes with other η^2-ligands such as η^2-COS, η^2-OCN and η^2-COTe have also been reported. $(Cp'_2NbCl)_2$ reacts with phenyl isocyanate PhN=C=O to give the adduct $Cp'_2NbCl(\eta^2\text{-}N,C\text{-}OCNPh)$. Similar dinuclear adducts are obtained from the reactions of $(Cp'_2NbCl)_2$ with 1,3- and 1,4-phenylenedi-isocyanate.[160]

5.5 Ketene and Ketenimine Complexes

Complexation of the ketene C=O bonds in, for example, $Cp'_2Nb(Cl)[\eta^2\text{-}O{=}C{=}CMe_2]$ (**37**) is usually observed. Ketene complexes are prepared from coordination of ketenes to Cp'_2NbCl[161] or deprotonation of η^2-acyl in $Cp'_2NbCl(\eta^2\text{-}O{=}C\text{–}CHEtPh)$.[162] Treatment of (**37**) with $(Ph_3C)(BF_4)$ leads to γ-hydride abstraction to give η^2-enacyl salts $[Cp'_2Nb(Cl)(\eta^2\text{-}OCCMe{=}CH_2)](BF_4)$.[163] The ketene complex $Cp'_2Nb(H)(\eta^2\text{-}C,O\text{-}O{=}C{=}CPh_2)$ reacts with MeCN or Bu^tNC to yield isocyanate and $Cp'_2Nb(H)(=C{=}CPh_2)$.[164] A synthetic strategy involving sequential hydride abstraction and proton abstraction has been developed to convert the η^2-*C*, *O* ketene ligand in $Cp'_2Nb(Cl)(\eta^2\text{-}OC{=}CREt)$ (R = Ph, Et) into a vinylketene ligand $\eta^2\text{-}OC{=}C(R)CH{=}CH_2$. These are the first vinylketene complexes exhibiting the η^2-C,O bonding mode.[165]

Ketenimine complexes such as $Cp'_2NbCl(\eta^2\text{-}C,N\text{-}Ph_2C{=}C{=}NPh)$ (**38**) reacts with $HBF_4{\cdot}OEt_2$ to give η^2-iminoacyl $[Cp'_2NbCl(\eta^2\text{-}C,N\text{-}Ph_2CHC{=}NPh)]^+$ BF_4^-.[166] Reduction of (**38**) with Na/Hg yields $Cp'_2Nb^{IV}(\eta^2\text{-}C,N\text{-}Ph_2C{=}C{=}NPh)$, which is oxidized by Cp_2Fe^+ in the presence of nitriles or isonitriles L to give $[Cp'_2Nb(\eta^2\text{-}C,N\text{-}Ph_2C{=}C{=}NPh)(L)]^+$, cationic derivatives of (**38**).[167]

5.6 Ketone, Aldehyde, Imine, and Related Complexes

Ketone and aldehyde complexes have been prepared from deprotonation of the relatively strong C–H acid $Cp'_2Nb(Cl)(OMe)^+$ to give $Cp'_2Nb(Cl)(\eta^2\text{-}OCH_2)$,[162] reaction of $Nb(NPr^iAr)_3Cl$ (Ar = 3,5-Me_2-C_6H_3) with $O{=}CPh_2$ to yield $Nb(\eta^2\text{-}OCPh_2)(NPr^iAr)_3$,[168] and double migration of alkyl groups in $Ta\{p\text{-}Bu^t\text{-}calix[4]\text{-}(OMe)(O)_3\}R_2$ (R = Me, Bz, p-MeC_6H_4, η^3-allyl **39**) in their reactions with CO to form $(calix[4]OMe)Ta(\eta^2\text{-}OCR_2)$. Reactions of (**39**) with

Bu^tNC yields related imine complexes (calix[4]OMe)Ta(η^2-$Bu^tN{=}CR_2$).[169,170] Although butadiene is π^2,η^4-bonded to the metal in Ta{p-Bu^t-calix[4]-(OMe)(O)$_3$}(η^4-C_4H_6), it behaves as if it were η^4,σ^2-π bonded in the migratory insertion reaction with Bu^tNC to afford an η^2-imine derivative.[169]

The η^2-formaldehyde complex $Cp'_2Nb(Cl)(\eta^2\text{-}CH_2O)$ undergoes facile Na/Hg reduction to produce the radical $Cp'_2Nb^{IV}(\eta^2\text{-}CH_2O)$, which then reacts with H_2 to give $Cp'_2Nb^{V}({=}O)Me$. In the presence of added alcohol, this reduction yields diamagnetic hydride $Cp'_2Nb(H)(\eta^2\text{-}CH_2O)$.[171]

Telluroformaldehyde complex $Cp^*_2Ta(\eta^2\text{-}TeCH_2)H$ (**40**) is prepared by the PMe_3-catalyzed addition of Te to the $Ta{=}CH_2$ in $Cp^*_2Ta({=}CH_2)H$. (**40**) is converted to its more stable isomer $Cp^*_2Ta({=}Te)CH_3$ under heating.[84]

5.7 η^2-Arene, η^2-Pyridine, and Related Complexes

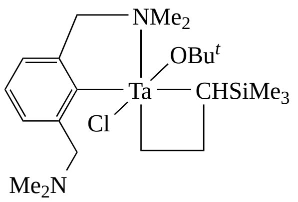
In contrast to some η^2-C,C-heterocycles containing other metals, Nb and Ta prefer to bind N-heterocycles in the η^2-C,N mode. The very first complex of this type, (silox)$_3$Ta(η^2-N,C-py), was reported by Wolczanski and coworkers in 1988.[172] Its Nb analogs (silox)$_3$Nb(η^2-N,C-L) (L = py, 4-picoline, 3,5-lutidine) are prepared by reduction of (silox)$_3NbCl_2$ with Na/Hg in pyridine or 4-picoline.[173–175] Heating the pyridine and lutidine adducts leads to the cleavage of the C=N bond. Similar reduction of (silox)$_2TaCl_2(NR_2)$ (NR_2 = pyrrolidide, piperidide) with Na/Hg in pyridine gives (silox)$_2Ta(NR_2)$(η^2-N,C-py), which react with $MeNH_2$ to yield imides (silox)$_2Ta(NR_2)({=}NMe)$.[175] Reduction of $(ArO)_3TaCl_2(\eta^1\text{-}N\text{-}L)$ (L = quinoline, 6-methylquinoline; Ar = 2,6-Pr^i_2-C_6H_3) leads to an $\eta^1(N) \rightarrow \eta^2(N,C)$ bonding rearrangement to give $(ArO)_3Ta(\eta^2\text{-}N,C\text{-}L)$.[176] Reaction of $NbCl_4(THF)_2$ with $LiNCy_2$ leads to the formation of imine Nb(η^2-N,C-CyN=C_6H_{10})$(NCy_2)_2Cl$ containing one metallated cyclohexyl ring.[177]

6 METALLACYCLIC COMPLEXES

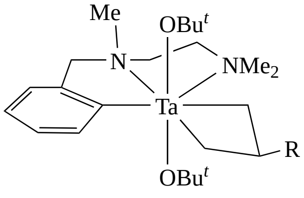
Metallacyclic (*see Metallacycle*) complexes of niobium and tantalum play an important role in understanding several catalytic and stoichiometric transformations of organic compounds. Some group 5 metallacycles are formed from the inter- or intramolecular hydride abstraction reactions. Most of the Nb and Ta metallacycles are prepared, however, from reductive coupling (*see Reductive Coupling*) of unsaturated organic substrates. To be included in this section, the metallacyclic ligand must have at least one M–C bond.

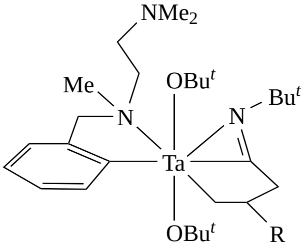
6.1 Metallacyclobutanes and Other Four-member Rings

Metallacyclobutanes are important intermediates in alkene metathesis (*see Alkene Metathesis*). Many Ta and Nb alkylidene complexes do not readily afford metathesis products upon reactions with alkenes. These reactions often lead to the formation of metallacyclobutanes. The alkylidene $Ta({=}CHSiMe_3)[NCN]Cl(OBu^t)$ is prepared from the metathesis of $Ta({=}CHBu^t)(NCN)Cl(OBu^t)$ (**24a**, Section 4.1) with $CH_2{=}CHSiMe_3$, and yet it does not undergo further metathesis with ethene. This reaction instead leads to the formation of the tantalacyclobutane complex (**41**).[116] Similarly, the dialkoxides $Ta({=}CHBu^t)[CNN](OBu^t)_2$ (**30b**) reacts with ethene to afford the tantalacyclobutane (**31a**) (Section 4.2).[123] (**30b**) and (**31a**) initiate ring-opening metathesis polymerization (*see Ring Opening Metathesis Polymerization Reactions*) of strained cyclic olefins such as dicyclopentadiene and norbornene. Metathesis of (**31a**) with propene and styrene gives substituted tantalacyclobutane complexes (**31b-c**). Insertion of Bu^tNC into the Ta–C bonds in (**31a–c**) affords $Ta[C({=}NBu^t)CH_2CHRCH_2\text{-}1,4][CNN](OBu^t)_2$ (R = H, Me, Ph, **42a–c**).[178]



(**41**)

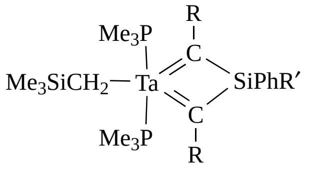




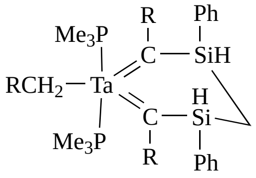
R = H, Me, Ph

(**31a-c**) (**42a-c**)

Ta alkylidenes $(RCH_2)_3Ta(L){=}CHR$ and $RCH_2Ta(L)_2({=}CHR)_2$ (R = $SiMe_3$, L = PMe_3) react with phenylsilanes $H_2SiR'Ph$ (R$'$ = Me, Ph) and $(PhSiH_2)_2CH_2$ to give bis(silyl)-substituted alkylidene complexes $(RCH_2)_3Ta{=}CR(SiHR'Ph)$ and novel metallasilacyclobutadiene (**43a**) and metalladisilacyclohexadiene complexes (**44**). Reactions of the mixed-ligand trimethylsilylmethyl neopentylidene complex $RCH_2Ta(L)_2({=}CHBu^t)_2$ with $H_2SiMePh$ also yield a metallasilacyclobutadiene complex (**43b**).[179,180]



R = $SiMe_3$; R′ = Me, Ph, (**43a**)
R = Bu^t; R′ = Me, (**43b**)

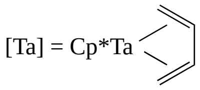


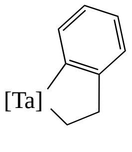
R = $SiMe_3$, (**44**)

6.2 Metallacyclopentanes, Metallacyclopentadienes, and Other Five-member Rings

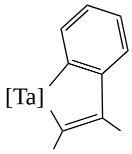
Metallacyclopentanes are of considerable importance as intermediates in catalytic alkene dimerization (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***).

The tantalacyclopentane Cp*(DippN=)Ta[$CH_2CH_2CH_2CH_2$] (**45**) and tantalacyclopentadiene Cp*(DippN=)-Ta[CPh=CPh-CPh=CPh] are obtained when Cp*-(DippN=)Ta[Si($SiMe_3$)$_3$]H (Dipp = 2,6-Pr^i_2-C_6H_3) is treated with ethylene and diphenylacetylene, respectively.[181] Cp*Ta-(=NDipp)Cl_2 reacts with excess EtMgCl in the presence of CH_2=CH_2, giving (**45**) as well. (**45**) undergoes exchange with C_2D_4 to give (**45**-d_8), and double CO insertion to yield a cyclic diacyl complex in which CO has inserted into both of the metallacyclic Ta–C bonds.[182]





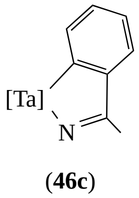
(**46a**)



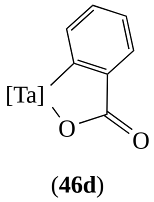
(**46b**)

Insertion of ethylene and 2-butyne into the Ta benzyne bond of Cp*Ta(η^4-butadiene)(η^2-C_6H_4) affords the metallacycles (**46a**) and (**46b**), respectively. Similar insertion of acetonitrile and carbon dioxide gives metallacycles (**46c**) and (**46d**).[145]

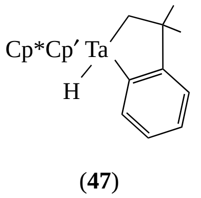
Alkylation of Cp*Cp′$TaCl_2$ with $LiCH_2CMe_2Ph$ gives the benzocyclic complex Cp*Cp′Ta(H)(η^2-CH_2-CMe_2-*o*-C_6H_4) (**47**). In comparison, the alkylation with Mg(CH_2Ph)$_2$(THF)$_2$ or $LiCH_2R$ (R = $SiMe_3$, Bu^t) gives bis(μ-alkylidene) complexes (Cp*Cp′Ta)$_2$(μ-CHR)$_2$ (R = Ph, $SiMe_3$, Bu^t).[183]



(**46c**)

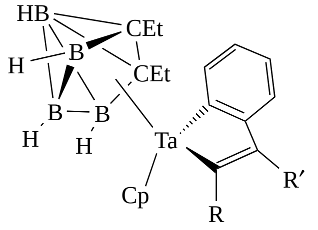


(**46d**)

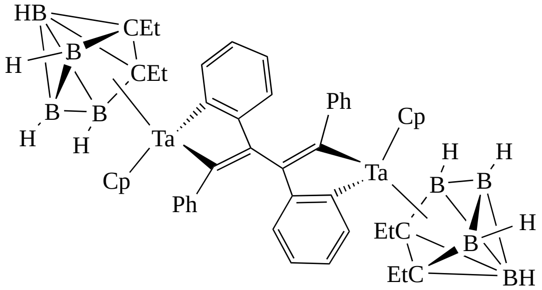


(**47**)

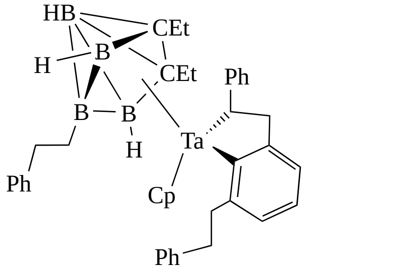
Thermolysis of ($Et_2C_2B_4H_4$)$CpTaPh_2$ (**48**) in the presence of alkynes and 1,4-diphenylbutadiyne leads to the formation of the five-membered metallacycles (**49a–b**). (**49a**) reacts with excess ($Et_2C_2B_4H_4$)$CpTaPh_2$, giving a bis-insertion product (**50**).[184] Reaction of (**48**) with excess styrene PhCH=CH_2 results in a novel triple-insertion process in which styrene units are added to both ortho positions of an aryl ligand and to the central B atom of the C_2B_3 ring in (**51**).[184]



e.g., R = R′ = Et, Ph (**49a**)
R = Ph, R′ = PhC≡C- (**49b**)



(**50**)



(**51**)

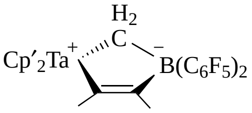
Tp*$NbCl_2$(PhC≡CR) (R = Me, **52a**; Ph, **52b**) reacts with allyl Grignard giving the five-membered niobacycles Tp*(Cl)Nb(=CPh–CR=CH–CHMe).[185] When (**52a**) is treated with EtMgCl, the formal dehydrogenation of an ethyl group gives the alkyne-coupled product Tp*NbEt(=CPh–CMe=$CHCH_2$).[133]

Protonation of the 3e-alkyne-η^2(3e)-nitrile complex Tp*Nb(CO)(PhC≡CMe)(EtC≡N) with HBF_4 induces nitrile/alkyne coupling to give Tp*NbF(=CPh-CMe=CPhNH)

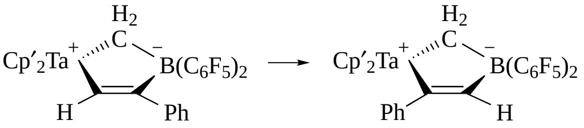
via [Tp*Nb(CO)(η^2-CPh=NH)(PhC≡CMe)](BF_4). Protonation of Tp*Nb(CO)(PhC≡CMe)$_2$ with HBF_4 leads to the niobacycle Tp*NbF[=CPh–CMe=C(–CMe=CHPh)O] in which CO is included in the alkyne coupling reaction.[135] Similar five-membered oxaniobiacycles Tp′Nb(OMe)(=CPh–CR=CMe–O) (R = Me, Et) and Tp′Nb(OMe)(=CPh–CEt=CPh–O) are prepared from the regioselective coupling of the coordinated alkyne with an acetyl or benzoyl group in the reactions of Tp′NbMe(OMe)(PhC≡CR) and Tp′NbPh(OMe)(PhC≡CEt) with CO.[186]

Reaction of Cp*Ta(CH_2SiMe_3)$_2$(=CHSiMe$_3$) with 2,6-Me$_2$-C_6H_3OH leads to H abstraction from the methyl group in Ta-(O-2,6-Me$_2C_6H_3$), giving the cyclic alkyl-alkoxo derivative Cp*Ta(CH_2SiMe_3)$_2${η^2-O(2-CH$_2$-6-MeC_6H_3)} with the elimination of $SiMe_4$.[120]

Cp′$_2$Ta[$CH_2B(C_6F_5)_2$](μ-H)(Me), generated via treatment of Cp′$_2$Ta(=CH_2)Me with HB(C_6F_5)$_2$, undergoes irreversible methane loss in the presence of an excess of MeC≡CMe and PhC≡CH, giving the tantala-3-boratacyclopentene compounds (**53a–b**). The kinetic product (**53b**) thermally rearranges to the thermodynamic product (**53c**).[187]



(**53a**)

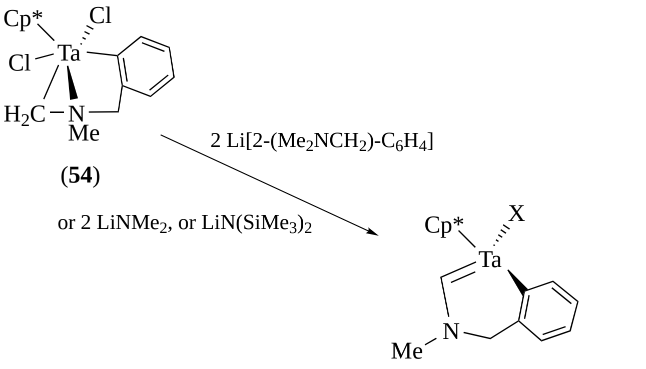


(**53b**) (**53c**)

(silox)$_3$TaH$_2$ thermally cyclometallates to (silox)$_2$(H)-TaOSiBu$^t_2$CMe$_2$CH$_2$, but is reconstituted with H_2. Reduction of (silox)$_3$(H)TaI with Na/Hg in THF produces a ring-opened THF complex (silox)$_3$Ta(H)[μ-CH$_2$(CH$_2$)$_3$O-]-Ta(H)(silox)$_3$.[188]

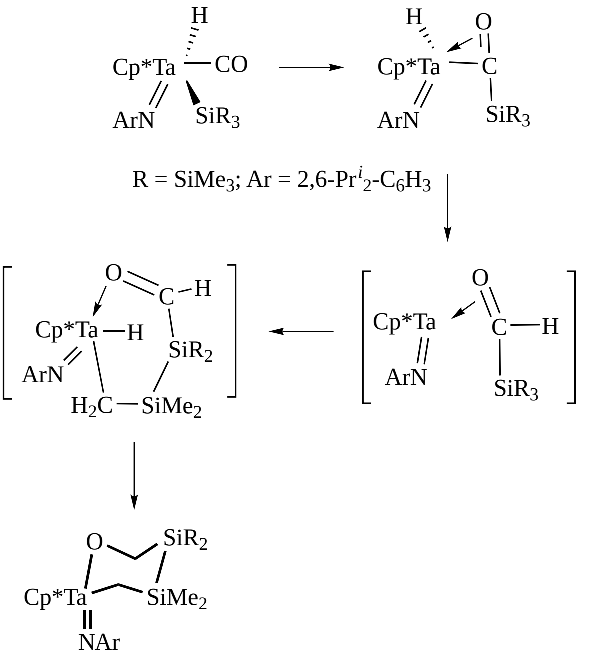
6.3 Other Metallacycles

Reaction of Cp*TaCl$_3$[η^2-C_6H_4(2-CH$_2$NMe$_2$)] with 1 and 3 equiv of Li[2-(Me$_2$NCH$_2$)C_6H_4] causes successive β-H abstraction at one of the methylamino groups, giving the cyclometallated (**54**) and alkylidene (**55a**). Similarly, the reactions of (**54**) with 2 equiv of LiNMe$_2$ and 1 equiv of LiN(SiMe$_3$)$_2$ yield the tantalacycloalkylidenes (**55b**) and (**55c**), respectively.[189]



X = η^2-C_6H_4(2-CH$_2$NMe$_2$) (**55a**)
= NMe$_2$ (**55b**)
= Cl (**55c**)

On standing at room temperature, the d^0 carbonyl complex Cp*(ArN=)Ta(CO)[Si(SiMe$_3$)$_3$]H transforms into the tantalacycle (**56**).[190]

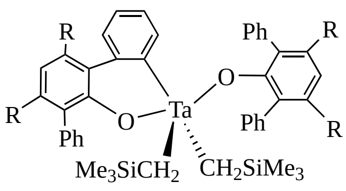


(**56**)

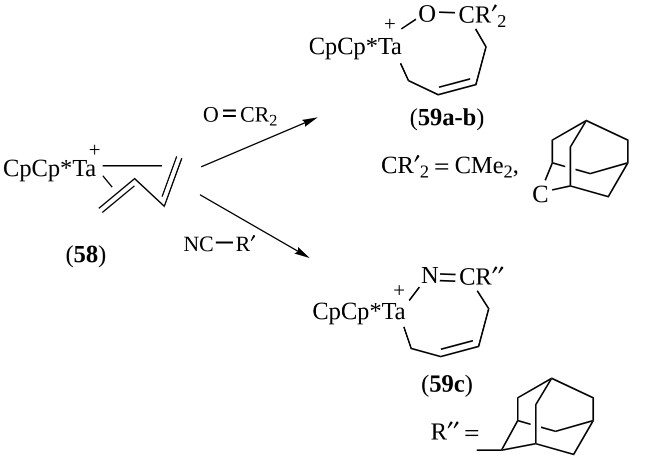
Photolysis of Ta(OAr)$_2$(CH_2SiMe_3)$_3$ (Ar = 2,6-Ph$_2$-3,5-R$_2$-C_6H; R = H, Ph, Me, Pr^i) generates alkylidenes Ta(OAr)$_2$(=CHSiMe$_3$)(CH_2SiMe_3), which undergo intramolecular cyclometallation (*see Cyclometalation*) of the aryloxide ligand, through the addition of an aromatic C–H bond to the Ta alkylidene, to form (**57**).[53]

The cation complex [(*s-trans*-η^4-butadiene)TaCp*Cp]$^+$ (**58**) was found to react with ketones such as acetone and adamantanone, as well as 1-cyanoadamantane to yield seven-membered 2-tantalatetrahydrooxepine (**59a-b**)

and 2-tantala-3,6-dihydro-2H-azepine (**59c**) cation complexes, respectively. Activation of (**58**) with methylalumoxane gives an active ethene polymerization (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***) catalyst.[191]



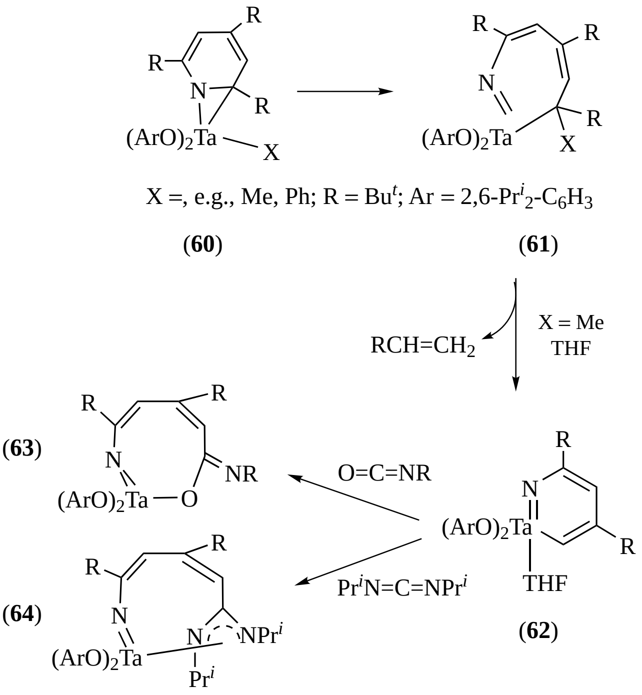
(**57**)



(**58**) (**59a-b**) CR′$_2$ = CMe$_2$, (**59c**) R″ =

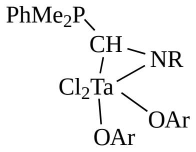
In the course of the model studies of hydrodenitrogenation (HDN) reactions (See Section 9.5), thermolysis of (η^2-*N*,*C*-2,4,6-Bu$^t_3$-NC$_5$H$_2$)Ta(OAr)$_2$X (**60**) leads to migration of alkyl (Me, Et, Pr^n, Bu^n) and aryl ligands from metal to ligand, giving the ring-opened compounds (**61**).[192] The reaction of (**60-Cl**) (X = Cl) with hydride LiBEt$_3$H similarly affords the C–N bond scission product (**61-H**) (X = H).[193] (**61-Me**) undergoes thermal decomposition in THF to give the metallapyridine (**62**) through elimination of Bu^{t}CH=CH$_2$. (**62**) reacts with electrophiles such as isocyanates and carbodiimides to afford insertion products (**63**) and (**64**).[194]

Ta(OAr)$_2$Cl$_2$(H)(PMe$_2$Ph)$_2$ (Ar = 2,6-Pr$^i_2$-C$_6$H$_3$) reacts with RNC (R = Ar, Xyl, Bu^t) to produce phosphine adduct η^2-iminoformyl complexes (**65**). Further reactions of XylNC with (**65-Xyl**) (R = Xyl) and of Bu^{t}NC with (**65-Bu^t**) (R = Bu^t) yield the ylide derivative (**66a**) and (**66b**), respectively. Ta(OAr′)$_2$Cl$_2$(H)(PMePh$_2$) (Ar′ = 2,6-Bu$^t_2$-C$_6$H$_3$) reacts with RNC (R = Xyl, Bu^t) to produce monocyclometalated complex (**67**) in which three H atoms have been transferred to the isocyanide substrate to give the amido ligand.[31]

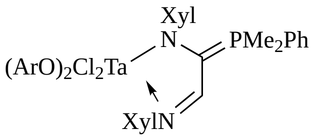


X =, e.g., Me, Ph; R = Bu^t; Ar = 2,6-Pr$^i_2$-C$_6$H$_3$

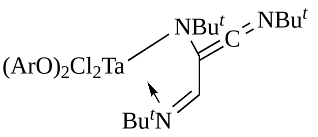
(**60**) (**61**) (**62**) (**63**) (**64**)



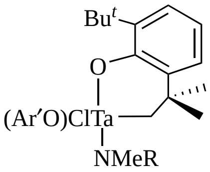
(**65**)



(**66a**)



(**66b**)



(**67**)

Reduction of Nb(OAr)$_3$Cl$_2$ (Ar = 2,6-Pr$^i_2$-C$_6$H$_3$) by Na/Hg in the presence of donor ligands leads to dehydrogenation of the *ortho*-isopropyl group of an aryloxide group yielding η^2-α-methylvinyl complex (**68**). The metallacyclopropane ring in (**68-THF**) (L$_n$ = THF) undergoes ring expansion (coupling of the olefin) with unsaturated substrates such as Ph$_2$C=O and PhC≡CR (R = H, Ph) to give 2-oxaniobacyclopentane (**69a**) and niobacyclopentene derivatives (**69b**).[195]

Bridging alkylidynes (cb)$_2$M(μ-CSiMe$_3$)$_2$M(cb)$_2$ (**70**) react rapidly with isocyanide XylNC to give bridging amidoalkyne complexes (**71**) through coupling of the isocyanide with one of the alkylidyne bridges in (**70**).[196] Similar coupling of alkynes with (**70**) yields nonplanar six-membered dimetallacycles (**72**).[197]

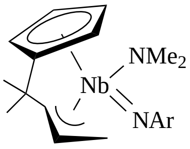
7 π-COMPLEXES OF CARBOCYCLIC, ENE, ENYL AND RELATED LIGANDS

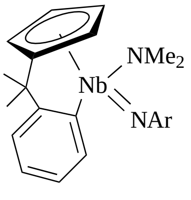
7.1 η^3-Complexes

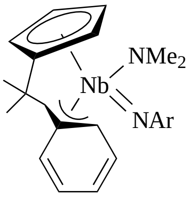
The stable bis(allyl)tantalum complex Cp*Ta(η^3-1-phenylallyl)$_2$ obtained from the reaction of Cp*TaCl$_4$ with PhCH=CHCH$_2$MgCl. Cp*Ta(η^3-allyl)$_2$ was only characterized by ^{1}H NMR and MS. In the formation of Cp*Ta(η^3-1-phenylallyl)$_2$, tantalum is reduced from Ta(V) to Ta(III), and dienes such as (PhCH=CHCH$_2$)$_2$ from the coupling of the allyl ligands are observed.[198] The presence of an imido ligand in Cp*Ta^V(=NR)Cl$_2$ prevents the reduction of the metal in its reaction with (allyl)MgBr, yielding the fluxional bis(allyl) complex Cp*Ta^V(=NR)(η^1-C$_3$H$_5$)(η^3-C$_3$H$_5$) (R = Bu^t, 2,6-Pr$^i_2$-C$_6$H$_3$).[199]

Nb(III) allyl and 1-azaallyl complexes Cp′$_2$Nb(η^3-CH$_2$CRCH$_2$) (R = H, Me, **73a**), Cp′$_2$Nb(η^3-CHR′CHCHR″) (R′ = R″ = SiMe$_2$Bu^t; R′ = H, R″ = SiPh$_3$, **73b**) and Cp′$_2$Nb[N(SiMe$_3$)C(Bu^t)-CH$_2$] (**73c**) have been prepared from reactions of (Cp′$_2$NbCl)$_2$ with the corresponding allyl Grignard (for **73a**), allyl potassium (for **73b**), and Li(1-azaallyl) reagents.[140,200] (**73a**) reacts with O$_2$ giving η^1-allyl oxo complexes Cp′$_2$Nb(=O)(η^1-CH$_2$CRCH$_2$).

Thermolysis of (η^5-C$_5$H$_4$CMe$_2$R)Nb(NMe$_2$)$_2$(=NAr) (R = CH$_2$CH=CH$_2$, Ph, CH$_2$Ph; Ar = 2,6-Pr$^i_2$-C$_6$H$_3$) leads to interesting intramolecular C–H activation with elimination of HNMe$_2$ to give *ansa*-type half-sandwich (*see Half-sandwich Complexes*) niobiocenes (**74a–c**).[201]







(**74a**) (**74b**) (**74c**) Ar = 2,6-Pr$^i_2$-C$_6$H$_3$

In addition to (**73c**), other heteronucles η^3 complexes have also been reported. Protonation of M(NMe$_2$)$_5$ with trialkylguanidines (RNH)$_2$C=NR produces dianionic guanidinate complexes M(NMe$_2$)$_3$[η^3-*N*,*C*,*N*-(RN)$_2$C=NR] (R = Pr^i, **75**, Cy).[202] Reaction of (**75**) with Me$_3$SiCl yields monoanionic guanidinate complex Ta(NMe$_2$)$_3$Cl[(Pr^{i}N)$_2$-CN(SiMe$_3$)Pr^i].[203] Carbodiimide insertion into M–amide bonds occurs in the reactions of M(NMe$_2$)$_5$ with RN=C=NR (R = Cy, Pr^i), yielding monoanionic guanidinate [η^3-*N*,*C*,*N*-(RN)$_2$C(NMe$_2$)]M(NMe$_2$)$_4$.[204] Benzamidinate complexes [PhC(NSiMe$_3$)$_2$]$_2$TaMe$_3$[24] and Nb(=ER)-[ArC(NSiMe$_3$)$_2$]$_2$Cl (ER = O, NBu^t; Ar = Ph, 4-Me-C$_6$H$_4$)[205] have been prepared from the reactions of Li[ArC(NSiMe$_3$)$_2$] with TaMe$_3$Cl$_2$ and Nb(=ER)Cl$_3$(py)$_2$, respectively. The reaction of Nb(=NBu^t)Cl$_3$(py)$_2$ with Li[PhC(NSiMe$_3$)$_2$] yields Nb(=NBu^t)[PhC(NSiMe$_3$)$_2$]-Cl$_2$(py).

Cyclooctatetraene (COT) binds to the early d-block metals in a variety of coordination modes. η^8-, η^4- η^3- and η^2-COT ligands have been reported. These include a series of η^3-COT Ta complexes such as (η^5-^{R}Cp)Ta(η^4-diene)(η^3-COT) (diene = butadiene, isoprene, 2,3-dimethylbutadiene; ^{R}Cp = Cp*, C$_5$H$_4$Me, Cp). They are prepared from the reactions of (η^5-^{R}Cp)TaCl$_2$(η^4-diene) with (COT)Li$_2$. The addition of B(C$_6$F$_5$)$_3$ to Cp*Ta(η^4-C$_4$H$_6$)(η^3-COT) affords Cp*Ta(η^4-C$_4$H$_6$)[C$_8$H$_8$B(C$_6$F$_5$)$_3$] containing a substituted bicyclo[5.1.0]octadienyl ligand.[206]

7.2 η^4-Complexes

Chemistry of Nb and Ta complexes with η^4-ligands has grown considerably. Among the η^4 complexes, those with η^4-butadiene (η^4-C$_4$H$_6$) are the best characterized, and they are the subject of a review by Nakamura and Mashima.[207] This paper focuses on complexes with other η^4-ligands such as η^4-arene, η^4-cyclodiene, and η^4-diazabutadiene.

η^4-Butadiene complex $CpTaCl_2(\eta^4\text{-}C_4H_6)$, prepared from the reaction of $CpTaCl_4$ with $(C_4H_6)Mg$, is treated with NaCp to yield the η^2-butadiene complex $Cp_2Ta(\eta^1\text{-}Cp)(\eta^2\text{-}C_4H_6)$ (**76**). Treatment of (**76**) and $CpCp^*TaCl(\eta^2\text{-}C_4H_6)$ with $(Cp_2ZrMe)^+[MeB(C_6F_5)_3]^-$ results in formation of $Cp_2Ta(\eta^4\text{-}C_4H_6)^+$ (**77a**) and $CpCp^*Ta(\eta^4\text{-}C_4H_6)^+$ (**77b**). In reactions of (**77a**) with ketones and nitriles, and (**77b**) with ketones, insertion of ketones and nitriles into the butadiene ligands is observed, giving cationic seven-membered metallacyclic σ-allyl complexes.[191,208] Similar reactions of (**77a**) with alkynes give metallacyclic (π-allyl)metallocene cations.[208]

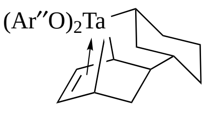
When the dialkylated complexes $Cp'NbR'_2(RCCR)$ (R = $SiMe_3$, R′ = Me, CH_2SiMe_3, Np) are treated with 1 equiv of isocyanide XylNC under heat, hydrogen migration occurs, giving diene complexes $Cp'Nb(=NXyl)[\eta^4\text{-}CHRCRCR'CHR'']$ (R′ = Me, R″ = H; R′ = CH_2R, R″ = R) and the niobacyclohept-2-ene $Cp'Nb(=NXyl)[\eta^2\text{-}CH_2CMe_2\text{-}CH_2CH(Np)CR{=}CR]$.[209]

In the Na/Hg reduction of aryloxides $Nb(OAr)_3Cl_2$ (Ar = 2,6-Ph_2-C_6H_2R, R = H, Ph) under H_2, 1,2-hydrogenation of an *ortho*-phenyl substituent occurs, leading to a cyclohexadiene group in $Nb(OC_6H_2RPh\text{-}\eta^4\text{-}C_6H_7)(OAr)_2$.[210] In the presence of 1,3-cyclohexadiene (C_6H_8), the Na/Hg reduction of $M(OAr')_nCl_{5-n}$ (n = 2, 3, Ar′ = 2,6-Pr^i_2-C_6H_3) leads to formation of cyclohexadiene adducts $M(OAr')_nCl_{3-n}(\eta^4\text{-}C_6H_8)$, respectively. The cyclohexadiene ligand binds strongly in the complexes, and does not readily undergo displacement with added reagents such as PMe_2Ph. One of the adducts, $Ta(OAr')_3(\eta^4\text{-}C_6H_8)$, catalyzes the disproportionation of 1,3-cyclohexadiene into cyclohexene and benzene as well as the hydrogenation of 1,3-cyclohexadiene and cyclohexene into cyclohexane. Addition of 1,3-cyclohexadiene to $Ta(OAr'')_2(H)_3(PMe_2Ph)_2$ (Ar″ = 2,6-Cy_2-C_6H_3, 2,6-Cy_2-3,5-Ph_2-C_6H) leads to $Ta(OAr'')_2(\eta^1\text{-}C_6H_{10}\text{-}\eta^4\text{-}C_6H_7)$ (**78**) containing a partially hydrogenated non-Diels–Alder dimer of 1,3-cyclohexadiene.[211]

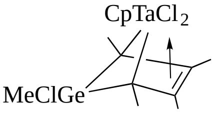
The first tris(arene)niobium complex, $[Nb(1\text{-}4\text{-}\eta^4\text{-}anthracene)_3]^-$, prepared by the Na or K anthracene reduction of $NbCl_4(THF)_2$, undergoes facile anthracene displacement in the presence of CO to afford $[K(18\text{-}crown\text{-}6)(THF)_2][Nb(CO)_6]$.[212] Reduction of $TaCl_5$ by sodium naphthalene provides $[Na(THF)][Ta(\eta^4\text{-}naphthalene)_3]$, the first homoleptic naphthalene complex of a third row transition metal. This complex reacts with CO and anthracene to give $[Ta(CO)_6]^-$ and $[Ta(1\text{-}4\text{-}\eta^4\text{-}anthracene)_3]^-$, respectively. The latter product reacts with cyclooctatetraene (COT) to give $[Ta(COT)_3]^-$.[213]

Half-sandwich (*see Half-sandwich Complexes*) complexes $Cp^*Nb\{\eta^4\text{-}o\text{-}(CH_2)_2C_6H_4\}Cl_2$ and $Cp^*Ta(\eta^4\text{-}C_{14}H_{10})Cl_2$ with an extended conjugated η^4-diene ligand such as o-xylylene and anthracene have been prepared from the reactions of Cp^*MCl_4 with $o\text{-}C_6H_4(CH_2MgCl)_2$ and $Mg(anthracene)(THF)_3$, respectively.[214]

The germole reagent $C_4Me_4Ge(Me)SiMe_3$ reacts with $TaCl_5$ to give $[(\eta^4\text{-}C_4Me_4GeMeCl)TaCl_3(Et_2O)_x]_2$ (x = 0.5–1.0), which reacts with CpTl to give air-stable $Cp(\eta^4\text{-}C_4Me_4GeMeCl)TaCl_2$ (**79**).[215]

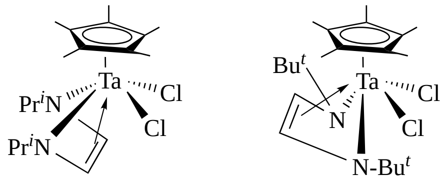


(**78**)

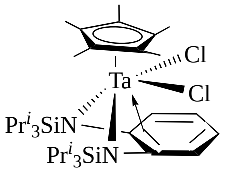


(**79**)

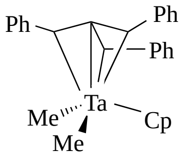
$Cp^*Ta(R_2\text{-}dad)Cl_2$ (R_2-dad = $RN\text{-}CH{=}CH\text{-}NR^{2-}$; R = Pr^i, Bu^t, **80**) are prepared from the reactions of Cp^*TaCl_4 with $Li_2(R_2\text{-}dad)$. The N,N'-disubstituted diazabutadiene (R_2-dad) ligands in these complexes are bound to the metal center with a $\sigma^2(N,N')$, $\pi(C,C')$-coordination mode.[216] The Nb ene-diamido ene-diolato complexes $Cp'NbCl_2$(Me,Ph-dad) and $Cp'NbCl_2[O(R)C{=}C(R)O]$ are prepared from the reactions of $Cp'NbCl_2(Me_3SiCCSiMe_3)$ with Me,Ph-dad (PhN=CMe–CMe=NPh) and diketones R–CO–CO–R (R = Me, Ph).[217] Similarly, Cp^*TaCl_4 reacts with $o\text{-}C_6H_4(NLiSiPr^i_3)_2$ giving (**81**), where the diamide ligand is coordinated in an η^4-fashion via donation of electron density from the phenylene ring to the metal.[218]



(**80**)



(**81**)



(**82**)

A neutral group 5 bent metallocene analog (**82**) containing the unusual η^4-TBM dianion (TBM = tribenzylidenemethane) has been prepared from the reaction of $(TBM)TaMe_2Cl$ and LiCp.[219] Both TBM^{2-} and Cp^- ligands are formally six-electron donors but differ in their respective charges. Compounds such as (**82**) are of interest as neutral group 4 counterparts of cationic metallocene alkyls that important homogeneous Ziegler–Natta polymerization catalysts (*see Ziegler–Natta Catalysts*).

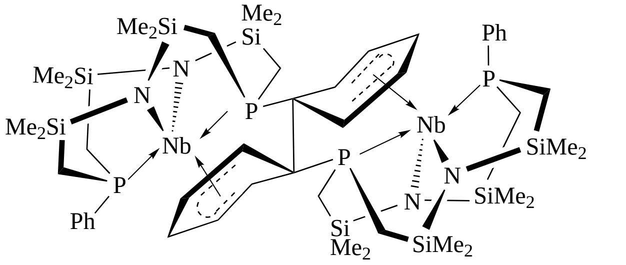
7.3 η^5-Complexes

Many Nb and Ta complexes containing cyclopentadienyl ligands have been described in other sections. 3-D

metallasiloxanes, prepared from reactions of Cp^*TaMe_4 with organosilanetriols $RSi(OH)_3$, as models for catalytically useful transition metals supported on silica was recently reviewed.[220] In this section, the η^5-ligands obtained from the reduction of arene rings will be described.

$M(\eta^5\text{-9-Ph-}C_{13}H_8)(CO)_4$ (9-Ph-$C_{13}H_8$ = phenylfluorenyl) have been prepared from $[M_2(\mu\text{-Cl})_3(CO)_8]^-$ and Li(9-phenylfluorenyl).[221]

Hydrogenolysis of $^R[P_2N_2]NbCH_2SiMe_3$ (R = Cy, Ph) in benzene and toluene causes hydride addition to the aromatic solvent, resulting in the formation of $^R[P_2N_2]Nb(\eta^5$-cyclohexadienyl) and $^R[P_2N_2]Nb(\eta^5$-methylcyclohexadienyl), respectively.[222] One-electron reduction of the P–Ph group in $^{Ph}[P_2N_2]NbCl$ yields (**83**) containing a cyclohexadienyl moiety formed via a C–C bond formation between the ipso carbons of the two Ph groups.[223] (ArN=)(ArNH)TaMe(OTf) (Ar = 2,6-dimesitylphenyl, **84a**) reacts with H_2 to convert one mesityl group into a η^5-cyclohexadienyl ligand, forming (ArN=)[2-(η^5-2,4,6-Me_3-C_6H_3)-6-mesitylC_6H_3NH]Ta(OTf) (**84b**).[224,225] D-labeling studies indicate that reaction proceeds through a hydride intermediate (ArN=)(ArNH)TaH(OTf) (**84c**), and a reversible intramolecular hydride transfer between Ta and the aromatic ring.



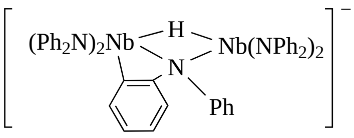
(**83**)

Reactions of 17-e $Nb^{II}(2,4\text{-}C_7H_{11})_2(L)$ species ($C_7H_{11}^-$ = dimethylpentadienyl; L = PEt_3, PMe_2Ph) with CO lead to spontaneous reduction of these complexes and formation of 18-e $Nb^I(2,4\text{-}C_7H_{11})(L)(CO)_3$. These products are also susceptible to reduction by alkali metals, presumably leading to the dianion $Nb(2,4\text{-}C_7H_{11})(CO)_3^{2-}$, which is oxidized under CO to give $Nb^I(2,4\text{-}C_7H_{11})(CO)_4$.[226]

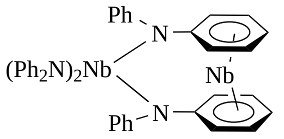
7.4 η^6-Complexes

η^6-Arene complexes are usually prepared by the following methods: (i) metal vapor synthesis (*see* ***Metal Vapor Synthesis of Transition Metal Compounds***).[227] (ii) Al/AlX_3 reduction of a metal halide in the presence of the arene; and (iii) alkyne cyclotrimerization (*see Cyclodimerization & -trimerization Reactions*). Synthetic procedures to obtain η^6-arene derivatives have been reviewed by Pampaloni and Calderazzo.[228] Over the past ten years, studies in this area have been focused on the reactivities of η^6-arene complexes.

Reaction of $(TMEDA)_2Nb^{II}{}_2Cl_5Li(TMEDA)$ with the amide Ph_2NK leads to the formation of several compounds including the Nb^{III} anion (**85a**) and neutral, diamagnetic Nb^0 (**85b**). (**85a**) is the product of oxidative addition (*see Oxidative Addition*) of two Nb centers to the *ortho* C–H bond of a Ph group. (**85a**) then undergoes reductive elimination (*see Reductive Elimination*) to restore the C–H bond to form (**85b**).[229]



(**85a**)



(**85b**)

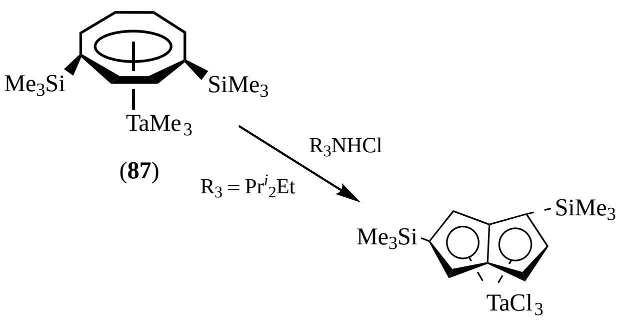
$[Nb(Mes)_2]^+$, produced from the 1-e oxidation of bis(mesitylene) complex Mes_2Nb, adds alkynes to give $[Nb(Mes)_2(RC{\equiv}CR)]^+$ (R = Me, Ph). Thermal treatment of $[Nb(Mes)_2(RC{\equiv}CR)](BAr_4)$ gives $(RC{\equiv}CR)Nb(\eta^6\text{-}C_6H_4X)_2B(C_6H_4X)_2$ (R = Me, X = H, *p*-F, **86a**; R = Ph, X = H, **86b**) containing Nb bonded to two of the four aromatic rings of the tetraphenylborato ligand in a bent fashion. Alkyne displacement in (**86a**) by CO gives $Nb(CO)(\eta^6\text{-}C_6H_4X)_2B(C_6H_4X)_2$ (X = H, *p*-F).[230] Mes_2Nb is oxidized by $XMn(CO)_5$ (X = Cl, I) and $XRe(CO)_5$ (X = Br, I) to give Mes_2NbX and $Mes(CO)_2Nb(\mu\text{-}X)_2Re(CO)_3$, respectively.[231]

η^6-Hexamethylbenzene alkyl and aryl Ta(III) complexes supported by aryloxide and arenethiolate ligands have been reported. These include $(\eta^6\text{-}C_6Me_6)Ta(OAr)_2Me$, $(\eta^6\text{-}C_6Me_6)Ta(OAr)RR'$ (R = R′ = Me, Et, CH_2SiMe_3, Ph; R = H, R′ = CH_2SiMe_3), $(\eta^6\text{-}C_6Me_6)Ta(OAr)(R)X$ (X = Cl, R = CH_2SiMe_3, Ph; X = Br, R = Me, Et) (Ar = 2, 6-$Pr^i{}_2$-C_6H_3).[232]

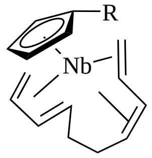
7.5 η^8-Complexes

$Ta(\eta^8\text{-COT}')Me_3$ (**87**) was prepared from the reaction of $TaCl_2Me_3$ with $Li_2(COT')$ [COT′ = 1,4-bis(trimethylsilyl)cyclooctatetraene]. It reacts with $(NHPr^i{}_2Et)Cl$ to yield η^8-pentalene (**88**).[233]

Complexes (**89**) containing a noncyclic η^8-tetraene ligand are prepared from reactions of $(RC_5H_4)NbCl_4$ with dimethylpentadienyl (dienyl) anion. The reactions initially give $(RC_5H_4)Nb(\eta^5$-dienyl)(η^3-dienyl), which subsequently undergo intramolecular coupling between the two dienyl ligands, yielding (**89**).[234]



(**87**) (**88**)

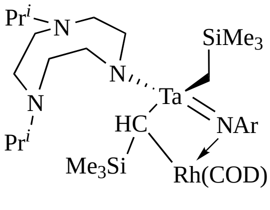


(**89**) R = H, Me

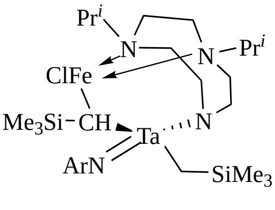
8 HETEROMETAL CLUSTERS

Heterobimetallic hydride and alkylidyne complexes are discussed in Sections 3.2.3 and 4.1, respectively. C–H activation of the alkylidyne (*see Alkylidyne*) complexes are discussed in Section 9.1 below.

The Ta–Li alkylidene (**29**) (Section 4.2) containing an anionic triazacyclononane ligand ($Pr^i{}_2$-tacn$^-$) reacts with $FeCl_2$(TEMDA) or $[RhCl(COD)]_2$ to form bimetallic (**90**) and (**91**), respectively.[121] In both products, the two metals in close proximity and linked by single-atom bridges.



(**90**)



(**91**)

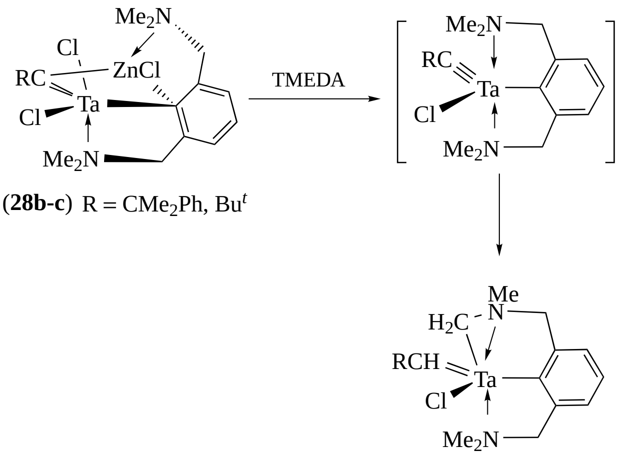
9 NIOBIUM AND TANTALUM COMPLEXES IN CATALYSIS AND METAL-MEDIATED ORGANIC SYNTHESIS

9.1 C–H Bond Activation

This section reviews C–H activation reactions that have not been discussed in earlier sections.

Silyl complexes, $Cp_2Ta^{III}(L)SiR_3$ (L = PMe_3, CO), activate C–H bonds of unhindered arenes such as benzene, toluene, and *m*-xylene. $Cp_2Ta(PMe_3)(SiBu^t{}_2H)$ reacts in neat arenes (ArH) to produce aryl complexes $Cp_2Ta(PMe_3)Ar$. Complexes with smaller silyl ligands give equilibrium mixtures of silyl and aryl complexes in which the silyl is favored. Thermodynamic studies reveal that the Ta–Si bonds in $Cp_2Ta(PMe_3)SiR_3$ ($R_3 = Bu^t{}_2H$; Me_3) are 5.4–7.9 kcal mol^{-1} weaker than the Ta–Ph bond in $Cp_2Ta(PMe_3)Ph$, and suggest that the strength of the Ta–Si bonds are probably comparable to or greater than that of a Ta–alkyl bond.[235]

Bridging alkylidyne (*see Alkylidyne*) complexes (**28a–b**) (Section 4.1) react with TMEDA, leading to C–H activation of the methyl group in $-NMe_2$ and the elimination of $ZnCl_2$, giving the alkylidene (**92a–b**).[41,119]

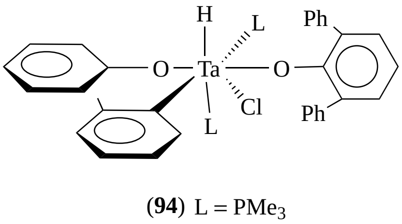


(**28b-c**) R = CMe_2Ph, Bu^t

(**92a-b**)

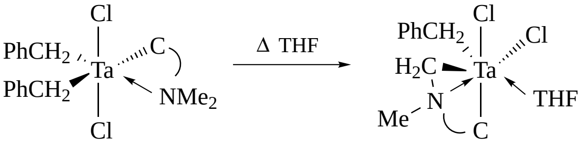
Silica-supported Ta hydride $(\equiv SiO)_2Ta–H$ (**93a**) presents unusual properties in the activation of alkanes. It catalyzes the metathesis reaction of alkanes to give higher and lower molecular weight alkanes, and the hydrogenolysis of alkanes such as ethane to methane.[236] This hydride also activates the C–H bonds of cycloalkanes to form the corresponding surface metal-cycloalkyl complexes, and catalyses the H/D exchange reaction between CH_4 and CD_4, producing the statistical distribution of methane isotopomers.[237]

C–H activation using the aryloxide supported Ta complexes has been discussed in Section 6.3.[53,238,239] Additional examples include the thermal conversion of the hydride Ta(O-2,6-Ph_2-$C_6H_3)_2(H)_2Cl(PMe_3)_2$ into the monocyclometalated complex (**94**).[60] Reaction of Cp^*TaCl_4 with (cb)K (>3 equiv) leads to the species $(C_5Me_4CH_2)Ta(cb)_2Cl$, in which one of the ring methyl C–H bonds of the Cp^* ligand has been cleaved.[240]

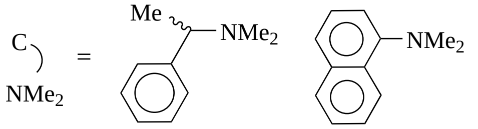


(**94**) L = PMe_3

Ta amide (**14**) and *ansa*-type half-sandwich (*see Half-sandwich Complexes*) niobiocenes (**74a–c**) from intramolecular C–H activation with elimination of $HNMe_2$ are discussed in Sections 7.1 and 3.1.1. The $-NMe_2$ group in (**95**) undergoes β-H abstraction by a benzyl ligand to give (**96**).[40] Alkylidyne-mediated C–H activation in the $-NMe_2$ group is observed in the formation of alkylidenes (**92a–b**) (Section 8).[41]



(**95**) (**96**)



9.2 Alkene Polymerization

The use of Nb and Ta cyclopentadienyl complexes as catalysts for olefin polymerization has been actively studied (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***). These complexes include (η^5-C_5R_5)(η^4-diene)$TaMe_2$ (R = H, Me),[241] (η^5-C_5R_5)(TBM)$TaMe_2$ and (fluorenyl)(TBM)$TaMe_2$ (TBM = tribenzylidenemethane),[242] borollide Cp*[η^5-C_4H_4BN-$(CHMe_2)_2$]$TaCl_2$,[243] and Cp*Ta(=NAr)(η^1-C_3H_5)(η^3-C_3H_5) (Ar = 2,6-Pr^i_2-C_6H_3).[199] They are typically activated with methylaluminoxane (MAO),[241–243] $(Ph_3C)^+$-$[B(C_6F_5)_4]^-$, or $B(C_6F_5)_3$.[199]

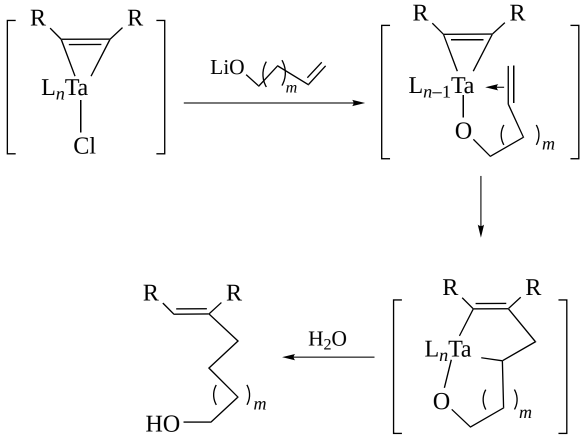
The catalytic activities of Nb and Ta complexes Cp*M(η^4-diene)Cl_2 (M = Nb, Ta; diene = 1,3-butadiene, isoprene, 2,3-dimethyl-1,3-butadiene) activated by MAO have been compared. They both give polyethylene with very narrow polydispersities at low temperature (M_w/M_n as low as 1.05). The Nb complexes are superior to the Ta complexes in terms of the catalyst activity and the polydispersity.[244,245] Cp*Ta(*o*-xylylene)Cl_2/MAO is twice as catalytically active and the molecular weight distribution of the polyethylene is much narrower than that using Cp*M(η^4-1,3-butadiene)Cl_2/MAO as catalysts.[246]

Substituted hydridotris(pyrazolyl)borato (Tp′) complexes Tp′$NbMe_2$(PhC≡CMe), when treated with $B(C_6F_5)_3$, polymerize ethylene. It is interesting to note that bulky ($Tp^{Me2,4-Cl}$)$NbMe_2$(PhC≡CMe) yields a catalyst that is far more active than Tp$NbMe_2$(PhC≡CMe).[247]

Insertion of $H_2C{=}CHX$ (X = OR; R = Me, Et, Pr^n, Pr^i, $CH{=}CH_2$, Ph) into $(Bu^t{}_3SiO)_3TaH_2$ affords $(Bu^t{}_3SiO)_3$(H)-$TaCH_2CH_2X$, which β-X-eliminates to give ethylene and $(Bu^t{}_3SiO)_3HTaX$. These reactions and their relevance to incorporation of functionalized monomers in Ziegler–Natta (*see Ziegler–Natta Catalysts*) copolymerizations have been studied. β-X-elimination rates are found to be inversely proportional to the size of R.[248]

9.3 Alkene Dimerization

Reduction of $TaCl_5$ with Zn in the presence of alkyne RC≡CR and solvents (L) is believed to yield Ta chloro alkyne complexes, which react with lithium alkoxides tethered to alkenyl groups to give chemo- and stereoselective addition of terminal alkenyl groups.[249] Alkoxy-directed insertion of C=C bonds into Ta-alkyne complexes plays a critical role through the following mechanism.



Reactions of $TaCl_5$ with alkylating agents such as MeLi are believe to give in situ $TaCl_3Me_2$, which catalyzes selective trimerization of ethene to 1-hexene.[250] Theoretical studies of the detailed mechanism of the olefin trimerization provide insights why this catalyst selectively trimerizes rather than dimerizes or polymerizes ethene.

The theoretical studies confirm intermediacy of tantalacycloheptane in the trimerization process. The conversion of tantalacycloheptane to the Ta-(1-hexene) complex follows. The dimerization is disfavored by the nonexistence of such concerted reductive elimination process for the tantalacyclopentane. The bimolecular process of tetramerization and possible higher oligomerization cannot compete with the facile reductive elimination (*see Reductive Elimination*).[251]

The silica-supported Ta hydride $(\equiv SiO)_2Ta$–H (**93a**) reacts with PMe_3 to give $(\equiv SiO)_2Ta(H)(PMe_3)$ (**93b**). In comparison to (**93a**), the phosphine hydrid (**93b**) is inactive toward metathesis of acyclic alkanes, but affords the oligomerization of ethylene into 1-butene and higher oligomers.[252]

9.4 Metathesis of Alkanes and Alkenes and Metathesis Polymerization

C–C and C–H bond activation of alkanes by silica-supported group 4 and 5 hydrides is the subject of a

recent review by Lefebvre and Basset.[253] Alkane metathesis catalyzed by $(\equiv SiO)_2Ta–H$ (**93a**) is discussed briefly in Section 9.1. Over (**93a**), ethane is transformed into an equimolar mixture of propane and methane.[236] ^{13}C-monolabeled ethane is converted, in addition to higher alkanes, to its unlabeled and dilabeled isotopomers.[254] The relative reactivity of Ta^{III} (**93a**) and Ta^{V} $(\equiv SiO)_xTa(=CHCMe_3)(CH_2CMe_3)_{3-x}$ ($x = 1$, 2, **97**) toward alkanes has been studied. The reaction of C–C bonds with a surface Ta complex containing both neopentyl and neopentylidene groups gives cross-metathesis products with the Bu^t markers. The studies using (**97**) as catalysts provide the first evidence for alkane cross-metathesis.[255]

As discussed in Sections 4.2 and 6.1, alkylidenes (**30a–b**) and tantalacyclobutane (**31a**) initiate ring-opening metathesis polymerization with strained cyclic olefins.[123] *cis*-Dialkyl Ta complexes $Cp^*TaR_2(\eta^4$-butadine) [$R_2 = (CH_2Ph)_2$, $(CH_2SiMe_3)_2$, Me(Np)] are catalyst precursors for ring-opening metathesis polymerization (ROMP) of norbornene to poly(norbornene) with a high *cis*-vinylene double-bond (97–99%) content. The *o*-xylylene analog $Cp^*Ta(CH_2Ph)_2[\eta^4$-*o*-$(CH_2)_2C_6H_4]$ is also an initiator to give poly(norbornene) with a high *trans*-vinylene double-bond (92–95%) content. These results indicate the control of stereoselectivity in the ROMP of norbornene by butadiene and *o*-xylylene ligands, as a result of the congestion between Cp* and these auxiliary ligands.[256]

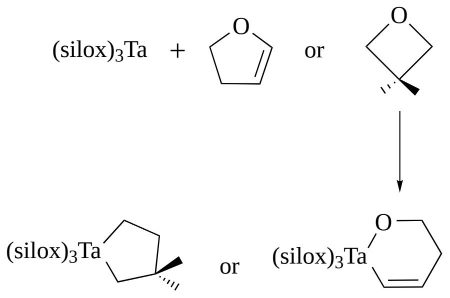
$NbCl_3$(DME) and *mer*-(DME)$Cl_3Nb{=}NPh$ serve as effective catalysts or precatalysts in imine metathesis of aldimines $RCH{=}NR'$ and $R''CH{=}NR^x$ to give $RCH{=}NR^x$ and $R''CH{=}NR'$.[257]

9.5 Hydrodenitrogenation and Hydrodeoxygenation

Catalytic hydrodenitrogenation (HDN) and hydrodeoxygenation (HDO) are the processes of removing nitrogen and oxygen, respectively, from petroleum feedstocks to provide more processable and environmentally compatible liquid fuels. A review of heterogeneous HDN process and homogeneous models summarized the research till ca. 1997.[258]

β-H abstraction of amide ligands to give η^2-*N*,*C*-heterocyclic complexes is discussed in Section 5.7. Thermolysis of $Ta(NC_9H_{10})(O\text{-}2,6\text{-}Pr^i{}_2\text{-}C_6H_3)R_2Cl$ ($NC_9H_{10}{}^- =$ tetrahydroquinolinyl; R = Me, Et), which are reactivity models for fundamental HDN reactions of pyridines, however, shows no evidence for the formation of η^2-*N*,*C*-heterocycles arising from metallation of a tetrahydroquinolinyl ligand.[259]

Treatment of $(silox)_3Ta$ with arylamines $H_2NC_6H_4X$ leads to the oxidative addition of N–H bonds to give $(silox)_3$-$Ta(H)[NH(C_6H_4X)]$ and/or C–N activation to yield $(silox)_3$-$Ta(NH_2)(C_6H_4X)$ (X = 4-NMe_2, 4-OMe, 4-Me, 4-F, 3-F, 3-CF_3, 3,5-CF_3, 4-CF_3, 4-Ph). $(silox)_3Ta$ activates the C–O bonds in 1,2-dihydrofuran and 3,3-dimethyloxetane, forming the cyclic complexes (**98a–b**).[260] These reactions mimic key steps in HDN and HDO processes.



(**98b**) (**98a**)

Structural models for the substrate-catalyst adduct in HDN catalysis have been prepared and compared with respect to O versus S-ancillary ligands. η^2-*N*,*C*-1,3,5-tributylpyridine complexes $(\eta^2\text{-}N,C\text{-}NC_5Bu^t{}_3H_2)Ta(OAr)_2X$ (X = OBu^t, SBu^t, Br) show a severe interruption of aromaticity within the pyridine heterocycle, different rotational preferences of the NC_5 plane with respect to the $Ta(OAr)_2X$ moiety, and structural differences in the aryloxide ligand. The comparison here support the ancillary ligand π-donor ability decreasing as $OBu^t > OAr > SBu^t > Cl \sim Br > Et$.[261]

9.6 Epoxidation of Olefins

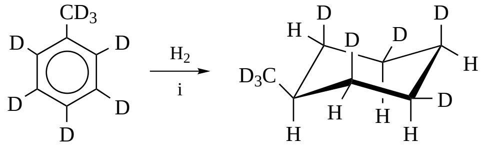
Silica-supported chiral tantalum alkoxides and $Ta(=CHCMe_3)(CH_2CMe_3)_3$ are, in the presence of (+)-tartrate, active catalysts for the asymmetric epoxidation of 2-propenol and *trans*-hex-2-en-1-ol by Bu^tOOH.[262,263] The enantioselective (*see Enantioselectivity*) catalytic epoxidation of unfunctionalized alkyl and aryl olefins by H_2O_2 was conducted using niobocene peroxide complex (R, R)-(+)-$Cp''_2Nb(O_2)Cl$ containing the C_2-symmetrical binaphthylcyclopentadienyl ligand (Cp″).[264] Enantiomeric excesses and activities range between 2–20% and 10–55 turnovers are observed in these epoxidation reactions.

9.7 Hydrogenation of Alkenes and Arenes

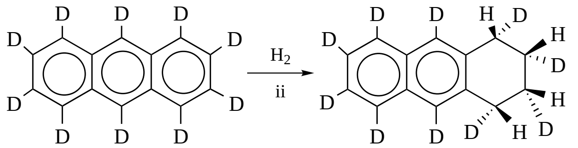
As discussed in Section 7.3, (ArN=)(ArNH)TaMe(OTf) (Ar = 2,6-dimesitylphenyl, **84a**) reacts cleanly with H_2 to convert one mesityl group to a η^5-cyclohexadienyl complex (**84b**) (Section 7.3). (**84b**) is in equilibrium with the hydride (Ar*N=)(Ar*NH)TaH(OTf) (**84c**). (**84b-c**) catalyze olefin hydrogenation, diene cyclization, and silane deuteration.[225] As discussed in Section 7.3 as well, hydrogenolysis of $^R[P_2N_2]NbCH_2SiMe_3$ (R = Cy, Ph) in, for example, benzene gives $^R[P_2N_2]Nb(\eta^5$-cyclohexadienyl). At a higher H_2 pressure, this hydrogenolysis causes the catalytic hydrogenation of benzene to cyclohexane and toluene to methylcyclohexane.[222]

Treatment of a mixture of $Nb(O\text{-}Ar)_2(CH_2SiMe_3)_2$, $Nb(O\text{-}Ar)_2(CH_2SiMe_3)(=CHSiMe_3)$ (Ar = 2,3,5,6-Ph_4-C_6H), and PMe_3 under 1200 psi of H_2 leads to hydrogenolysis

of Nb alkyl/alkylidene bonds but also the intramolecular hydrogenation of the *ortho*-phenyl rings of the aryloxide ligands to give $Nb(O\text{-}2,6\text{-}Cy_2\text{-}3,5\text{-}Ph_2\text{-}C_6H)_2(H)_2(PMe_3)_2$.[265] Similar reactions are discussed in Section 7.2. These hydride derivatives containing bulky ancillary aryloxide ligands are catalysts for high regio- (*see Regioselectivity*) and stereoselective (*see Stereoselectivity*), all-*cis* hydrogenation of benzenes and polynuclear aromatic hydrocarbons. The Nb complexes also rapidly hydrogenate arylphosphine ligands such as PPh_3 to PPh_2Cy, $PPhCy_2$ and PCy_3 as a new procedure for the synthesis of cyclohexylphosphines.[59] As discussed in Section 7.2, $Ta(OAr')_3(\eta^4\text{-}C_6H_8)$ catalyzes the hydrogenation of 1,3-cyclohexadiene and cyclohexene into cyclohexane.[211]



i, $Nb(O\text{-}2,3,5,6\text{-}Ph_4\text{-}C_6H)_2Cl_3$ / $3Bu^nLi$



ii, $Ta(O\text{-}2,6\text{-}Pr^i{}_2\text{-}C_6H_3)_2(H)_3(PMePh_2)$

The bridging alkylidyne compounds $(Me_3SiCH_2)_4M_2(\mu\text{-}CSiMe_3)_2$ supported on silica catalyze the exhaustive hydrogenation of a variety of aromatic substrates. Hydrogenation of benzene at 1200–1400 psi of H_2, for example, gave 100% cyclohexane.[266]

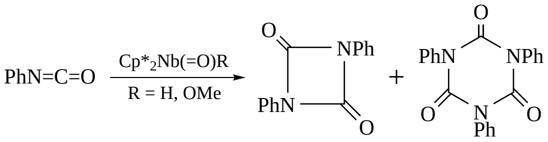
9.8 Metal-mediated Hydroboration of Olefins

Olefin complexes $Cp^*{}_2M(CH_2{=}CHR)(H)$ (R = H, Me) react with catecholborane (HBCat) and $HBO_2C_6H_3\text{-}4\text{-}Bu^t$ (HBCat′) to give $Cp^*{}_2M(H_2BCat)$ and $Cp^*{}_2M(H_2BCat')$ and the anti-Markovnikov hydroboration (*see Hydroboration*) products $CatBCH_2CH_2R$ and $Cat'BCH_2CH_2R$, respectively. D-labeling studies suggest a mechanism through which HBCat reacts with the alkyl intermediates $Cp^*{}_2MCH_2CH_2R$, via σ-bond metathesis (*see σ-Bond Metathesis*) or oxidative-addition (*see Oxidative Addition*) and reductive elimination (*see Reductive Elimination*) sequences, to generate the alkylboranes and the hydride $Cp^*{}_2MH$.[267]

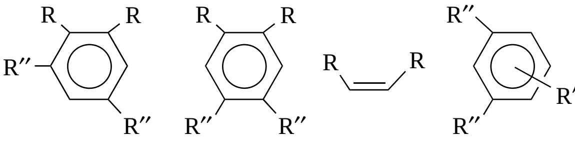
9.9 Cross-coupling of Unsaturated Organic Substrates

$NbCl_3(DME)$ is found to be a useful reagent for the intermolecular pinacol coupling of aliphatic aldehydes RCHO to give diols RCH(OH)–RCH(OH). The high anti-diastereoselectivity (*dl meso* $\geq 9/1$) is consistent with the mechanism involving an insertion of the oxo-group into the Nb–C bond of the intermediate niobiooxirane $[Nb](\eta^2\text{-}C,O\text{-}CHR{=}O)$.[268]

Reaction of $Cp^*{}_2Nb^{III}({=}O)H$ with excess isocyanate PhN=C=O gave a mixture of heterocycles $(PhNCO)_2$ and $(PhNCO)_3$.[269] $Cp^*Ta^{III}(1\text{-phenylallyl})_2$ is also a catalyst for the dimerization of isocyanates RN=C=O (R = Et, Bu^t, Cy) to $(RNCO)_2$.[198]



Treatment of tantalum-alkyne complexes, prepared in situ from $TaCl_5$, Zn and RC≡CR (R = n-C_5H_{11}), with the lithio-imine Li–N=CR′Me (R′ = n-C_8H_{17}), followed by aqueous NaOH, gives primary (*E*)-allylic amines *E*-RCH=CR–CR′Me(NH_2).[270] Treatment of these complexes with the terminal alkyne R″C≡CH (R″ = *n*-C_6H_{13}), followed by aqueous NaOH, yields tetrasubstituted benzene derivatives (**99a-d**).[271]



(**99a**) (**99b**) (**99c**) (**99d**)

Ta reagents 'Ta–Nu', prepared by the transmetallation of organotin compounds (Bu^nSn-Nu) with $TaCl_5$, promote the conjugate allylation of enones RC(=O)CH=CR′R″. The reactions, followed by treating with MeOH, give $RC({=}O)CH_2CR'R''(Nu)$ (e.g., R = Me, R′ = Ph, R″ = H, Nu = allyl).[272]

$TaCl_5\text{-}SiO_2$ has been used as an efficient Lewis acid (*see Lewis Acids & Bases*) catalyst for the three-component coupling (*see Coupling*) of aldehydes or ketones, aromatic amines, and $HOP(OEt)_2$ to produce α-amino phosphonates. Thus, coupling reaction of PhCH=O, $PhNH_2$, and $HOP(OEt)_2$ is catalyzed by $TaCl_5\text{-}SiO_2$, forming $PhNHCH(Ph)\text{–}P({=}O)(OEt)_2$ in 90% yield.[273]

Glossary

Activation: a characteristic phenotypic change in immune cells (including macrophages) upon specific stimulation by cytokines and/or bacterial products that renders them able to recognize and kill foreign or abnormal cells, through mechanisms that can involve production of •NO
Agonist: a general biological term for certain substances that activate a given biological response
Autocrine: a mechanism whereby one cell affects itself
Calmodulin: a soluble protein present in all types of cells that binds calcium. The calcium complex binds to and affects the activity of a variety of enzymes
Cellular immunity: recognition and neutralization of foreign cells, pathogenic organisms, and abnormal host cells through a mechanism that is typically triggered by antibody but, once activated, does not involve antibody; also termed nonspecific immunity
Complement: a series of proteins that bind to foreign antigens or cells, and that can induce lysis or activate other immunological processes
Cytokines: a family of small soluble proteins that are ‘immune hormones’, that is, they are produced under specific conditions of immune activity and act to transmit messages from one immune cell to another. They are extraordinarily important to the control of the complex repertoire of the entire immune defense mechanism
Cytostatic: does not kill cells, but inhibits their proliferation (division and growth)
Cytotoxic: kills cells
Cytotoxic activated macrophages (CAMs): macrophages that have been treated either in vivo or in vitro by exposure to a combination of bacterial products (such as endotoxin) plus cytokines (particularly interferon-γ), rendering them able to kill or damage abnormal cells (cancerous or infected with pathogenic microbe or virus) or pathogen. An important component of the CAMs armamature for this cytotoxic mechanism is production of •NO
Cytotoxic effector: substances produced by certain immune cells (such as •NO) that result in killing of their targets, typically abnormal cells or invading pathogen
Denitrification: the microbial transformation of nitrite and nitrate to N_2
Digitonin: a mild detergent that permeabilizes the plasma membrane of most mammalian cells without affecting organelles such as the mitochondria
Endothelial cells: cells that line the inside (lumen) of the blood vessels, that produce •NO for the regulation of blood pressure
Endothelial-derived relaxing factor (EDRF): a small, diffusible molecule that is released by the vascular endothelial cell and diffuses to the overlying smooth muscle cell, where it induces relaxation and resulting vasodilation. EDRF is either •NO alone or a bound form of •NO
Endotoxin: a molecular component of certain bacteria that is recognized by certain cells of the immune system (most especially macrophages) and triggers the activation of many immune functions, including synthesis of •NO; also called lipopolysaccharide
EPR: electron paramagnetic resonance spectroscopy
Guanylyl cyclase: a heme-containing enzyme that is stimulated by •NO and results in the formation of cyclic guanosine monophosphate, which signals a variety of processes in the cell including relaxation of smooth muscle cells in the vasculature
Hepatic: pertaining to the liver
Homodimers: a protein composed of two identical protein subunits tightly bound to each other
Humoral immunity: immune defense mechanisms that involve the participation of antibodies against foreign antigens; also termed specific immunity
Hypotension: low blood pressure
Immune surveillance: the hypothesis that cancerous cells are continually developing, but that the body’s immune system normally is capable of identifying and removing these dangerous cells
Immunohistochemical method: a method using specific antibodies to detect the presence and microscopic location of

individual proteins or groups (e.g. nitrotyrosine) microscopically in tissues or cells
Interferons: a class of cytokines that were originally discovered because they interfered with viral replication inside mammalian cells, but are now known to perform many other functions, including transmission of information from one immune cell to another; interferon-γ is the most potent cytokine known to induce ·NO formation by activated macrophages
Interleukins: a subset of the cytokines, denoted by the designation IL-1, IL-2, and so on, and each has specific functions in regulating the immune reaction
Lymphotoxin: a cytokine, similar to tumor necrosis factor
Lipopolysaccharide: a molecular component of certain bacteria, that is recognized by certain cells of the immune system (most especially macrophages) and triggers the activation of many immune functions, including synthesis of ·NO; also called endotoxin
Lymphocytes: immune cells that orchestrate the immune response
Macrophages: a phagocytic cell of the immune system that performs many functions critical to defense against foreign or pathogenic organisms
Murine: from a mouse
Necrosis: a type of cell death or nonspecific tissue decay
Neoplastic: cancerous
Neurotransmitter: a molecular messenger that is released by one cell of the nervous system and induces a specific signal in another cell
Neutrophils: a phagocytic immune cell, whose central function is to kill invading organisms
Nitrovasodilators: certain compounds such as nitroglycerine, nitroprusside, and isosorbide dinitrate, that act to cause decrease in blood pressure by releasing ·NO
Nonspecific immunity: recognition and neutralization of foreign cells, pathogenic organisms, and abnormal host cells through a mechanism that is typically triggered by antibody but, once activated, does not involve antibody; also termed cellular immunity
Paracrine: a mechanism whereby one cell affects another
Peritoneal cavity: the body cavity that houses the organs of the gut
Phagolysosome: a membrane-surrounded compartment in phagocytic cells where certain products are assembled for further processing and secretion; the pH of this compartment is low (4 or less)
Posttranslational Protein Modification: a mechanism of biological control of protein activity by covalent modification after protein synthesis
Reactive Oxygen Species: intermediates of O_2 between O_2 and H_2O that are involved in oxidative cellular injury ($\cdot O_2^-$, H_2O_2, ·OH)
Sepsis: a serious infection that results in the presence of bacteria and bacterial products in the circulation
Septic shock: a serious and life-threatening clinical condition where massive bacterial products and bacteria in the circulation results in an excessive immune response
Specific immunity: immune defense mechanisms that involve the participation of antibodies against foreign antigens; also termed humoral immunity
Transformed: a term applied to mammalian cell cultures that have become 'immortalized', that is, they grow and divide and thus resemble cancerous cells
Tumor necrosis factor (TNF): a multifunctional cytokine that is capable of specifically stimulating certain cells to perform a wide variety of immune functions, and also induces a 'suicide' response in many abnormal cells (cancerous, infected with pathogenic microbe or virus)
Vascular smooth muscle cells: the cells that surround the blood vessels and control blood pressure by relaxing or contracting in response to specific signals, including ·NO
Vascular tone: the degree of contraction of the vascular smooth muscle cells that regulates blood pressure
Vasodilation or vasodilatation: expansion of the blood vessels as a result of relaxation of the smooth muscle cells that overlie the vessels, resulting in decreased blood pressure

Abbreviations

BH_4 = Tetrahydrobiopterin; CAM = Cytotoxic activated macrophage; cNOS = Constitutive nitric oxide synthase; CPR = Cytochrome P450 reductase; EDRF = Endothelial-derived relaxation factor; EPR = Electron paramagnetic resonance spectroscopy; IL-1 = Interleukin-1; iNOS = Inducible nitric oxide synthase; LPS = Lipopolysaccharide, or endotoxin; NMMA = N^G-monomethyl-L-arginine; NOS = Nitric oxide synthase; ROS = Reactive oxygen species; SOD = Superoxide dismutase; TNF = Tumor necrosis factor.

1 INTRODUCTION

As documented by the selection of nitric oxide (·NO, nitrogen monoxide) by *Science* as 'Molecule of the Year' for 1992, followed by the 1998 Nobel Prizes for Physiology or Medicine, research into the remarkable and multiple roles of ·NO in biology has exploded since 1987 (with nearly 70 000 publications, most appearing within the last five years). It is probably true that ·NO is involved in one way or another in virtually every common pathophysiological state by virtue of its importance in the normal maintenance of many important physiological phenomena (such as blood pressure, neurotransmission, and gastrointestinal function) as well as in the host response to disease (immune and inflammatory stimulation, cancer, and cardiovascular disease) (Figure 1).

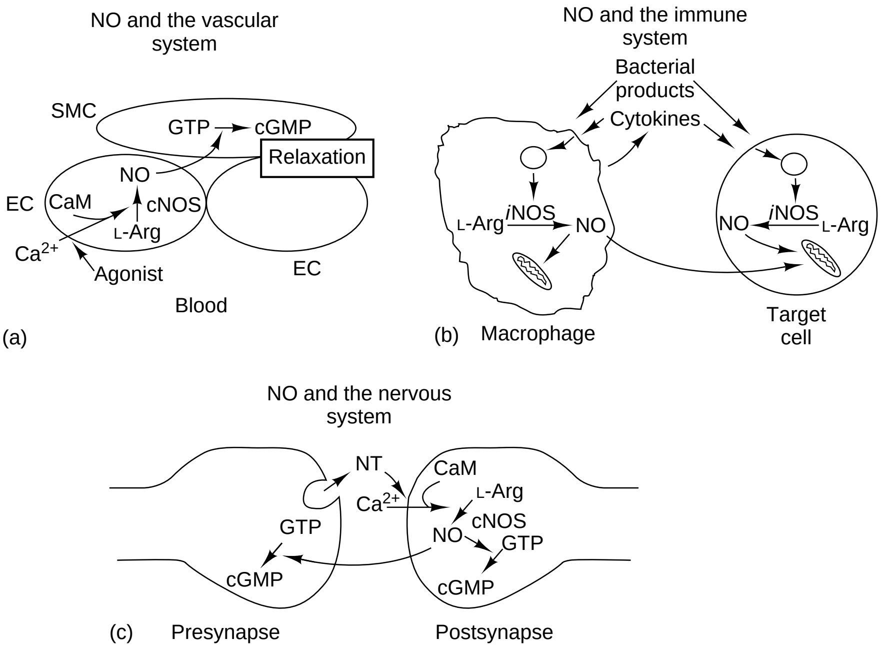

Figure 1 Schematic representation of the three major roles of •NO in mammalian biology. (a) As the messenger responsible for vascular dilation (EDRF), •NO is produced in the endothelial cell (EC) that line the lumen of the blood vessels upon stimulation with certain specific agonists (and also, although not shown in the diagram, physical changes in the flow of blood). These agonists act by stimulating an influx of Ca^{2+} into the EC, which binds to calmodulin and this calcium-calmodulin complex binds to the constitutive nitric oxide synthase (cNOS), which catalyzes the formation of •NO and citrulline from L-arginine. The •NO diffuses into the surrounding vascular smooth muscle cell (SMC), and stimulates the enzyme guanylyl cyclase to produce cyclic GMP cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP); this stimulation occurs because •NO binds to a heme group, specifically required for maximal enzymatic activity. The increase in cGMP acts upon the contractile apparatus of the SMC (by a largely unknown mechanism) to induce relaxation. (b) In the immune system, particularly the macrophage, activation by exposure to bacterial products and/or cytokines induces the de novo transcription and translation of the gene for the inducible isoform of nitric oxide synthase (iNOS), which produces •NO and citrulline from L-arginine in a largely calcium-independent manner. The •NO interferes with the normal energetic metabolism of both the macrophage and the target cell, by inhibiting iron-containing enzyme function. (c) In the neural system, the production of •NO resembles that for the vascular system in that •NO is synthesized by a constitutive NOS (although it is different from the enzyme in EC cells) in response to increased internal Ca^{2+}; however, the signals that trigger this response are certain neurotransmitters, that are released by the presynaptic terminal and diffuse to another adjacent cell at the postsynaptic terminal. •NO produced in the postsynaptic cell affects that cell and possibly also the presynaptic cell in a ‘feedback’ manner, in both cases through the heme-mediated stimulation of guanylyl cyclase

This article is written as a general review that is intended to bridge many interdisciplinary gaps ranging from chemistry, biochemistry, and spectroscopy to physiology, neuroscience, immunology, and biomedicine. Because of the extraordinary range of scientific literature on •NO, it is possible to obtain great insight into this unique molecule’s multiple actions by combining concepts on this multifaceted molecule from these disciplines. The trade-off for such an approach, however, is that a sufficient amount of background material must be provided for the nonspecialist in each area. Although we will provide the reader with appropriate citations for entry into the original literature and reviews in the many fields that have been affected by this fast-moving area, our focus will be upon what is presently known about the molecular mechanisms of action of •NO in mammalian physiology and pathophysiology, much of which has come from studies in immunology. We will not attempt to cover the entire range of biological roles of •NO, which is covered in many books and reviews,[1–38] including methods for measurement and preparation and handling of •NO[39–43] and the chemistry and biochemistry of its reactions with biological targets.[44–47] There are also three books of proceedings of international conferences that have appeared on the biology of •NO,[48–50] and volumes 268, 269, 301, and 359 of *Methods in Enzymology* are devoted to various aspects of •NO chemistry and biochemistry. There are also books dealing with metal-nitrosyls[51] and their electron paramagnetic resonance (EPR) spectroscopy[52] as well as various biomedical aspects of •NO.[53–55] In addition, a recent book on •NO, its chemistry, and its biochemistry has appeared[56] and is a superb resource, especially for chemists interested in the biological roles of •NO and the basics of its mechanistic actions. Finally, Carl Djerassi has written an entertaining fictional (but chemically informative and historical) novel entitled ‘NO’.

As we shall see, a thorough appreciation for the chemistry and biochemistry of •NO is essential for any fundamental understanding of its critical roles in a multitude of biologically

and medically important areas and can provide important new insights and tools for its study.

2 NITRIC OXIDE CHEMISTRY

Owing to its unpaired electronic configuration, the reactions of •NO with the highest rate constants involve either its association with a transition metal ion or recombination reactions with other radical and paramagnetic species. Iron is the most prevalent transition metal ion, being required for a variety of essential functions. In addition, several iron-containing proteins such as hemoglobin, myoglobin, the cytochromes P450, and cytochrome oxidase are specifically designed to bind O_2 and since •NO is similar in structure, it can bind to these proteins as an oxygen surrogate (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***, ***Iron: Heme Proteins, Mono- & Dioxygenases***, ***Cytochrome Oxidase***). Under physiological conditions, most heme in hemoglobin is oxygenated. In this case, •NO reacts extremely rapidly, essentially 'extracting' the equivalent of superoxide from the ferroheme and generating nitrate and the oxidized heme:[57–59]

$$\bullet NO + O_2 - Fe^{2+} \longrightarrow NO_3^- + Fe^{3+} \qquad (1)$$

Quantitatively, this reaction probably represents the major in vivo route for •NO conversion into stable metabolites.[60] •NO also reacts with oxygen complexes of other metalloproteins, including lipoxygenase[61] and myeloperoxidase (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***).[62,63] When •NO encounters hemoglobin in the reduced deoxy state (in the absence of O_2), it binds to the heme iron atom in a fashion very similar to that of O_2. Under physiological conditions, this reaction is probably not functionally relevant given the respective concentrations of O_2 and •NO. However, the inhibitory effects of •NO on cytochrome oxidase, involving binding to both heme and copper, may have important regulatory effects on mitochondrial electron transfer[34] and also diffusion of •NO and O_2 away from the blood vessel.[64]

In addition to hemoproteins, the other major metabolically active pool of intracellular iron is the nonheme iron-sulfur proteins (*see* ***Iron–Sulfur Proteins***), which function primarily as electron carriers, most especially in the mitochondrial electron transfer chain. In vitro treatment with •NO has been shown to result in conversion of the iron in these clusters into dinitrosyliron thiol complexes ($(RS\text{-})_2Fe(NO)_2$).[65] As described in more detail below, these complexes exhibit a characteristic EPR signal, which has been observed in both •NO-producing activated macrophages and their tumor cell targets, suggesting that such complexes may also be formed in vivo.

In addition to transition metals, •NO also reacts with biological radicals. •NO reacts with dioxygen in aqueous solution via a fairly complex reaction to eventually produce nitrous acid (called autoxidation) with an overall stoichiometry:

$$4\bullet NO + O_2 + 2H_2O \longrightarrow 4H^+ + 4NO_2^- \qquad (2)$$

The kinetic expression for •NO autoxidation is rate $= 4k[\bullet NO]^2[O_2]$ with $k = 2\text{–}2.9 \times 10^6\,M^{-2}\,s^{-1}$.[66–68] Thus, for physiological concentrations of •NO (1–50 nM) the consumption of •NO via autoxidation is slow (half-life 2–100 h) and will not account for the loss of significant amounts. However, this reaction may have enormous biological consequences as it results in the formation of species with potent biological activities. In addition, this reaction is accelerated by a factor of nearly 300-fold (on a per volume basis) when it occurs in hydrophobic compartments such as membranes.[69]

In contrast, the reaction of •NO with superoxide is extremely rapid ($k = 1.9 \times 10^{10}\,M^{-1}\,s^{-1}$):[70]

$$\bullet NO + \bullet O_2^- \longrightarrow ONOO^- \qquad (3)$$

After much confusion over the past 10 years, it is now clear that in aqueous buffer in the absence of another reactant, peroxynitrous acid (ONOOH, $pK_a = 6.8$) undergoes two subsequent reactions, isomerization to produce nitrate (yield 71%) and homolysis to produce hydroxyl radical (•OH) and nitrogen dioxide (•NO_2) (yield 29%).[71] Both of these species are highly oxidizing and much speculation has been directed toward their involvement in biologically damaging actions of •NO production (see below). However, under biological conditions, peroxynitrite will undergo at least two other reactions long before isomerization and homolysis, two-electron oxidation of cellular thiol (forming the sulfenic acid and nitrite),[72] and reaction with CO_2 to form the nitrosoperoxocarbonate anion ($ONOOCO_2^-$). This extremely short-lived species undergoes either heterolytic scission, producing nitrate and CO_2 (67% yield) or homolytic scission producing •NO_2 and the carbonate anion radical (•CO_3^-) (33% yield).[73] Thus, in the biological milieu, reaction of •NO with superoxide generates two potent oxidants, linking •NO and cellular oxidizing species with mild activity to form potent new stressors. The production of both •NO and •O_2^- are deliberately upregulated in locations of inflammatory stimulation, indicating that this reaction plays a key role in oxidative stress (and also, perhaps, signaling).

NO also undergoes radical recombination reactions. Reaction with •CO_3^- yields CO_2 and HNO_2.[74] The reaction with •NO_2, produced from the reaction of •NO with both O_2 and •O_2^-, yields the potent nitrosating agent nitrous anhydride (N_2O_3).[75] N_2O_3 reacts with water, which, in addition to the nitrosation reaction, generates nitrite. The two most important targets for nitrosation are amines and thiols.[76] In the case of amines, the subsequent chemistry is different for each type of amine. For primary amines, the nitrosamine is the initial

product that rapidly forms a diazo compound. The diazo is an excellent leaving group, which results in the formation of an alcohol and so the net result is the conversion of a primary amine into an alcohol. For secondary amines, the nitrosamine is stable but is metabolized in cells to yield a variety of highly reactive and mutagenic species.[77] Correspondingly thiols also are excellent nitrosation acceptors, yielding nitrosothiols. As described below, this covalent modification has been proposed to be an important mechanism of posttranslational protein modification. In addition, •NO (and also $\cdot NO_2$) reacts with radical species produced by one-electron oxidation. One important species is the initial product of lipid peroxidation (e.g. peroxyl species), which results in the formation of several different nitrolipid species.[23] This action represents a potent antioxidative activity of •NO and $\cdot NO_2$ since it results in radical chain termination, and there is also recent evidence that these species may possess specific regulatory and anti-inflammatory signaling activity as well.[23,78] Finally, $\cdot NO_2$ will recombine with tyrosyl radical thus resulting in the formation of stable nitrotyrosine. Nitrotyrosine can also be formed from an ill-defined reaction of peroxynitrite with metals[79] and also metals (including peroxidases) in the presence of nitrite and H_2O_2.[80,81]

The biological transformations of •NO described above are all oxidative. Although chemical studies have shown that reduction of •NO to form nitroxyl (HNO) can occur via some biochemical mechanisms (e.g. superoxide dismutase (SOD),[82] •NO synthase,[83] mitochondrial metabolism,[84] and reaction of nitrosothiols with thiols[85]), little evidence has been presented to suggest that functionally relevant quantities of nitroxyl are produced in vivo.[86,87]

3 NITRIC OXIDE AND BIOLOGY PRIOR TO 1980

Nitric oxide is one of the most extensively investigated molecules in inorganic and bioinorganic chemistry, having been originally discovered in 1620 by the Belgian chemist Jan Baptist van Helmont when an ‘air’ was generated upon pouring nitric acid over metal filings.[88] Priestley is generally credited with the original discovery of •NO,[89] and this is correct in the sense that he recognized it as distinct from other gases. It is noteworthy that Dalton utilized the reactions of •NO with air to perform the first accurate determination of the content of oxygen in the atmosphere,[90] which of course requires a proper appreciation of the concepts of reaction stoichiometry. Because of its close resemblance to dioxygen (one atomic number different) and its paramagnetism (15 total electrons), •NO has been used extensively as an O_2 surrogate to probe the metal environment of a variety of metalloproteins. In particular, •NO has been shown to bind to Fe^{2+} in heme-containing oxygen transporting proteins (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***) in a fashion nearly identical to O_2, with the important consequence of rendering the complex paramagnetic and so visible by EPR spectroscopy.[91] Because the unpaired electron assumes appreciable iron d orbital character, analysis of the EPR characteristics of hemoprotein nitrosyl complexes yields a great deal of information on both the ligand binding environment around the heme and on the conformational states of the protein (*see* ***Iron Porphyrin Chemistry***). Indeed, much of the classic work delineating the ligand-induced T to R allosteric transitions in hemoglobin were based on EPR studies of nitrosylhemoglobin,[92,93] first described in detail by Hideo Kon in a classic paper in 1968.[94]

Prior to the 1980s, studies on the biological roles of •NO were confined almost exclusively to five areas: its actions as an atmospheric pollutant,[95] as a potent stimulator of the mammalian enzyme soluble guanylyl cyclase[96] (which presaged its roles as an intercellular messenger as described below), its properties as a food preservative,[97] and its roles in the microbial nitrogen cycle[98] and in the actions of certain nitrogen-containing carcinogenic compounds.[95] However, as described in more detail below, there was EPR evidence for endogenous nitrosyl production of unknown origin in mammals in the late 1960s and early 1970s. In an early study published in 1916, Mitchell, Shonle, and Grindley[99] provided evidence that more nitrate is excreted in the urine of Man than is ingested, suggesting the presence of an endogenous mechanism for production of inorganic nitrogen oxides. This one paper presaged the remarkable discoveries of •NO in mammalian biology that occurred more than 60 years later.

Data published in the 1970s[100,101] indicated that •NO may be a protein-bound (although probably not freely released) intermediate in the assimilatory reduction of nitrite to ammonia in plants. Nitrite and nitrate, the one- and three-electron oxidation products of •NO, respectively, are the precursors for microbial denitrification, which is the reduction of these nitrogen oxides to N_2. Early reports described a red haze over molasses vats where denitrification occurs, suggesting •NO production and subsequent oxidation to $\cdot NO_2$ and N_2O_4.[102] •NO production was also observed in soil samples during denitrification,[103] and in extracts of certain denitrifying bacteria[104–106] and purified heme-containing nitrite reductases.[107–109] As described in several studies,[110,111] it is only recently that •NO has been shown to be a true intermediate in this process, as opposed to a transient, protein-bound and only slowly releasable intermediate, as mentioned above for plants.

4 CELL-MEDIATED IMMUNITY, CYTOTOXIC ACTIVATED MACROPHAGES, AND CYTOKINES

As we will describe in more detail below, •NO has been shown to play an important role in (among other areas) mammalian immunology, and it is these studies that have provided most of the information about the molecular

mechanisms of ·NO effects upon cells (the central focus of this article). In this section, we provide a brief overview for the nonspecialist of the principal components of cellular immunity specifically related to ·NO; readers familiar with this area should skip to the next section.

There are two 'arms' to the immune defense mechanism. Humoral (or specific) immunity, the most familiar, is the production of specific antibody to foreign antigen, which triggers a panel of different immune responses including lysis of invading cells by the complement cascade and opsonization (specific adsorption of antibody or complement components to the foreign material), which enables recognition by specific phagocytosing cells that engulf and inactivate the antigen. No detailed studies have linked ·NO to the mechanisms of antibody production.

Cellular (or nonspecific) immunity, on the other hand, does not involve the active participation of antibody, although antigenic stimulation activates it.[112] The historical development of the concept of nonspecific immunity lies in studies carried out in the 1950s and 1960s, which demonstrated that once an immune reaction occurs against a specific antigen, oftentimes certain cells of the immune system (most especially the macrophage) become 'activated' and are capable of recognizing and killing not only the pathogen that initiated the response but also unrelated organisms.[113,114] Remarkably, isolated macrophages that have been activated in vivo by infection with microbes and intracellular pathogens (such as *Corynebacterium parvum*, Bacillus Calmette-Guérin, or *Toxoplasma*) are capable of inactivating in vitro not only the pathogen that initiated the activation, but also unrelated pathogenic microbes, viruses, and even tumor cells. Indeed, Hibbs, in particular, has championed the notion that this killing of tumor cells by macrophages serves as an 'immune surveillance' mechanism whereby cancerous transformation is continually opposed in vivo.[115] Subsequent research demonstrated that purified components of bacterial cell walls (including lipopolysaccharide (LPS) from gram-negative organisms, also called endotoxin) will replace intact microbes in inducing this cross-resistance.[112]

At the turn of the century, Dr. William B. Coley, a young surgeon in New York City, made the remarkable discovery that injection of live or inactivated pathogenic bacteria into patients with otherwise incurable cancers would oftentimes induce dramatic necrosis (a specific type of cell death) and regression of the tumors.[116,117] Owing to a number of factors including lack of standardization of the potency of the bacterial injections, toxic side effects, variability and sometimes total lack of effect, and the simultaneous advent of radiotherapy, these intriguing results were not followed up until much later.

In 1975, Lloyd Old and colleagues discovered that transfer of serum from the blood of donor mice that had been previously injected with endotoxin into recipient mice harboring tumors would induce necrosis of the tumors.[118] They dubbed the transferrable substance responsible 'tumor necrosis factor', or TNF. Remarkably, TNF was also shown to induce killing in vitro of two different neoplastic cell lines in tissue culture, but had no effect on normal mouse embryo fibroblast cultures. TNF is now known to be a member of an extraordinarily important family of small, soluble proteins called cytokines.[119] These proteins (most of which have been cloned and pure recombinant proteins are now available) function as 'immune hormones', and act as messengers to relay information between different cells involved in the immune response. In this capacity, cytokines orchestrate the incredibly complex immune response to infection and inflammation. In addition, several cytokines (including TNF, interferons α and γ, interleukin-1β, and lymphotoxin) are capable of inducing a 'suicide' response in vitro in cultured cells that are abnormal (infected with virus or pathogenic microbe, or transformed to a cancerous phenotype). Because this effect obviously does not involve antibody, cytokines are usually considered key components of nonspecific immunity; however, this distinction is not strict because antibody production is also regulated by cytokine production and by cell-specific responses to specific cytokines.[112] Cytokines act by binding to specific receptors on the surface of the responding cell, and act via receptor-mediated signal transduction. Different cells have different receptors for different cytokines, and there can be considerable interaction between different cytokine actions on even the same cell. The result of this complexity is redundancy, synergism, or antagonism of different cytokine effects on a given cell type, conferring exquisite control over the signals transmitted depending on the cytokine(s) present and the cell type as target. Nitric oxide plays an important role in many cytokine actions on isolated cells, as well as on the nonspecific mechanism of macrophage injury and killing of pathogens and tumor cells.

5 METABOLIC BASIS OF ACTIVATED MACROPHAGE CYTOTOXICITY TOWARD TUMOR CELLS: STUDIES PRIOR TO 1987

What are the specific intracellular derangements that occur in target cells (specifically, tumor cells) in response to activated macrophages? In 1980, Krahenbuhl[120] studied the in vitro (in culture) effects of murine cytotoxic activated macrophages (CAMs, produced by injection of killed *C. parvum*) on EMT-6 cells, a murine cell line originally derived from explantation of a mammary tumor. These and subsequent studies on the mechanism of CAM-induced injury were greatly facilitated by the fact that this and certain other tumor cell lines are 'injured' by CAMs (do not proliferate) but not 'killed' (do not lyse). He observed a dramatic and early (within 2 h) inhibition of DNA synthesis in the CAM-injured EMT-6 cells. Shortly thereafter, Granger, Taintor, Cook, and Hibbs[121] examined murine L1210 tumor cells after incubation with macrophages isolated from the peritoneal cavity of mice after they had been pretreated with endotoxin to induce the activated state. Like EMT-6 cells, CAMs are cytostatic against L1210 cells but not cytotoxic.

The striking results revealed that survival of the L1210 cells after CAM coincubation exhibited an absolute requirement for exogenous glucose in the medium, whereas uninjured L1210 cells had no such requirement. The ability of other sugars to substitute (mannose and fructose) correlated quantitatively with their capacity to support glycolytic metabolism, and inhibition of glycolysis with 2-deoxyglucose prevented the ability of glucose and mannose to prevent eventual lysis of the cells. Also, unlike control cells (not pretreated with CAMs), injured cells exhibited no Pasteur effect, meaning lactate production was the same in the presence or absence of oxygen. Finally, oxygen consumption by the injured L1210 cells was 85% inhibited compared to the control cells. These results suggested that CAMs induce an inhibition in mitochondrial oxygen consumption leading to energetic deprivation that can be partially alleviated by glycolytic metabolism.

There are several possibilities for the decreased oxygen consumption in CAM-injured L1210 cells, including defects in required substrate uptake from the medium, imbalances in intracellular ion homeostasis, and critical cofactor depletion. In 1982, Granger and Lehninger[122] performed a careful analysis, using now classic techniques, for determining whether the lesion is a direct inhibition of mitochondrial electron transfer. Using digitonin to selectively permeabilize the L1210 plasma membrane (thus allowing direct measurement of mitochondrial respiration with exogenously added substrates) and selective inhibitors and electron donors of segments of the electron transfer chain, it was found that oxygen reduction from NADH and from succinate as electron donors was inhibited in mitochondria in CAM-injured L1210 cells. However, electron transfer to O_2 from α-glycerophosphate, which donates electrons on the oxygen side of coenzyme Q, or from the addition of ascorbate plus tetramethylphenylenediamine, which donates electrons at the level of cytochrome *c*, was relatively unaffected. This suggests that there is a site-specific malfunction in the mitochondrial electron transfer chain, localized to complexes I (NADH-coenzyme Q reductase) and II (succinate-coenzyme Q reductase). It is important to point out here that these regions of the chain are especially rich in nonheme iron-sulfur centers. Importantly, simple cessation of cell division does not induce mitochondrial inhibition, and the time course of this inhibition resembled that for inhibition of DNA synthesis. In addition, mitochondrial respiration in the presence of oligomycin (an inhibitor of the proton-translocating adenosine triphosphate (ATP) synthase) was low and similar in both untreated and CAM-injured cells, indicating that there is no defect in the energy-coupling ability of the mitochondria but rather a direct inhibition of electron transfer.

In 1984, Hibbs, Taintor, and Vavrin[123] reported that CAMs cause L1210 cells to lose up to 64% of their intracellular iron, and the time course of this release is similar to that of CAM-induced mitochondrial inhibition. In 1986, Drapier and Hibbs[124] showed that aconitase (an iron-sulfur-containing enzyme (*see* ***Iron–Sulfur Proteins***)) is also a target for CAM injury, and that the injured cells recover aconitase activity upon addition of Fe^{2+} to the medium. It was speculated that the inhibition of DNA synthesis may be due to inhibition of ribonucleotide reductase, which catalyzes the rate-limiting step in this pathway and which contains nonheme iron essential for activity. Wharton, Granger, and Durack[125] subsequently found that NADH dehydrogenase and succinate dehydrogenase are depleted of iron, as judged by ^{55}Fe radioactivity in isoelectric focusing gel slices corresponding to these complexes. These results indicated that iron-sulfur-containing enzymes are important targets for the CAM-induced injury.

6 MACROPHAGE PRODUCTION OF NITROGEN OXIDES

In the early 1980s, Tannenbaum's laboratory definitively showed that humans and rats excrete more urinary nitrate than is ingested,[126,127] as originally suggested for humans in the early study by Mitchell *et al.*[99] A clue to the formation of the nitrate came from work by Tannenbaum's group[128] as well as Hegesh and Shiloah[129] who found that urinary nitrate levels are much higher than normal in infants or adults with diarrhea, suggesting an origin related to infection. Indeed, Tannenbaum and colleagues subsequently demonstrated that nitrate levels in rat urine are elevated also by injection of endotoxin.[128,130]

Stuehr and Marletta and colleagues provided key insight into this phenomenon in the mid-1980s by demonstrating that isolated mouse macrophages, when activated in vivo by injection with *Mycobacterium bovis* or Bacillus Calmette-Guérin or treated in vitro with endotoxin and/or cytokines (including interferon-γ), are stimulated to produce nitrite and nitrate.[131–134] In addition, it was shown that these activated macrophages cause N-nitrosation of morpholine, which is not induced by the addition of nitrite to macrophages that had not been activated.[135] This result suggests that the active agent responsible for N-nitrosation is an active precursor of nitrite + nitrate, and Marletta *et al.*[136] showed that in macrophages •NO is indeed the precursor to nitrite and nitrate, which are produced by the reaction of •NO with O_2.

In 1987, Hibbs, Taintor, and Vavrin published a seminal paper in the field of mammalian nitric oxide production.[137] By using a medium that was depleted in specific components, it was found that the formation of nitrite + nitrate in CAMs requires L-arginine, produces L-citrulline, and is inhibited by the L-arginine analog N^G-monomethyl-L-arginine (NMMA) (Figure 2). Importantly, addition of NMMA prevents not only formation of nitrogen oxides and citrulline but also inhibition of aconitase and DNA synthesis in tumor cells cocultured with the CAMs. Subsequent studies by Hibbs' laboratory demonstrated that the macrophages themselves are also subject to the same L-arginine-dependent damaging effects that occur in the tumor target cells[138] as well as cytokine-treated isolated tumor cells (in the absence of CAMs) under certain conditions.[139,140] Thus, macrophage activation

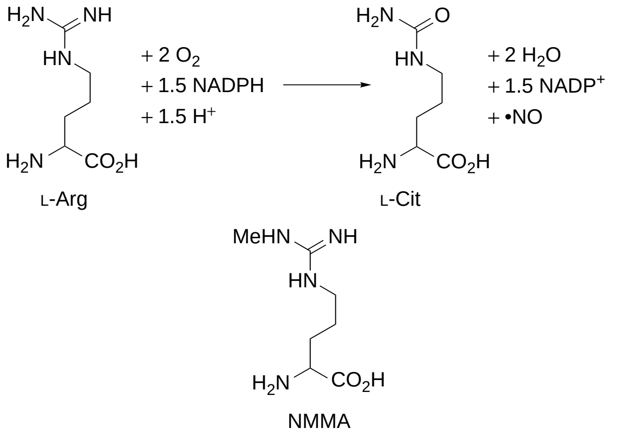

Figure 2 Stoichiometry of the enzymatic mechanism of formation of •NO, and the structure of a competitive inhibitor, N^G-monomethyl-L-arginine (NMMA). •NO is synthesized by all NOS's by a similar mechanism, involving the NADPH-dependent mixed-function oxidation of a guanidino nitrogen of the amino acid L-arginine (L-arg) to produce L-citrulline (L-cit) and •NO. The nonintegral stoichiometries are explained in the text. NMMA inhibits NOS as a competitive inhibitor

or treatment of isolated cells with cytokines under certain conditions involves the deimination of L-arginine to form L-citrulline and an active precursor to nitrite + nitrate that inhibits intracellular iron-containing enzyme function in either tumor target cells or pathogenic organisms (although there are L-arginine-independent effects of CAMs and cytokines[112]). As we shall see, this intermediate is nitric oxide.

7 NITRIC OXIDE AS A MESSENGER MOLECULE

Unexpectedly, parallel research in two separate fields, vascular physiology and neurophysiology, converged with these immunological studies in 1987 and 1988, united by the demonstration that the L-arginine-dependent pathway also produces •NO as a messenger molecule for intercellular signal transmission. Although there are distinct differences in the enzymological regulation of •NO formation when it functions as a cytotoxic effector (immune) versus a messenger (vasodilation and neural signal transmission), the fundamental biochemistry of the formation of •NO and its interactions with its targets are similar, namely, synthesis from the mixed-function oxidation of a guanidino nitrogen of L-arginine and cellular effects exerted by interaction with iron-containing proteins.

The vasculature is composed of two principal cell layers, an endothelial cell lining the lumen and a surrounding layer of smooth muscle cells (SMC) (Figure 1). Vascular relaxation/contraction (vascular tone) is effected by relaxation/contraction of the smooth muscle layer. In 1867, Brunton reported the use of amyl nitrite for the treatment of angina.[141] Since that time, nitrovasodilators have been one of the most commonly prescribed pharmacologic agents, including the compounds nitroglycerin and nitroprusside. These compounds are potent inducers of systemic decrease in blood pressure (hypotension) and their mechanism of action has been a major area of research in cardiovascular physiology. In the 1970s, Murad's laboratory provided convincing evidence that the ability of this heterogenous class of compounds to induce vasodilatation is determined by their ability to release nitric oxide, either by cellular metabolism or by spontaneous liberation, and stimulate the intracellular synthesis of the messenger molecule cyclic cGMP.[142,143] Craven and DeRubertis showed that •NO and •NO-liberating compounds stimulate guanylyl cyclase through binding to heme.[144] In 1980, Furchgott and Zawadzki discovered that the endothelial cell layer releases a diffusible substance (termed Endothelial-Derived Relaxing Factor or EDRF) that travels to the overlying smooth muscle cell layer and induces relaxation.[145] Combining these observations with the stimulatory actions of nitrovasodilators, in 1986 Furchgott and Ignarro simultaneously proposed that EDRF is nitric oxide, although no biochemical mechanism was then known to account for the production of •NO in mammals.[146,147]

One year later, Ignarro[148,149] and Palmer, Ferrige, and Moncada[150] demonstrated that EDRF, produced by endothelial cells (EC), has properties indistinguishable from •NO, using the analytical techniques employed. It was shown soon thereafter that, like Hibbs demonstrated for the activated macrophage, L-arginine is the precursor, L-citrulline is formed, and NMMA inhibits both •NO formation and the production of EDRF.[151–153] It is important to point out that there are also other important molecules produced by the endothelium that regulate vascular tone, including the potent prostaglandin prostacyclin and the small peptide endothelin as well as a so far unidentified mediator of dilation *via* smooth muscle cell membrane hyperpolarization.[154] Nevertheless, substantial modulation of blood pressure in vivo can be accomplished by administration of agents that activate (nitrovasodilators) or attenuate (NMMA) this mechanism of vasorelaxation.[10,11] The importance of •NO in the vascular system was highlighted in 1998 when the Nobel Prize for Physiology or Medicine was awarded to Furchgott, Ignarro, and Murad 'for their discoveries concerning nitric oxide as a signaling molecule in the cardiovascular system'.

The stimulation of soluble guanylate cyclase (sGC) by •NO is arguably the most physiologically important reaction of •NO. Early work had demonstrated that isolated sGC contains heme, which is a requirement for stimulation by •NO, and that various heme species stimulate the activity of the enzyme.[144] Further work has led to the hypothesis that •NO stimulates the enzyme by binding to the distal position and inducing formation of a pentacoordinate complex, thus resulting in breakage of the proximal histidine bond to the iron (*see* ***Iron Porphyrin Chemistry***).[155] Although this model still holds generally, there is evidence that •NO may also exert a modulatory effect on activity, presumably at a second site, although this point is in contention.[156,157]

In 1988, Garthwaite demonstrated that cultured cerebellar neurons stimulated with the neurotransmitter glutamate release ·NO, providing an explanation for the previously established glutamate-induced elevation in neuronal cGMP levels[158] (Figure 1). Soon thereafter, it was shown that brain extracts[159] and slices[160,161] synthesize ·NO from L-arginine. As described in more detail below, these results sparked a series of studies on the physiological and pathological roles of ·NO in neurotransmission, an area that is one of the most intensely investigated in the biological roles of this molecule.

Remarkably, a critical target of ·NO is the cytosolic form of aconitase, which in fact possesses either of two biological activities; in one form, which is dominant under conditions of cellular iron depletion, the protein functions as iron regulatory protein-1 (IRP-1) and is a key control in regulation of iron homeostasis (*see* ***Metalloregulation***) by acting as a transcription factor increasing expression of transferrin receptor and ferritin.[162] This form possesses no aconitase activity; however, under conditions of iron repletion the protein acquires aconitase activity and loses IRP-1 activity. The mechanism of this conversion involves the presence (aconitase active, IRP-1 inactive) or absence (aconitase inactive, IRP-1 active) of an intact iron-sulfur center (*see* ***Iron–Sulfur Proteins***). Cellular ·NO formation, by disrupting the intactness of the iron-sulfur cluster, thus induces a cellular response (in terms of iron homeostasis) similar to iron depletion. Indeed, there is evidence that at least part of the effect of ·NO on the IRP system is due to its depletion of cellular iron pools.[163–165] ·NO also activates the iron-sulfur-containing bacterial transcription factor SoxR, which is involved in regulating defensive responses to oxidative stress (*see* ***Iron–Sulfur Proteins***).[166] The precise mechanism of action of ·NO in protein-bound iron-sulfur centers is not clear, with the three possibilities being disruption of the cluster via direct attack of ·NO, as described above,[163,167] similar direct disruption via reactive nitrogen oxide products resulting from ·NO (e.g. peroxynitrite[167]), and loss of activity from nitrogen oxide-induced thiol modification.[168] It is, however, difficult to demonstrate experimentally direct effects of ·NO (as compared to actions of higher nitrogen oxides) since such a demonstration would require anoxic, unphysiological conditions, which among other effects would dramatically increase the concentration of ·NO.[64] In any event, it does appear that disruption of iron-sulfur center function can be a deleterious cellular injury since cells possess mechanisms for their repair (*see* ***Iron–Sulfur Proteins***).[123,169,170]

8 POSTTRANSLATIONAL COVALENT PROTEIN MODIFICATION BY ·NO-DERIVED SPECIES

Nitrosation of thiols to form nitrosothiols as a result of endogenous ·NO synthesis can occur for both small molecules such as glutathione and large molecules, especially the cysteine residues of proteins. In an analogous manner to nitration, not all cellular thiol groups are equally susceptible to nitrosation[171–173] and there is evidence that nitrosation of protein thiols may serve as a mechanism for regulation of protein function.[174] However, a critical unresolved issue is the mechanism of this nitrosation, which is largely unknown.[175] The direct reaction of ·NO with thiols, which results in disulfide formation, is too slow to be of biological relevance with physiological ·NO concentrations.[176] Espey *et al.* have demonstrated that under conditions of slight excess of ·NO production over superoxide production, rapid nitrosative chemistry can occur.[177] Thus, peroxynitrite acts to oxidize a target, which then reacts with ·NO, presenting a plausible pathway for nitrosothiol formation. Once formed, the nitrosothiol group can be exchanged between thiols via transnitrosation. Therefore following an initial reaction such as nitrosoglutathione (GSNO) formation, different nitrosothiols can readily be formed downstream of the original nitrosation event. The stability of nitrosothiols is also heavily dependent on the nature of the substituent group, generating a large variation in half-lives and corresponding biological effects. Additionally nitrosothiols, in the presence of even trace amounts of transition metals (especially Cu^{1+}), will break down to liberate ·NO.[178] Overall, there is at present little to no unequivocal evidence for a functional role for thiol nitrosation as a widespread and physiologically significant mechanism of regulation of protein function.[179]

A mechanism of protein thiol nitrosation of special interest is hemoglobin (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***), wherein nitrosation of cysβ-93 has been proposed to serve a function as ‘preserver’ of ·NO biological activity in the face of the very rapid irreversible consumption of ·NO via oxidation.[180] In addition, since changes in the accessibility of this thiol to covalent modification upon changes in the oxygenation state of hemoglobin has been known for many years,[181] a respiratory cycle has been proposed where uptake of O_2 and ·NO are proposed to exhibit positive cooperativity and so hemoglobin will deliver both O_2 and ·NO from the lung to O_2-deficient tissues.[174,182] However, important mechanistic details regarding formation, movement to the target (smooth muscle cell guanylate cyclase), and vasodilation from the nitrogen oxide species responsible are lacking. This controversy is still very much ongoing, with several recent reviews pro[183,184] and con.[36,185,186] Very recently, a novel interaction between nitrite and deoxyhemoglobin has been reported that could accomplish delivery of ·NO to tissue that is low in O_2.[187]

Metallothionein (MT) is a small protein (~6 kDa) that binds zinc tightly via cysteine residues (*see* ***Metallothioneins***).[188] The ability of these thiolate clusters to bind zinc is dependent on the redox states of the sulfur ligands, with oxidation resulting in expulsion of the zinc ion. Control of zinc homeostasis (*see* ***Metallochaperones & Metal Ion Homeostasis***) is an important regulatory function, as zinc is an essential component of many protein structures including DNA transcription factors and metabolic enzymes. Nitrosation

of the MT cysteine ligands as a result of ·NO formation releases the chelated metal and so allows ·NO to regulate zinc concentration.[189] This provides an elegant example of transduction of the nitrosative stimulus from a short-lived redox active species to the more stable, redox inert, zinc ion. In addition to the regulation of iron homeostasis via aconitase this provides another mechanism whereby the effects of ·NO production can continue to exert an effect on the cell long after the actual stimulus has finished.

9 EPR OF BIOLOGICAL IRON-NITROSYL COMPLEXES

Nitric oxide has been a favorite tool of biochemical spectroscopists, dating back to at least 1937 when Keilin and Hartree demonstrated nitrosylation of the heme group of cytochrome *c* (*see* ***Iron: Heme Proteins & Electron Transport***) under anaerobic conditions.[190] Numerous studies have employed ·NO as an oxygen surrogate for O_2-carrying hemoproteins, most especially utilizing the fact that ·NO binds to the heme ferrous iron in hemoglobin and myoglobin in a configuration essentially identical to O_2 with the added 'bonus' that the complex is paramagnetic and EPR visible (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***). As described in more detail below, these findings provided a spectroscopic tool to examine whole blood by EPR from animals stimulated to produce ·NO endogenously by immune stimulation or in humans administered ·NO-donating nitrovasodilators.

The first detailed EPR studies of biological nonheme iron-nitrosyl complexes were carried out primarily by the laboratories of Commoner, Kayushin, and Vanin. Utilizing the results of a study by McDonald *et al.* on small inorganic complexes,[191] the characteristic axial $g = 2.04$ signal resulting from the exposure of biological samples to ·NO or ·NO-generating systems,[192–197] as well as feeding of animals nitrite or nitrate plus or minus iron[196–204] (and in some cases untreated yeast cells[205] or animals[202,206]), was attributed to the formation of complexes of the general formula $[(RS)_2Fe(NO)_2]$ with the iron in approximately tetrahedral geometry.[207,208] Similar complexes are formed in cells stimulated by cytokines to produce ·NO endogenously by ·NO synthase, as described below. Early studies by Dervartanian *et al.*[209] and Salerno *et al.*[65] demonstrated the appearance of these signals in ·NO-treated isolated mitochondrial Complexes II and III. Since then, similar signals have been reported for other purified iron-sulfur-containing enzymes (*see* ***Iron–Sulfur Proteins***),[210–212] and numerous studies have shown that this complexation results in destruction of enzymatic activity. Indeed, destruction of the native chromophoric iron-sulfur cluster of *Clostridial* ferredoxin has been used as a spectrophotometric assay to detect cellular ·NO formation in vitro.[213]

What is the physiological relevance of this damaging reaction in the biological actions of ·NO? In the late 1960s Commoner showed the formation of these EPR-detectable complexes in the liver of rats fed carcinogenic compounds in the diet; the signal appeared and then disappeared many weeks prior to the appearance of hepatic tumors and so generated a great deal of interest because of its potential use as an early indication of neoplastic transformation. This conclusion is bolstered by the observation of similar signals (as well as heme-nitrosyl signals) in other tumors of noncarcinogenic compound origin including stably transformed transplantable tumor cells.[214,215] However, Commoner and others subsequently demonstrated that the carcinogen-induced appearance of the $g = 2.04$ signal is dependent on high dietary nitrate consumption, which is apparently not consistent with an origin of ·NO from the L-arginine-dependent ·NO synthase reaction.[216] In addition, it was shown that similar iron-nitrosyl signals are observed in nonspecifically necrotic tissues.[215,217] These results, combined with the lack of indication at that time for a mechanism of mammalian nitrogen oxide synthesis, unfortunately discouraged further research on this interesting phenomenon.

Sodium nitrite is commonly utilized in food preservation.[218] In spite of its known potential for metabolism to carcinogenic nitrosamines, nitrite supplementation is still in widespread use in nutrition because the addition of nitrite (plus a reducing agent such as ascorbate) has two desirable effects: it imparts a red color to meats (primarily a result of the production of nitrosylheme from myoglobin[219]) and, perhaps more importantly, the organism responsible for botulism (*Clostridium botulinum*) is exquisitely sensitive to this treatment.[220] There is indeed a massive literature on the role of ·NO and its reactions in foods in the nutrition fields and is worthy of scrutiny by researchers in the biological effects of endogenously produced ·NO in mammalian systems.

Capitalizing on the facts that nonheme iron-sulfur proteins are critically important to the anaerobic metabolism of *Clostridia* in general[221] and the earlier EPR studies showing destruction of these centers by nitrite addition in vitro, in 1983 we performed an EPR examination of whole cells of *C. botulinum* under conditions approximating those during food preservation.[222] We indeed observed the formation of an intense $g = 2.04$ signal in these cells when treated with nitrite. The facts that the formation of these signals is increased when ascorbate is also added and that the EPR signal from the native intracellular iron-sulfur clusters are concomitantly decreased suggested that the antibotulinal mechanism involves the ·NO-mediated destruction of nonheme iron-containing enzymes. Although the mechanism of formation of these nonheme iron-nitrosyl complexes may not be as straightforward as direct reaction with iron-sulfur proteins,[211,223] these results indicate that disruption in cellular iron functions by ·NO complexation is damaging to the cell, a mechanism that is also important when ·NO is produced by mammalian cells as described below.

In 1990, we[224] and simultaneously Drapier and Henry and colleagues[225] showed that similar $g = 2.04$ signals are observed in CAMs, and subsequently Drapier and Henry showed similar signals in the injured tumor cell targets of CAMs[212] providing a similar rationale for the destruction of mitochondrial activity that is responsible for the cytostatic and cytotoxic activity of immune-produced endogenous ·NO synthesis (Figure 1). Although it appears likely that these signals do not in all cases represent direct observation of nitrosylated iron-sulfur proteins (as opposed to other cytosolic forms of nonheme iron), similar signals are indeed observed in several different cell types exposed to inflammatory stimuli.[52,53]

10 NITRIC OXIDE SYNTHESIS

Because of the extraordinary range of clinically significant actions of ·NO in pathophysiology (see below), numerous research groups have been mobilized to investigate the fundamental enzymatic mechanism(s) and regulation of ·NO synthesis.[30,226] Insight into these mechanisms holds great promise for the design of new effective therapies ranging from carcinogenesis to cardiovascular disease and immunity.

There are three major isoforms of nitric oxide synthase (NOS). The first to be described is termed inducible, because inflammatory agents such as endotoxin and/or cytokines trigger the de novo transcription and translation of inducible nitric oxide synthase (iNOS) molecules. It is likely that, at least in rodents, every nucleated cell is capable of being triggered to produce iNOS; the different sensitivities to signals probably lie only in the differing mechanisms of signal transduction between cell types.

The two other major types of NOS are constitutive, that is, present continually, and both produce much smaller quantities of ·NO. Here, ·NO acts as a diffusible intracellular and intercellular messenger to stimulate soluble guanylyl cyclase in both the source cell and its neighbors thus effecting both autocrine (one cell affecting itself) and paracrine (one cell affecting another) signal transmission. The two primary physiological functions of ·NO as a messenger are in control of vascular tone and in neurotransmission.

The first NOS to be isolated and the gene sequenced was the rat cerebellar enzyme, by Bredt and Snyder in 1991.[227,228] Since then, the sequences for all three isoforms have been determined: human brain, human and bovine endothelial, mouse macrophage, and recently the cytokine-inducible NOS from human hepatocytes. There is substantial sequence identity between the same isoforms in different species: rat and human brain (93%[229]) and bovine and human endothelial (94%[230]). The identity between different isoforms (even in the same species) is substantially less, between 50 and 60%.[228,230–236] An exception is the homology between the human hepatocyte and the mouse macrophage enzymes, which is only 80%,[236] a puzzling result because both enzymes are induced by cytokines and LPS and thus are of the 'inducible' type.

A key observation made by Bredt and Snyder during the purification of the constitutive NOS from rat cerebellum was that this enzyme is greatly stimulated by calcium plus the calcium binding regulatory protein calmodulin (*see* ***Calcium-binding Proteins***).[227] It is now known that the mechanism of stimulation of all constitutive signal-transducing NOS's involves the induction by specific extracellular agonists of increased levels of cytosolic calcium that binds to calmodulin and activates the enzyme. Nathan's laboratory[237] showed that even the highly purified inducible isoform contains tightly bound calmodulin, even though this enzyme is not generally thought to be regulated by intracellular calcium levels. Indeed, the sequences for all three isotypes contain consensus regions for calmodulin binding. Structural and functional analysis has revealed the presence of an autoinhibitory control element in the constitutive enzymes that is released upon calmodulin binding, which is a major factor in the mechanism of calcium regulation of activity.[238]

As illustrated in Figure 2, the basic reaction of ·NO formation is identical for all three isoforms, involving a three-electron mixed-function oxidation of a guanidino nitrogen of L-arginine to produce citrulline and ·NO.[239] The reaction consumes three electrons from 1.5 NADPH equivalents and two moles of O_2. Two of these oxygen atoms are reduced to water, and one is incorporated into citrulline and one into ·NO.[240,241] Thus, since only three electrons are donated by NADPH, as pointed out by Stuehr and Griffith[239] L-arginine must provide the fourth electron for the reduction of the two O atoms to $2H_2O$. The fact that NADPH is an obligatory two-electron donor means that during catalytic turnover the enzyme must cycle between two oxidation states differing by one electron. Indeed, EPR studies of the resting enzyme has revealed the presence of a flavin radical,[242] suggesting that flavins function as electron reservoirs and are capable of stabilizing odd-electron states as in other flavin-containing oxidoreductases.[243]

Beginning with the first NOS sequence published by Bredt and Snyder,[227] all sequences so far reveal consensus regions for the binding of NADPH, FMN, and FAD, and analysis of purified enzymes confirms the presence of one FMN and one FAD per monomer.[239] The stimulation of the enzyme by added FAD suggests weak binding of this cofactor. Thus, NOS is the only mammalian enzyme known besides cytochrome P450 reductase (CPR) that contains both FAD and FMN, as evidenced by the substantial sequence homology between the two enzymes in addition to the consensus regions for flavin binding.[228,239] Indeed, like CPR, NOS reduces several artificial electron acceptor dyes ('diaphorase' activity) as well as molecular oxygen and also cytochrome P450. The deduced molecular weights from the cloned sequences of the endothelial and inducible enzymes from all species examined so far are comparable, approximately 133 kDa; the brain

enzymes from rat and human are larger, 160 kDa, primarily resulting from a substantial N-terminal segment. This segment contains a PDZ domain that targets nNOS for binding to a variety of other proteins within the cell and may well be an important factor in certain diseases such as Duchenne muscular dystrophy.[244,245] All NOS isoforms are composed of specific domains, and catalytic reactivity involves two of these, a reductase domain (containing the NADPH, FMN, and FAD binding sites where electron flow enters the protein and electrons are 'stored' during turnover) and an oxidase domain (containing the substrate, heme, and tetrahydrobiopterin (BH_4) binding sites). All NOS isoforms are functionally active as homodimers and, remarkably, arranged 'head-to-tail' such that electrons from the reductase domain of one subunit flow to the oxidase domain of the other subunit.[246]

Early studies by Stuehr and Nathan and colleagues[247,248] demonstrated a specific stimulation of NOS activity in crude subcellular fractions by BH_4, which is true for all purified NOS enzymes to date. BH_4 is important both as a stabilizer of protein conformation and also as an electron transfer component.[226,249] The activity of the enzyme intracellularly can be affected by modulations in cellular BH_4 levels, and this may have important consequences under physiological and pathophysiological conditions.[250–252]

All NOS proteins contain a cytochrome P450-type heme.[242,253–255] Because of the well-established functions of cytochromes P450 in mixed-function hydroxylations (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***),[256] most attention is now directed toward the potential role of this prosthetic group in carrying out an O-atom transfer reaction in the enzyme (thermodynamically driven by the reduction of O to H_2O), supported by the inhibition of enzymatic activity by carbon monoxide[242,253,254] and nitrogenous bases,[257] which are heme-binding ligands.

The first step in •NO synthesis is hydroxylation of a guanidino nitrogen of L-arginine to produce N^G-hydroxy-L-arginine:[239] during turnover a relatively small but significant quantity of this intermediate is released from the enzyme and it is a competent substrate for •NO production. Like L-arginine, •NO formation from N^G-hydroxy-L-arginine requires the presence of BH_4 and consumes NADPH, but the stoichiometry for NADPH is 0.5 mol per •NO instead of 1.5. Thus, the overall reaction for L-arginine is a two-electron hydroxylation to produce N^G-hydroxy-L-arginine followed by another that reduces O to H_2O from one electron from NADPH (probably through the intermediacy of a semiquinone flavin(s)) and one electron from the N^G-hydroxy-L-arginine and forms •NO and citrulline. The kinetic characterization of each of the individual reaction steps is well under way, and a particularly important concept is that the newly synthesized •NO binds to ferriheme and is an important regulator of activity.[226]

There is increasing attention to the biological importance of mechanisms of •NO formation not involving •NO synthase. Although it has been known for decades that nitrosothiols can produce •NO, and could be important in certain circumstances as a source for vasodilation,[258] it is only recently that •NO formation from these species has been characterized. Probably the most important mechanism for •NO formation from nitrosothiols in the biological milieu involves metal catalysis.[259,260] Another mechanism, first identified by Furchgott,[261] is via photoactivation; it has recently been demonstrated that this phenomenon is in all probability due to photolysis of nitrosothiol.[262] A major problem with the possibility that nitrosothiol represents a physiologically significant 'reservoir' for •NO (other than under inflammatory conditions where massive amounts of •NO are formed) is that no specific protein-mediated mechanism for •NO formation from nitrosothiol has been identified that could fulfill the requirement for regulation. Another potential mechanism for non-NOS •NO production is through acidification of nitrite, which has attracted attention in regards to acidic compartments biologically (in the stomach and in acidic phagolysosomes),[263] although this has been questioned on kinetic grounds.[264]

11 NITRIC OXIDE DIFFUSION

The chemistry of •NO at any specific biological location will be defined not only by the rates of •NO formation but also by the diffusion of •NO from distal locations. Since •NO is freely permeable through biological membranes and exhibits one of the highest diffusion constants known, its actions are not confined to a specific cellular compartment or even a single cell producing it.[265,266] This property places •NO in a unique category of cellular messengers in that it is able to transmit its signal virtually instantaneously after it is produced by •NO synthase. In addition, because of its reactivity, •NO will disappear relatively rapidly and so there is no need for a mechanism of deactivation.

The rapid diffusibility of •NO has critically important implications for its chemistry in the biological setting. The speed with which •NO moves by random diffusion can be illustrated by consideration of its root mean square distance of displacement, which describes the distance a single •NO molecule will move in any time interval based on its diffusion constant D (which is similar for aqueous solution and also tissue (brain)[267]):

$$\langle \Delta \bar{x} \rangle^2 = 2Dt \tag{4}$$

An illustration of the extraordinarily rapid diffusibility of •NO is given by applying this relationship to ask how long, on average, it takes before •NO will escape a cell that produces it. For a cell of 5 μm diameter, equation (4) reveals that, on average, this time will be no more than:

$$t = \frac{(2.5\ \mu\text{m})^2}{2 \times 3300\ \mu\text{m}^2\text{s}^{-1}} \approx 0.001\ \text{s} \tag{5}$$

In terms of chemical reactivity, we can now ask how rapid an intracellular reaction must be in order to prevent this 'escape'. To a first approximation, the half-life of such a reaction should be in the range of this 'escape' time, and so we calculate the rate for a reaction with this half-life:

$$rate = \frac{\ln 2}{0.001\ \text{s}} = 6.93 \times 10^2\ \text{s}^{-1} \qquad (6)$$

Assuming a second-order reaction between ·NO and a reactant R (rate $= k$[·NO][R]) and a very high intracellular R concentration (1 mM), the value for the rate constant k is given by:

$$k = \frac{6.93 \times 10^2\ \text{s}^{-1}}{10^{-3}\ \text{M}} = 6.93 \times 10^5\ \text{M}^{-1}\ \text{s}^{-1} \qquad (7)$$

This is the rate constant for a quite rapid reaction. In addition, in order to provide continual inhibition of ·NO escape the reactant R must be continually maintained at this high concentration. Experimental support for the general concept that ·NO will rapidly escape a cell producing it is provided by the observation that coincubation of ·NO-producing isolated rat hepatocytes with intact erythrocytes eliminates the reaction of ·NO with targets within the ·NO-producing hepatocyte; it can be shown from first principles that the only explanation for this effect is if, on average, any individual ·NO molecule that acts within an ·NO-producing cell had at some time previously existed in the volume outside the cell.[268,269] Similar conclusions have recently been reported for formation of intracellular nitrosothiol.[270] In vivo, different cell types produce different reactive oxygen and nitrogen species. Spatially, this means that the appearance (flux) of these reactive species at any point location will be determined by the distance from this point to the cells producing these species. Thus, the precise chemistry that occurs at different locations can be very different, especially when dealing with highly interactive networks of interreacting species.

12 NITRIC OXIDE IN PATHOPHYSIOLOGY

Without doubt, the action of ·NO that has provided the single most attention in human disease is its role in penile erection,[271] thus providing the mechanistic basis for the most widely prescribed oral agent in medicine, Viagra (Sildenafil).[272] Production of ·NO by the corpus cavernosum results in relaxation of the vessels and engorgement of the organ with blood and consequent erection. The dilating action of ·NO lies at the beginnings of the realization of its biological actions and its clinical applications, since the use of nitrovasodilators to attenuate a variety of cardiovascular problems is nearly 140 years old.[141]

Abnormal production of ·NO, either too much or too little, has been linked to a remarkable number of clinically important conditions. In two important early papers, it was shown by Kilbourn and Lodato that excessive ·NO contributes to the serious and life-threatening hypotension (loss of blood pressure) that occurs during systemic bacterial infection (sepsis).[273,274] Prior to these studies it had been demonstrated that severe hypotension accompanying sepsis is a result of the stimulation of lymphocytes and macrophages by bacterial products (most notably endotoxin), which results in massive production of circulating cytokines.[275] Indeed, injection of two cytokines (TNF and IL-1), in particular, in animals and humans produces many symptoms that are identical to septic shock, including hypotension, and administration of neutralizing antibodies or antagonists to these cytokines is capable of marked attenuation in the hypotensive response to injection of bacterial products. Kilbourn and Lodato showed that a similar protective response occurs against TNF or endotoxin injection in dogs when NMMA is administered to inhibit ·NO formation and this restoration in blood pressure is reversed (blood pressure again decreases) when L-arginine is subsequently injected.[273,274] The effect of NMMA is attributable to its prevention of ·NO formation by NOS and its reversal by excess substrate (L-arginine) is a classic example of competitive enzyme inhibition (Figure 2).

Some 600 000 patients annually are stricken with septic shock, with an estimated in-hospital mortality rate of 18%.[276] In humans, the importance of ·NO in maintaining normal vascular tone (blood pressure) was originally demonstrated by Vallance *et al.*,[277] and several early reports demonstrated restoration of near normal blood pressure in humans with sepsis, including one report where it appears to have saved a life.[278] In addition, it has been shown that septic patients have high circulating NO_3^- levels[279] (indicating excess ·NO formation). In the only large-scale clinical trial of the effects of NOS inhibitors on septic shock, NMMA was tested on a total of 797 patients[280] and, in spite of initial trials indicating beneficial effects,[281] patients administered NMMA exhibited increased mortality. Unfortunately, this has been a severe setback for further studies of the use of NOS inhibitors for this dread affliction, and investigators have been disappointed that this study using such a nonselective NOS inhibitor was pursued; as has been pointed out,[282] it is still quite possible that a new generation of iNOS-selective inhibitors could provide beneficial results.

A central paradigm in the field is that ·NO is 'Janus-faced'[1] in its roles in pathophysiology, exhibiting protective actions under some conditions and damaging effects in others. The possible mechanistic explanations for this paradoxical result can be viewed from two perspectives, cellular/tissue and molecular. In terms of cellular/tissue actions, one of the most important biological actions of ·NO is its potent inhibition of vascular coagulation and aggregation, which was reported more than 20 years ago.[283] This is a very important biological effect that will be protective in the many disorders involving aggregation and adhesion of blood cells, which interrupts the

free flow of blood and results in sites of vascular plugging and local inflammation.[284] Additional salutatory effects of •NO in the vascular system are the inhibition of smooth muscle cell proliferation (thus attenuating disorders such as restenosis) and also promotion of angiogenesis (the growth of new blood vessels).[284] This latter action is an excellent illustration of the 'Janus-faced' roles of •NO, where new blood vessel formation is beneficial for wound healing but •NO has been implicated in the formation of new vessels to supply blood to tumors.[285]

The most commonly cited mechanistic explanation for the paradoxical roles of •NO in cell and organ injury involves the interaction of •NO with reactive oxygen species (ROS). The complexity of these reactions, many of which are mentioned above, leaves ample room to interpret results in terms of 'good' versus 'bad' by emphasizing one or another collection of reactions. Central to ROS biological actions is the metal-catalyzed Haber-Weiss reaction:[286,287]

$$\begin{array}{l} \cdot O_2^- + Fe^{3+} \longrightarrow O_2 + Fe^{2+} \\ H_2O_2 + Fe^{2+} \longrightarrow \cdot OH + OH^- + Fe^{3+} \\ \hline \cdot O_2^- + H_2O_2 \longrightarrow O_2 + \cdot OH + OH^- \end{array} \quad (8)$$

According to this mechanism, it is actually the highly toxic and reactive hydroxyl radical (•OH) that causes most damage, produced by the interaction of $\cdot O_2^-$, H_2O_2, and iron. The reaction that actually produces •OH (the Fenton reaction) is the reduction of H_2O_2 by Fe^{2+}. The function of $\cdot O_2^-$ is twofold, both as a reductant for Fe^{3+} and also because it is a source for H_2O_2, either enzymatically (SOD) or by spontaneous dismutation. Although there is disagreement about how literally this scheme should be taken, it is a good paradigm within which to discuss •NO/ROS interactions.

It is well-established that a major response to septic stimuli in general is the activation (primarily by cytokines and bacterial products, conditions that as described above also can induce •NO synthesis) of phagocytic cells (neutrophils, macrophages) to produce ROS, through the respiratory burst mechanism;[288,289] this is a major immune mechanism for combating infectious agents but also can be damaging to the host.

In terms of potential chemical interactions, the effects of •NO on ROS-induced injury are multiple, and some effects can be classified as 'prooxidant' and others may be classified as 'antioxidant'; still others can be classified as both. In terms of the metal-catalyzed Haber-Weiss reaction, there are two primary effects of •NO. The binding of •NO to metal ions will prevent the Fenton reaction and thus results in an antioxidant action.[290–292] Another important antioxidant action of •NO (and its oxidized product $\cdot NO_2$) is its reaction with lipid radicals, thus resulting in radical chain termination.[23]

One of the first pieces of evidence supporting the identification of EDRF as •NO was the demonstration that $\cdot O_2^-$ reacts rapidly with EDRF.[293] Early work suggested that •NO could be protective against oxidative injury by reacting with, and thus scavenging, ROS.[294] However, in a landmark paper in 1990, Beckman *et al.*[295] brought attention to the fact that the product of the $\cdot NO/\cdot O_2^-$ reaction, peroxynitrite, possesses highly oxidizing properties, thus, •NO effectively converts a rather mild oxidant ($\cdot O_2^-$) into a strong oxidant ($ONOO^-$). This concept has become a central paradigm for interpretation of all prooxidant effects of •NO, although its validity has been questioned.[296] In particular, since the rate of reaction of superoxide with •NO is similar in magnitude to the rate of reaction with SOD, appreciable $ONOO^-$ formation will occur only at locations where the •NO concentration is greater than SOD concentration. The concentration of SOD inside most cells is quite appreciable (in the micromolar range) and so relatively high •NO concentration would be required. This may be less of a problem extracellularly, where SOD levels are lower and also where appreciable superoxide is formed from phagocytic cells.[297] Nevertheless, in at least one case (motor neuron death in a model of amyotrophic lateral sclerosis, Lou Gehrig's disease) there is good evidence that intracellular peroxynitrite formation from •NO and $\cdot O_2^-$ is responsible for toxic effects.[298]

The major 'curse' of working with short-lived species such as radicals and oxidants is the dirth of methods to unambiguously demonstrate their existence and actions in situ (i.e. biologically). This has been especially true for peroxynitrite. In 1994 Beckman *et al.* introduced the use of antibodies directed to protein nitrotyrosines as an immunohistochemical method.[299] This was a very exciting development because at the time it was believed that this was a specific marker for peroxynitrite, based on the demonstration of nitrotyrosine formation from $ONOO^-$.[300] This has been followed by a deluge of papers using this method to demonstrate nitrotyrosine formation in a vast array of inflammatory disease states, thus inferring the presence of peroxynitrite in vivo. Unfortunately, it is now known that nitrotyrosine can be formed from a variety of mechanisms, involving principally metals (including peroxidases) in the presence of nitrite and H_2O_2.[80,81] The mechanistic link between these various conditions is the formation of $\cdot NO_2$, which combines with tyrosyl radical (formed from a number of possible oxidants) to form nitrotyrosine.[301]

In summary, in terms of chemistry the interactions of •NO with ROS are many and complex.[38] The general paradigm that has emerged is that at low levels •NO exerts beneficial effects, through several mechanisms including cellular signaling (e.g. inhibition of vascular aggregation and adhesion, vasodilation) and radical chain termination. At higher levels, and especially in the context of increased ROS (specifically, $\cdot O_2^-$) formation, •NO can greatly contribute to cellular injury. The chemical bases and understanding for this paradigm (if indeed accurate) in terms of reaction patterns of the network of reactive oxygen and nitrogen chemistry are largely unexplored.

13 NOVEL BIOLOGICAL ROLES OF •NO

Researchers in many previously unrelated fields of biology have recently become united by the discovery that •NO plays important roles in their systems. The typical experimental tools used in these numerous studies are the modulation of the observed biological effects by the addition of agents that attenuate (NMMA, hemoglobin, $\cdot O_2^-$) or potentiate (•NO donors, L-arginine) •NO production, as well as the correlation of •NO formation (NO_2^-, NO_3^- appearance) with the biological phenomenon of interest. In addition, it is possible to identify specific cells that are exceptionally rich in NOS and thus correlate the specific sites of •NO production with microanatomical function. In this last section, we briefly describe a few of these novel findings.

The endogenous production of •NO appears to be a phylogenetically widespread phenomenon. The initial reports of endogenous •NO in nonmammalian systems involved birds[302] and invertebrates.[303] It has also been shown that certain blood-sucking insects produce •NO in their salivary glands, and that it is delivered to the blood stream of its victims as a complex to a ferric iron-containing protein named nitrophorin (*see* ***Iron Porphyrin Chemistry***).[304,305] Since •NO binds relatively poorly to Fe^{3+} (compared to Fe^{2+}),[207] the •NO dissociates and induces vascular dilation at the site of the bite. •NO is also involved in the mechanism of control of firefly flashing[306] as well as in other insects (including *Drosophila*) where it appears to perform a variety of signaling and immune roles,[307] as well as in plants where in fact the first enzymatic formation of •NO was reported.[100,101] •NO also plays a biological role in unicellular organisms, including protozoa; one clinically important aspect is that many pathogenic organisms produce •NO for unknown reasons.[308] •NO has been known for many years to be a component of the biological nitrogen cycle, being produced by bacteria during denitrification (*see* ***Copper Enzymes in Denitrification***).[309] However, its role as a messenger in these bacteria is only now being appreciated.[310] Remarkably, *C. botulinum* has recently been shown to possess an •NO sensor that detects •NO down to the femtomolar range.[311] As described above, this organism, which produces the most toxic substance known to humans (the botulinum toxin), is extremely sensitive to nitrite and this sensitivity has been proposed to involve •NO.[222]

Undoubtedly other novel roles for •NO in biology will be discovered; its chemical properties are indeed unique and Nature will always find ways to exploit any chemical opportunity.

1 INTRODUCTION

Together with the transition metal carbides and borides, the transition metal nitrides belong to a family of materials that features an unusual combination of outstanding properties, among which are exceptional hardness, high melting point, metallic luster with sometimes vivid colors, and simple metallic structures combined with excellent electrical and thermal conductivities. This combination of these properties has attracted considerable attention and has resulted in numerous technical applications.[1–4] Lengauer[5] has recently compiled several features of transition metal nitrides and carbonitrides. Many of the nitride phases closely resemble metallic alloys, with broad ranges of homogeneity, particularly if the structure of the metallic host lattice is one of the types encountered in typical metals. They often form solid solutions with structurally related compounds such as other transition metal nitrides or carbides and are easily wetted by liquid metals of the iron group.

The chemical stability of transition nitrides is considerable; they are not readily attacked by dilute acids except by oxidizing acids and hydrofluoric acid or alkaline solutions. The thermal stability is determined by their free energies of formation; the stability decreases with increasing group number. While TiN, ZrN, and HfN can be melted without decomposition at ambient pressure, the nitrides of the other groups decompose by liberating nitrogen before melting points are reached.

Table 1 gives a brief survey of the most important properties of the well-characterized binary transition metal nitrides. It should, however, be emphasized that practically all properties are significantly influenced by the nitrogen to metal ratio (Section 6) and by impurities.

2 STRUCTURE AND BONDING

2.1 Structures: General Features

Transition metal nitrides together with the structurally closely related transition metal carbides belong to the family of ‘interstitial compounds’ or alloys. The common features of this class of materials are the very simple metallic structures with the smaller nitrogen atoms in the interstitial voids of the frequently dense-packed host lattice. The simple conceptual Hägg model in which the basically metallic character of the host metal is thought to be only modified by insertion of nonmetal atoms into the voids had to be substantially restructured in the light of modern bonding theories in order to account for the strong binding energies observed between transition metal atoms and nonmetal atoms. Nevertheless, the rather approximate interstitial alloy concept has proved helpful for gaining insight into the basic principles governing the structures of interstitial alloys and compounds.

Because of structural similarities, transition metal nitrides usually form solid solutions with transition metal carbides. However, there are important differences, possibly owing to the different bonding character of nitrogen as compared to that of carbon. Transition metal carbides and nitrides generally have face-centered cubic (fcc) or hexagonal close-packed (hcp) metal lattices with nonmetal atoms more or less randomly distributed on the interstitial sites; deviations from this simple concept are much more frequently encountered with nitrides. If the immediate neighborhood of the nonmetal X (X = C, N) is considered, one can define the structural elements of interstitial alloys.[6] In the group 4 and 5 transition metals, the common structural element of the nitrides and carbides is the T_6X octahedron. With increasing radius ratio r_X/r_T, the trigonal prismatic group T_6X is favored over the octahedral group. Therefore, the transition metal carbides of groups 6–9 feature trigonal prismatic T_6X elements in different crystallographic arrangements. In transition metal nitrides, a third structural element is occasionally observed, particularly in group 5 compounds, consisting of T_5X square pyramids. These prevail even in the complex nitrides, such as the Z-phases NbCrN, TaCrN, NbMoN, and TaMoN with the filled Θ-CuTi-type structure. With this square pyramid, which has lower symmetry than an octahedron, such nitrides have more complicated structures (Section 5.2) than the corresponding carbides.

Because of the formation of structural elements other than T_6N octahedra, the fcc structure of δ-nitrides is destabilized increasingly with increasing group number and, within a group, with increasing periodic number. For example, the nitrides of group 4, δ-TiN_{1-x}, δ-ZrN_{1-x} and

δ-HfN_{1-x} crystallize in the sodium chloride structure. No low-temperature modifications of these stoichiometric nitrides are known. In group 5, all three metals form stoichiometric fcc nitrides, too, but δ-$VN_{1.00}$ transforms below 205 K into a tetragonal modification,[7] δ-$NbN_{1.00}$ below around 1320 °C into hexagonal η-NbN,[8] and δ-$TaN_{1.00}$ below around 1920 °C congruently into hexagonal ε-TaN.[9] In group 6, these fcc nitrides are increasingly less stable: fcc CrN is nearly a line compound at low temperature with a reduced thermochemical stability and transforms below approximately 280 K into a tetragonal antiferromagnetic compound,[10] and fcc γ-MoN_{1-x} apparently does not even occur with a nitrogen content approaching the ideal composition $MoN_{1.00}$ (except perhaps at very high pressures) but rather in the vicinity of $MoN_{0.50}$. Face-centered cubic $MoN_{0.50}$ also transforms into a tetragonal modification with an ordered arrangement of nitrogen atoms in the interstitial sites. This tendency proceeds further in the Mn–N and Fe–N systems, where ferromagnetic fcc phases with the stoichiometry T_4N are observed with an ordered arrangement of N atoms.[11] Ordered manganese nitride phases with respect to the arrangements of nitrogen and a concurrent tetragonal distortion of the metal host lattice are found. An fcc MnN_{1-x} was recently prepared by high-rate reactive sputtering.[12]

An extensive compilation of nitride phases is contained in Pearson's handbook[13] and in the ASM binary phase diagram compilation.[11]

The different stacking of close-packed metal layers can be described by the Jagodzinski–Wyckoff notation, where close-packed stacking ABC,ABC, ... is designated as 'c' and hexagonal close-packed stacking AB,AB, ... is designated as 'h'. Figure 1 shows these structures and lists several metal nitride and carbide phases that can be described with this formalism.

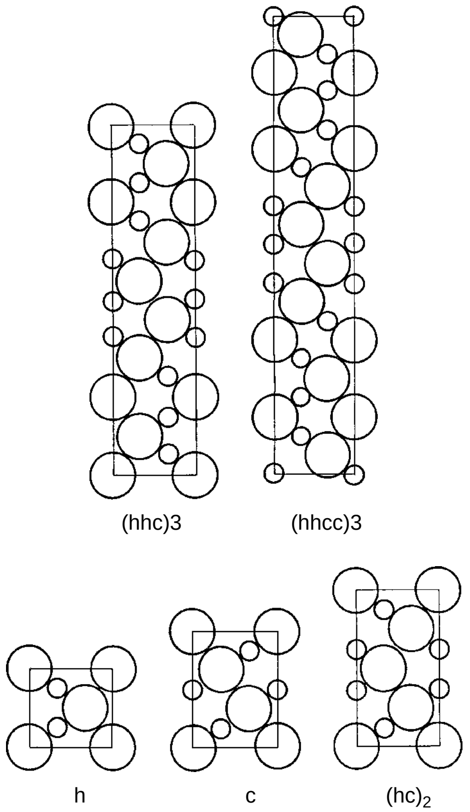

Figure 1 Close-packed structure types observed for various transition metal nitrides. Large circles designate metal atoms, small circles designate nitrogen atoms. In h sequences, only 50% of the interstices can be occupied. The following transition metal nitrides crystallize in these structures: h: β-V_2N, β-Nb_2N, β-Ta_2N, ε-Cr_2N, ζ-Mn_2N, ε-Fe_2N; c: δ-TiN_{1-x}, δ-ZrN_{1-x}, δ-HfN_{1-x}, δ-VN_{1-x}, δ-NbN_{1-x}, δ-TaN_{1-x}, γ-MoN_{1-x}; $(hc)_2$: ScNbN, ScTaN, Mn_3TaN_{4-x}; $(hc)_2$ with metal and nonmetal sites exchanged: η-NbN, η-TaN; $(hhc)_3$: η-Ti_3N_{2-x}, η-Hf_3N_{2-x}; $(hhcc)_3$: ζ-Ti_4N_{3-x}, ζ-Hf_4N_{3-x}

2.2 Bonding

The bonding in transition metal carbides and nitrides can be described as a mixture of metallic, covalent, and ionic components.

The metallic character is immediately noticed in the high electrical conductivities of these compounds. The bonding mechanism has been described extensively by a variety of approaches for calculating the density of states (DOS) and hence the electron density in fcc transition metal nitrides, carbides and oxides.[14] In the DOS of these compounds, there is a minimum at a valence electron concentration (VEC) of eight that corresponds to the stoichiometric composition of group 4 carbides TiC, ZrC and HfC. Figure 2 compares the decomposed and the total DOS of TiN and TiC[15] with respect to the s, p, and d bands. At low energies of <0Ryd the s band is characterized by a large contribution of the nonmetal 2s state. Above 0Ryd the p band follows and there is a significant contribution of d states to this band, too. At higher energies, the d band composed of d states follows with the Fermi energy E_F located well within this band. The DOS at E_F is higher for TiN than for TiC, consistent with the observed superconducting properties (TiN, $T_C = 5.4$ K; TiC, $T_C < 1.2$ K) and room-temperature electrical conductivities (Section 6.3).

An illustrative picture of covalent bonding in these compounds can be drawn in the molecular orbital (MO) scheme[16] where atomic orbitals of atoms are combined to form bonding and antibonding states. Figure 3 shows a schematic drawing of these bonds between metal d and nonmetal p orbitals in the (100) plane of the fcc structure, which can be decomposed into two different bonding symmetries, t_{2g} and e_g. It can be shown that the calculated electron densities in this plane reflect the change of e_g bonding symmetry in TiC to t_{2g} bonding symmetry in TiN. Thus the exchange in bonding strength from a strong Ti–C interaction in TiC toward a more pronounced Ti–Ti interaction in TiN is to be expected.

The ionic contribution to the binding mechanism of transition metal nitrides and carbides can be estimated from

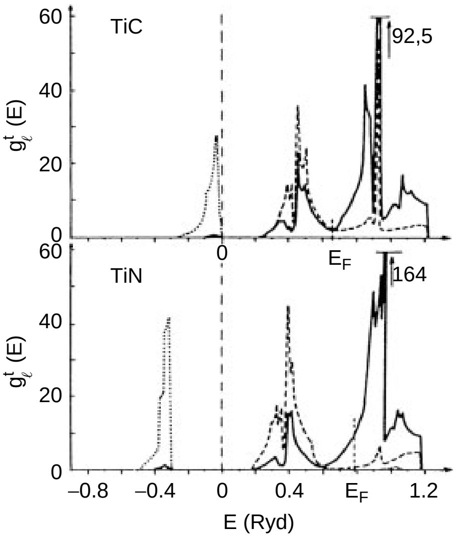

Figure 2 Density of states (DOS) for TiC and TiN. (Ref. 15. Reproduced by kind permission of Kluwer Academic Publishers)

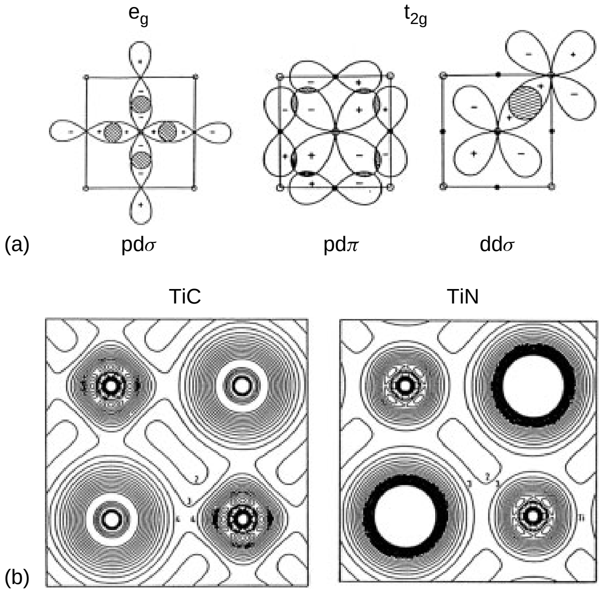

Figure 3 Bonding schemes: (a) of different symmetries in the (100) plane and calculated electron densities and (b) of TiN and TiC showing the change around Ti from e_g symmetry TiC to t_{2g} bonding symmetry in TiN. (Ref. 16. Reproduced by permission of Wiley, Inc)

the charge transfer from the metal atom to the nonmetal atom. It is about half an electron per atom, which contributes to the electrostatic interaction of metal and nonmetal.

The bonding of 4d transition metal nitrides and carbides can be treated in a very similar way; the nonmetal contribution to the electron density is about the same, whereby the contribution from 4d electrons causes a more spatial extension of electron density than in 3d compounds. In 5d transition metal nitrides and carbides, relativistic effects due to the heavy cores have to be taken into account.

3 PREPARATION

Transition metal nitrides can be prepared by allowing the metal or the metal hydride in powdered or compact form to react with molecular or atomic nitrogen or flowing ammonia:

$$Ti + \frac{1}{2}N_2 \longrightarrow TiN \quad (1)$$

$$ZrH_2 + \frac{1}{2}N_2 \longrightarrow ZrN + H_2 \quad (2)$$

$$Mo + NH_3 \longrightarrow MoN + \frac{3}{2}H_2 \quad (3)$$

The pressure of molecular nitrogen at a given temperature that is necessary to obtain a specific nitride phase is defined by the nitrogen potential (partial free energy of nitrogen) of the nitride. In flowing ammonia, very high nitrogen potentials can be maintained as long as the thermal decomposition of ammonia into $N_2 + 3H_2$ can be minimized.

The formation of nitrides from oxides is performed in the presence of carbon as a reducing agent, according to the overall reaction

$$TiO_2 + 2C + \tfrac{1}{2}N_2 \longrightarrow TiN + 2CO \quad (4)$$

This reaction usually proceeds over several intermediate products and the resulting nitride may contain oxygen and carbon.

For the preparation of nitrides from metal powders, the exothermic heat of formation can be utilized in the self-sustaining high-temperature synthesis (SHS) process. If the reaction is exothermic enough, that is, if the heat generated is sufficient to reach the reaction temperature, then the starting material is converted to the nitride and the heat is dissipated. For the preparation of large crystals, zone-annealing techniques have been developed.[17] Similar to the zone-melting process, a heated zone is passed along a rod in a nitrogen atmosphere. The starting materials are either solid-state sintered nitride powders or metal powders pressed into rods. The applied temperatures must be very high (ca. 3000 °C) in order to overcome the low diffusivity of nitrogen in nitrides, but they must not exceed the melting temperatures of the compounds in order to avoid incongruent melting and decomposition. Crystals on the order of 1 cm^3 have been produced by this technique. While they still may show some concentration gradients, they are suitable for solid-state investigations such as neutron diffractometry.

A great variety of methods have been applied to the preparation of nitride layers. These can be divided into three main groups (Section 7.1 gives more details).

- Chemical vapor deposition (CVD) – a volatile transition metal compound such as a chloride is reacted in the gas phase with ammonia, nitrogen/hydrogen or ammonia/hydrogen/nitrogen mixtures. The high-melting nitride that forms as a reaction product in the gas phase nucleates on any solids present, for example, hard metals, and forms compact strongly adhering layers at temperatures around 1000 °C.
- Physical vapor deposition (PVD) – the transition metal is evaporated by electron beam or plasma heating or sputtered by glow discharge and reacted with low-pressure nitrogen (typically in the range of 10^{-4} mbar). Numerous modifications of PVD methods have been developed. The nitride layers that are deposited on the substrate often have high lattice defect concentrations and hence exhibit significant deviations from generally known bulk values (lattice parameters, hardness, composition, etc.).
- Surface nitridation is widely used for surface hardening and can be achieved by subjecting the material surface to the action of ammonia, molecular or atomic nitrogen, or nitrogen ions. Case-hardening techniques also make use of cyanide salt baths to form nitrides or carbonitrides on material surfaces. Reactive plasma techniques and high-pressure techniques have been developed to keep the workpiece temperature low and to avoid thermally induced changes in the workpiece. Laser irradiation together with an N_2 jet directed on the heated spot is employed for locally limited heating of the sample. This nitridation method is applicable to titanium alloys (e.g. Ti6Al4V) used to create wear- and corrosion-resistant layers on steam turbine blades for protection against droplets having supersonic velocity.

4 CHARACTERIZATION

4.1 Chemical Analysis

Several procedures have been applied for the analysis of nitrogen and impurities such as oxygen and carbides in nitrides.

- Combustion analysis[18] according to the Dumas method – the sample is heated at temperatures of up to 1200 °C in oxygen and/or with oxidizing agents such as V_2O_5, CuO, or Cu_2O. The evolved N_2 is either measured volumetrically in an azotometer or via a gas chromatograph[19] equipped with a thermoconductivity detector. With the latter equipment, C and H can also be determined simultaneously via the combustion products CO_2 and H_2O. The accuracy of the method is better than 1 rel %N for finely powdered samples if combustion can be completed within a rather short time span.
- Carrier gas hot extraction – the sample is heated to more than 2000 °C in the presence of carbon and an auxiliary bath of metal such as platinum and in a stream of a carrier gas such as He. Nitrogen is liberated as N_2 and is usually measured in a thermoconductivity cell. Oxygen combines with C to give CO and can thus be analyzed. Because of the high temperatures involved, the method is suitable for powder samples with larger grain size or even for small solid pieces. The accuracy of the method is on the order of 1–2 rel %N.
- Kjehldahl analysis – this involves the dissolution of nitrides in acids whereby the nitrogen is converted into ammonium ions. The dissolution process may be time consuming since some nitrides, such as δ-TiN_{1-x}, are chemically very stable against acids and must be dissolved using severe conditions such as by the action of hydrofluoric acid in Polytetraflourethylene (PTFE) containers at 100–200 °C. It is doubtful whether all of the nitrogen can be converted into NH_4^+ so systematic errors may arise.

4.2 Physical Analysis

Among the microphysical methods used for the analysis of nitrogen in nitrides, e.g. electron probe microanalysis (EPMA), Auger electron spectroscopy (AES), ultraviolet X-ray spectroscopy (UPS) and X-ray spectroscopy (XPS), secondary ion- or neutral mass spectrometry (SIMS, SNMS) and Rutherford backscattering (RBS), EPMA is considered to have the highest reproducibility and accuracy, provided that the lateral resolution of only a few microns is sufficient. The main problem in EPMA is the rather low energy of $N_{K\alpha}$ radiation. Even with windowless detector systems, a high background-to-peak ratio together with low net intensities are the result.[20] High-accuracy EPMA requires external or internal standardization[21] together with a wavelength-dispersive spectrometer equipped with high-quality crystals (e.g. W-Si multilayer or lead stearate crystals). For standardization, diffusion couples have been used in which diffusion layers are broadened.[22–24] Such samples can even be prepared in single-phase form upon increase of diffusion time so that the gross chemical composition is the same as the phase composition, a necessary prerequisite for application of different analyzing techniques and for true standardization.[25] By such a method, single-phase standards of TaN,[26] CrN,[27] and ζ-Hf_4N_{3-x}[28,29] have been prepared. These phases have a very narrow homogeneity range at least at a certain temperature.

Neutron activation analysis (NAA) making use of the nuclear reaction $^{14}N(n,2n)^{13}N$ can be applied for bulk determination of nitrogen.

5 THERMODYNAMICS

5.1 Nitrogen Partial Pressure

The nitrogen partial pressure of the transition metal nitrides is a function of temperature and increases substantially with increasing group number. This is reflected in the Richardson diagram shown in Figure 4. The lower (the more negative) the free energy of formation the lower is the equilibrium nitrogen pressure of the nitride. Group 4 nitrides can easily be obtained by nitridation of the metals with molecular nitrogen under low pressures even at high temperatures, whereas for the group

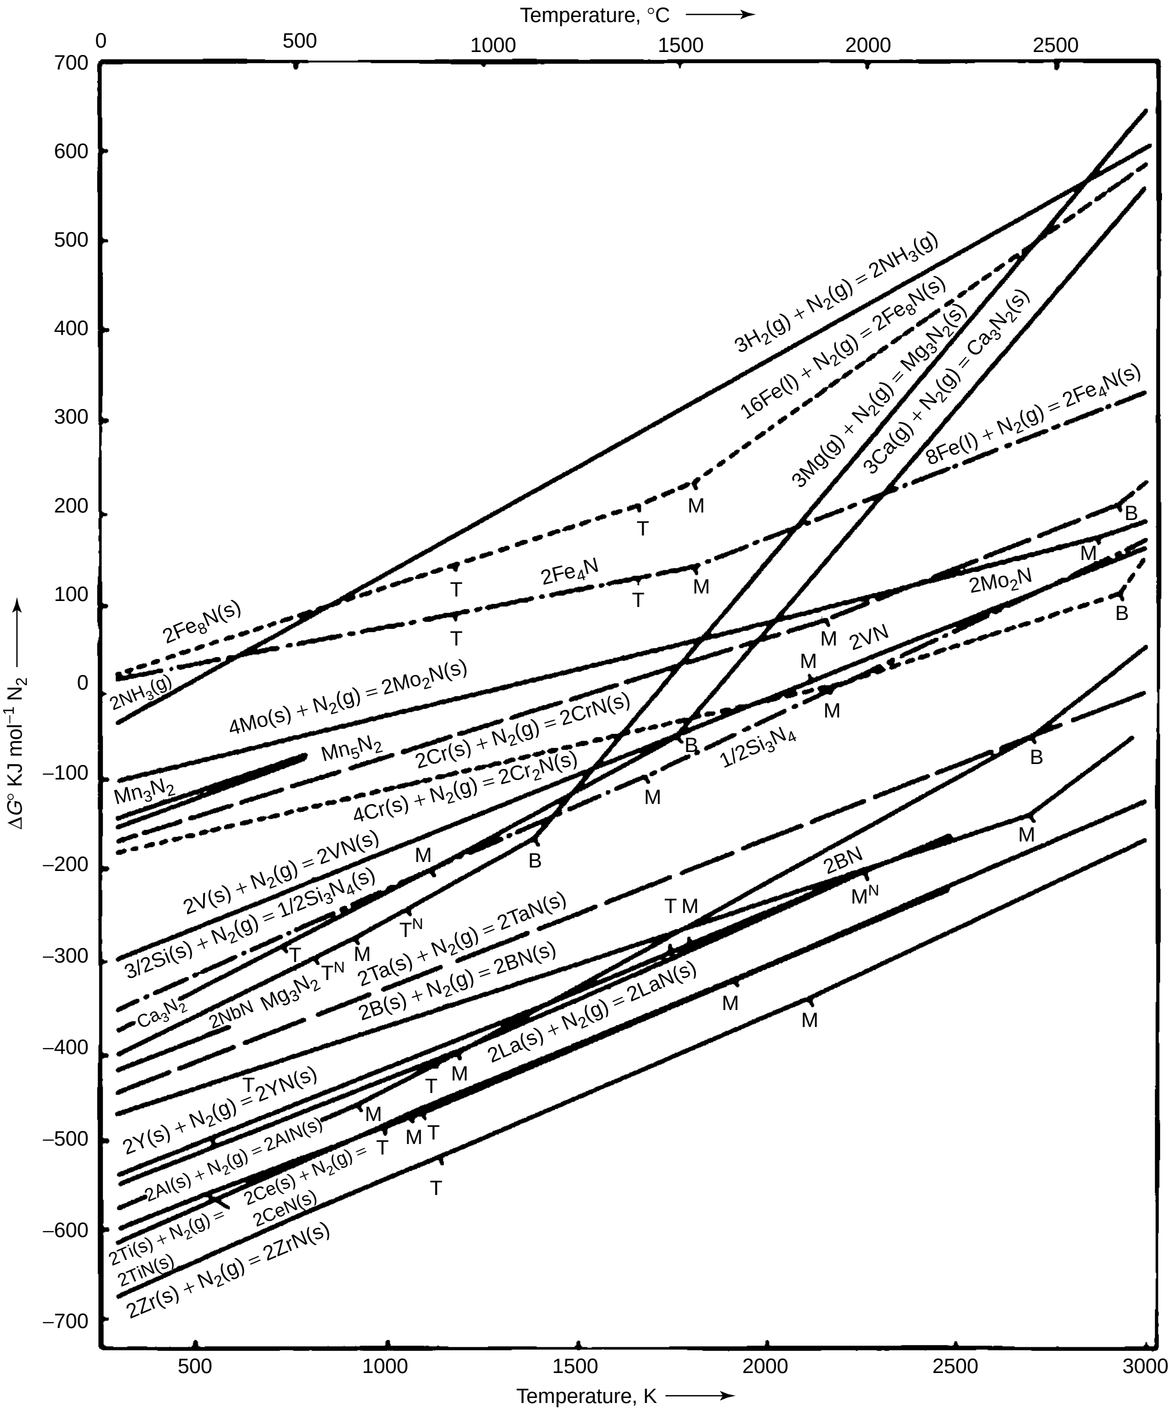

Figure 4 Richardson diagram of various transition metal mononitrides (together with other nitrides) giving the free energy of formation as a function of temperature. (Ref. 4. Reproduced by permission of Wiley VCH)

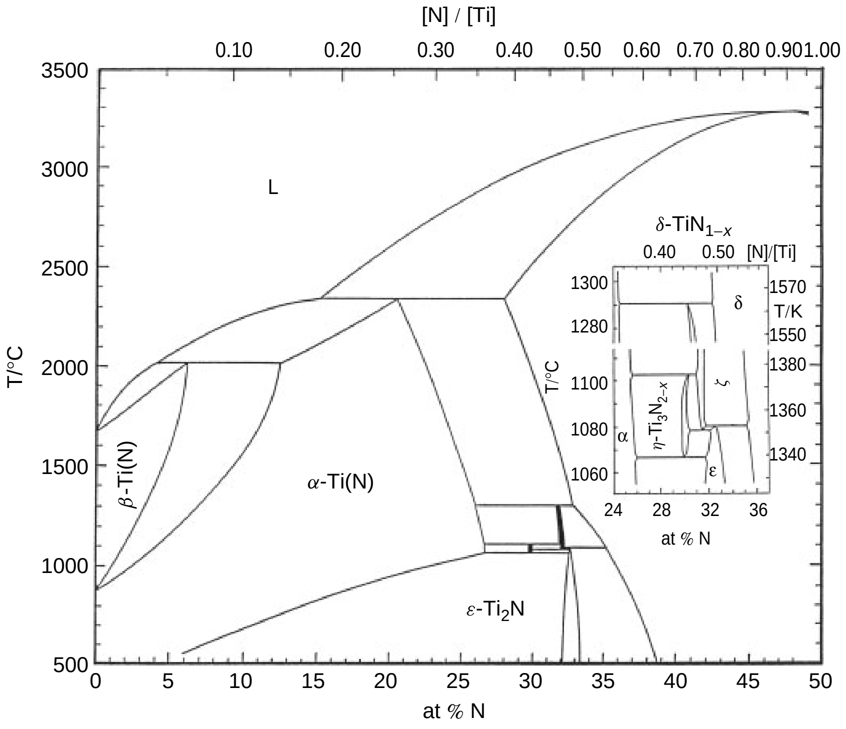

Figure 5 Phase diagram of the Ti–N system. (Reprinted from Ref. 31. © 1991, with permission from Elsevier)

5 nitrides the nitrogen pressure must already exceed normal pressure at temperatures above 1400 °C, and even higher pressures or more energetic nitriding conditions must prevail for the preparation of group 6 nitrides.

The nitrogen pressure determines the composition of the nitride if equilibrium is attained. Thermochemical models have been established that correctly predict pressure-temperature-composition (p-T-x) relationships for nitride phases.[30]

Nitride phases with a nonmetal to metal ratio greater than one have been obtained with high-pressure nitrogen or at high nitrogen potentials, such as those prevailing in flowing ammonia or ionic nitrogen atmospheres. Either an extension of the mononitride phase field to compositions $N/T > 1$ has been observed such as in the Nb–N, Hf–N, and Ta–N systems, or distinct nitride phases are observed such as in the Zr–N, Nb–N, and Ta–N systems.

Ion implantation techniques can lead to nitrides having extremely high nitrogen to metal ratio such as $TiN_{1.5}$ but these phases are probably metastable.

5.2 Phase Equilibria and Structural Features

Several of the transition metal-nitrogen systems are not yet fully established. This is especially the case for some of the metals in groups 6–9, probably because of the lower technical relevance of the nitrides and the high nitrogen pressures needed for equilibrium investigations.

5.2.1 The Ti–N System

The Ti–N system[31] features a high solubility of nitrogen in α-Ti, the three subnitride phases η-Ti_3N_{2-x}, ζ-Ti_4N_{3-x} and ε-Ti_2N, and the fcc phase δ-TiN_{1-x} with the sodium chloride structure. η-Ti_3N_{2-x} and ζ-Ti_4N_{3-x} have been found to be isostructural with the hafnium subnitride phases and are characterized by metal atom layers comprising cubic- and hexagonal stacking sequences (Figure 1). Figure 5 shows the phase diagram of the Ti–N system.

In δ-$TiN_{0.50}$, the random distribution of nitrogen atoms undergoes an ordering process[32] below about 880 °C with a concurrent tetragonal distortion of the metal lattice.[33] The so-formed δ'-$TiN_{0.5}$ phase is only formed from δ-TiN_{1-x} by lattice distortion and is not an equilibrium phase (e.g. it is not formed in isothermal diffusion couples in the form of a phase band).

5.2.2 The Zr–N System

If the solid solution of nitrogen in Zr, α-Zr(N), which exists up to a composition 'Zr_2N', is not considered as a nitride phase, the Zr–N system is characterized by the presence of only one nitride phase, δ-ZrN_{1-x} up to a composition of approximately [N]/[Zr] = 1. It should be mentioned that none of the subnitride phases that exist in the neighboring systems Ti–N and Hf–N occur here. In Massalski's compilation[11]

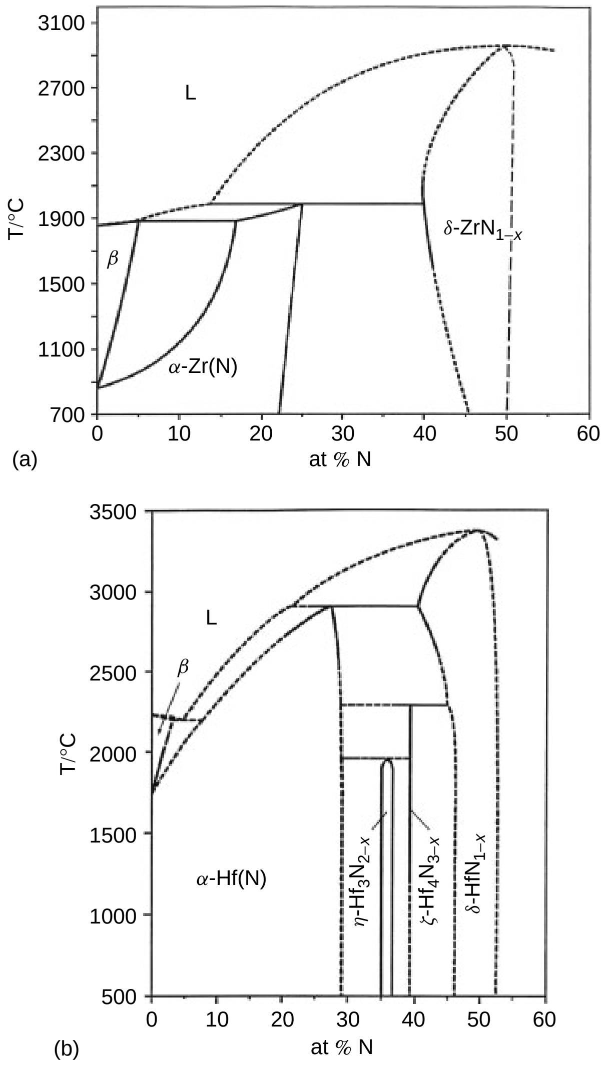

Figure 6 Phase diagrams of group 4 transition metal-nitrogen systems. (a) Zr–N. (Ref. 11. Reproduced by permission of Materials Information Society/ASM International), (b) Hf–N. (Reprinted from Ref. 28. © 1991, with permission from Elsevier)

(Figure 6), the Zr_3N_4 phase[34] that can be obtained by reacting $ZrCl_4$ with NH_3 has not been included.

5.2.3 The Hf–N System

Besides the fcc δ-HfN_{1-x}, the Hf–N system contains two subnitride phases,[35] η-Hf_3N_{2-x} and ζ-Hf_4N_{3-x}. Only a few phase equilibria studies have been performed for this system. Figure 6 shows the compiled phase diagram together with results from diffusion couples.[28,29] The homogeneity ranges of the subnitride phase could be established. The decomposition temperatures of these phases need to be reinvestigated.

5.2.4 The V–N System

In the vanadium–nitrogen system, the phases β-V_2N and δ-VN_{1-x} have cph and fcc structures, respectively. Carlsson *et al.*[36] have reviewed the V–N system and reinvestigated the vanadium-rich portion. Compiled data and results of a phase diagram study based on diffusion couples[37] have been used to construct the phase diagram shown in Figure 7.

Stoichiometric VN undergoes a phase transition into a tetragonal phase below 205 K.[7] At a composition of around $VN_{0.80}$, a transition into a tetragonal phase occurs at 500 °C. Two different versions of the phase diagram at temperatures below 500 °C have been reported,[39,40] one with a eutectic and one with a peritectic phase reaction between tetragonal $VN_{0.83}$ and δ-VN_{1-x}.

5.2.5 The Nb–N System

Brauer *et al.*[41,42] made careful studies on p-T-x relationships in the Nb–N system. In recent years, the phase reactions in this system have been investigated by high-temperature X-ray diffraction as well as by use of diffusion couples.[38,43,44] The phase reactions could be assumed as established (Figure 7). Interestingly, γ-Nb_4N_{3-x} is formed by a martensitic transformation from δ-NbN_{1-x}, hence an interface between δ-NbN_{1-x} and γ-Nb_4N_{3-x} does not form in diffusion couples.[38]

Near the composition NbN, at least three phases have been observed. For η-NbN, two different structures have been proposed with respect to the nitrogen positions. It contains trigonal prismatic and octahedral T_6N structure elements and features a metal layer sequence AABB. η-NbN undergoes a phase transition at about 1320 °C (depending on the nitrogen pressure) into fcc δ-NbN_{1-x} with a sodium chloride structure. Another phase, δ'-$NbN_{0.97}$ is most probably oxygen stabilized or occurs as metastable phase with phase transitions and is not included in the phase diagram. By reacting Nb powder with nitrogen under high pressure, the composition of the δ-NbN_{1-x} phase can be extended beyond N/Nb = 1. At even higher nitrogen pressure, the phase Nb_5N_6 can be prepared. Nb_5N_6 is isotypic with Ta_5N_6 and features T_5N square pyramides structural elements. These structural elements have not been observed in the analogous carbide systems and are probably linked to the higher electron concentration in nitrides.

5.2.6 The Ta–N System

The lower stability of the tantalum nitride phases as compared to the nitrides of the group 4 metals is reflected in the substantially higher equilibrium pressures (Figure 7).[45] In order to prepare the high-temperature fcc phase δ-TaN_{1-x}, the nitrogen pressure must exceed 10 bar but can be stabilized at lower pressures and temperatures by minute amounts of carbon. It is the hardest known transition metal nitride phase. The Ta_2N phase belongs to the ε-Fe_2N type at low temperatures and undergoes an order-disorder transition to

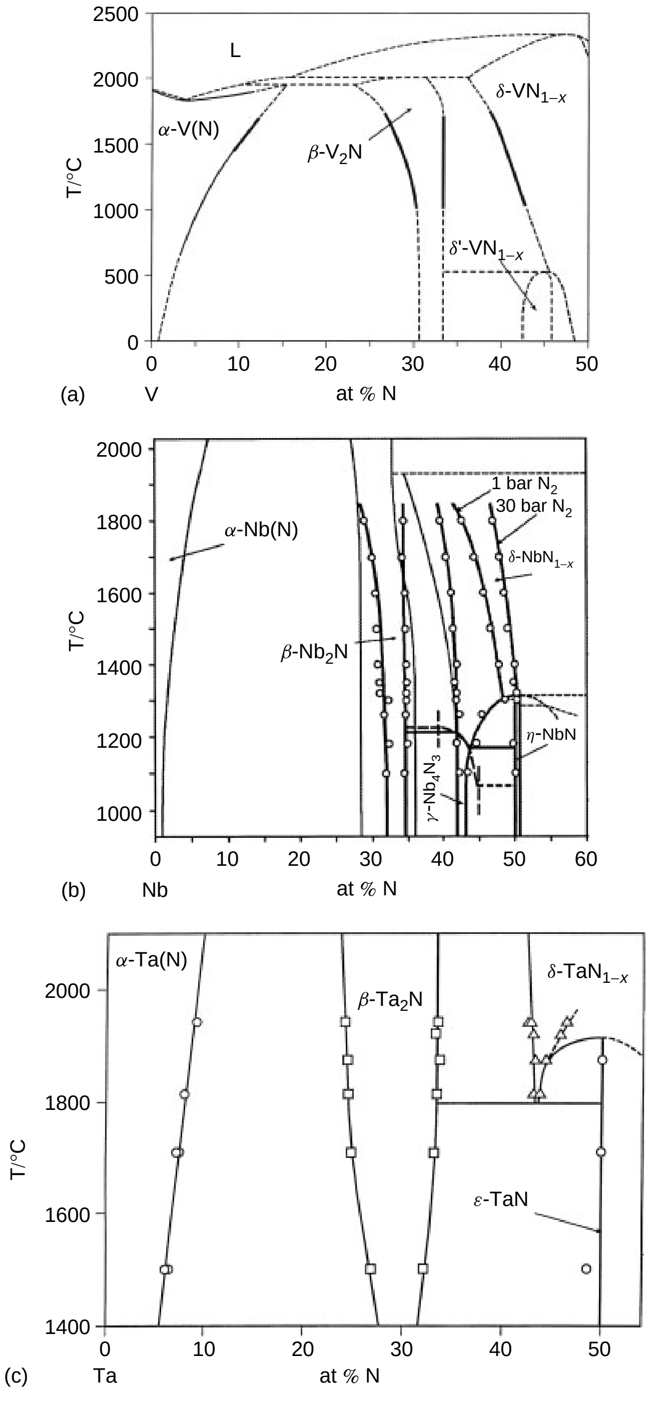

Figure 7 Phase diagram of group 5 transition metal-nitrogen systems. (a) V–N. (Ref. 37. Reproduced by permission of Materials Information Society/ASM International); (b) Nb–N. an L′3 type between 1600 and 2000 °C. The often cited melting point of TaN of 2950 °C is probably incorrect and has to be attributed to Ta_2N. TaN is expected to melt at about 2800–3000 °C and nitrogen equilibrium pressures of 1–3 kbar. The θ-TaN phase with a WC-type structure is often observed in the reaction products of Ta powder with nitrogen or ammonia at temperatures below 1100 °C and is believed by Brauer *et al.*[46] to be a high-pressure phase that is metastable under normal conditions. ε-TaN has a structure not encountered in carbides, featuring an arrangement of Ta_5N squared pyramids. There are three stoichiometric phases in the Ta–N system with decreasing metallic character. The one with the highest nitrogen content, red Ta_3N_5 is nonmetallic and has been synthesized by the reaction of $TaCl_5$ with NH_3. In this rhombohedral phase, the nitrogen atoms are situated in the centers of tetrahedra while the tantalum atoms are still sixfold coordinated by nitrogen atoms in the form of slightly distorted octahedra.

5.2.7 The Cr–N System

The Cr–N system is characterized by the nitride phases Cr_2N_{1-x} and CrN. The former has an appreciable homogeneity range. The arrangement of the metal atoms is cph and the nitrogen atoms are distributed in an ordered arrangement in the interstitial voids corresponding to the ε-Fe_2N-type structure. CrN crystallizes in the sodium chloride type structure and its homogeneity range at low temperature is rather narrow whereas it is substantially broadened above about 1230 °C.

Cr_2N_{1-x} is readily dissolved by dilute acids, whereas CrN appears to withstand acid attack for prolonged periods. CrN is paramagnetic at room temperatures and undergoes a paramagnetic-antiferromagnetic first-order transition at temperatures between 276 and 286 K, depending on the composition.[10] The phase equilibria in the Cr-N system are strongly dependent on the nitrogen pressure. A phase diagram based on literature compilation and a study by diffusion couples is shown in Figure 8.[27]

5.2.8 The Mo–N and W–N Systems

In the Mo–N system (phase diagram[47] in Figure 8), three nitride phases have been reported. An fcc phase, originally named γ-Mo_2N because of its composition around 33 at %N, should instead be written as δ-MoN_{1-x} to be consistent with the notation for other fcc nitrides. Diffusion couple studies gave a homogeneity range at 1000 °C of 28.5–38.2 mol %N.[48] Since fcc–Mo_2N_{1-x} has been reported to exist at nitrogen contents above 33 at % and since it forms solid solutions with fcc δ-CrN, it can be assumed to be basically of the fcc δ-nitride type. This compound undergoes an ordering transition of the nitrogen atoms and a concurrent tetragonal distortion of the metal lattice into β-Mo_2N between 400 and 850 °C, depending on the composition. A hexagonal phase, Mo_2N, which would be expected by analogy with the other transition metal nitride systems, appears to be thermodynamically less stable than the cubic phase because in the ternary system Mo–C–N the

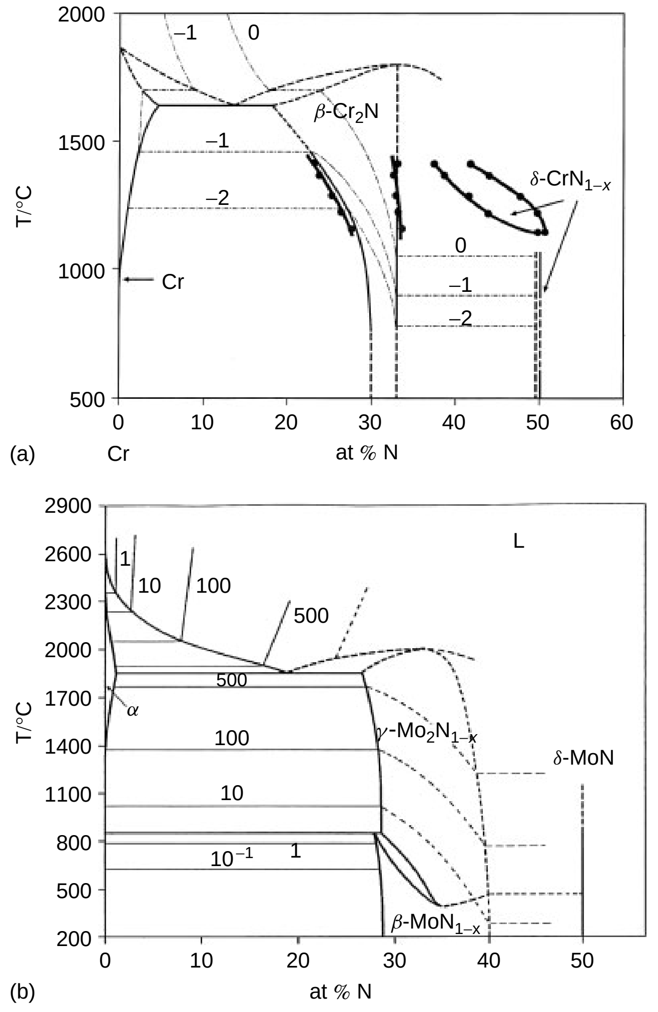

Figure 8 Phase diagrams of group 6 transition metal-nitrogen systems. (a) Cr–N system. (Ref. 11. Reproduced by kind permission of Springer Science & Business Media)

compositional range of the hexagonal solid solution $Mo_2(C,N)$ extends from Mo_2C to approximately $Mo_2(C_{0.35},N_{0.65})$.[49]

Another phase, δ-MoN, with a structure similar to that of WC, has been prepared by various methods including nitridation of Mo powder with flowing ammonia and reaction of $MoCl_5$ with NH_3. It has been structurally characterized to have several types of ordered arrangements of nitrogen in the centers of trigonal prismatic structure elements.[50]

While at least 15 different nitride phases with compositions ranging between W_2N and WN_2 have been reported, none of them appear to be very well characterized. As for the Mo–N system, an fcc nitride WN_{1-x} appears to exist since nitridation experiments[51] under pressure in the Mo–W–N system have shown that the fcc MoN_{1-x} phase is able to form extended solid solutions with the isotypic phase WN_{1-x}. The pressure required to bring molecular nitrogen to reaction with tungsten powder at such temperatures, where kinetics are favourable, appears to be beyond the pressures available in standard laboratories. It is quite probable that another phase, WN with a WC-type structure, exists; it has at least been shown that nitrogen stabilizes the quaternary solid solution (Mo,W)(C,N) with a WC-type structure. Except for the solubility of nitrogen in bcc WN, no reliable data for this system are available.

5.2.9 The Mn–N, Fe–N, Ni–N and Co–N Systems

The Mn–N system[11] bears some resemblance to the Cr and Fe nitride systems. The correspondence to the Cr–N system manifests itself by the existence of the Mn_2N_{1-x} phase with a cph arrangement on Mn atoms as well as two nearly cubic phases with compositions η-Mn_4N_3 and δ-Mn_6N_5.

Similarity to the Fe–N system is reflected by the extensive solid solubility of nitrogen, particularly in the fcc manganese (austenite) phase and the occurrence of a ferromagnetic Mn_4N phase. The nitrides with higher nitrogen contents, η-Mn_4N_3 and δ-Mn_6N_5, can only be prepared by the reaction of ammonia with manganese powder at rather low temperature, suggesting that the equilibrium pressures of nitrogen are very high even at moderate temperatures. η-Mn_4N_3 resembles in its structure the ordered phases Mn_4N_3 and β-Mn_2N, where ordering of the nitrogen atoms at the interstitial sites is accompanied by a tetragonal distortion of the cubic lattice. The θ-Mn_6N_5 phase comes very close to the stoichiometric composition MnN but still has a clearly visible tetragonality of the basically fcc lattice. CrN apparently stabilizes an fcc solid solution extending from CrN up to $(Cr_{0.2}Mn_{0.8})N_{1-x}$ at 1000 °C and 800 bar N_2.[52]

The solubility of nitrogen in austenite (γ-Fe) is much higher than that in α-Fe, and in this respect nitrogen behaves similarly to carbon. Upon cooling of nitrogen−containing austenite, a structure develops that is similar to pearlite and is consequently called *nitrogen pearlite*. Unlike carbon, nitrogen forms an ordered Fe_4N phase that is ferromagnetic below 480−508 °C. At about 680° Fe_4N transforms into ε-Fe_2N_{1-x} and in that respect the close similarity to the Mn–N system becomes apparent. Besides ε-Fe_2N with an ordered arrangement of nitrogen atoms on the interstitial sites between the hexagonal arranged metal atoms, the ζ-Fe_2N phase with a slightly higher nitrogen content and an orthorhombic distortion of the cph metal lattice has been reported. Figure 9 presents the Fe–N system with pressure isobars.[53]

Various iron nitrides and carbonitrides are formed during case hardening of steels and alloyed steels.[54] These iron nitrides are hard, highly wear resistant and usually do not lead to dimensional changes in the case-hardened items.

While there are no phase diagrams available for the Co–N and Ni–N systems, it can be supposed that they are similar to the Fe–N system but with even higher equilibrium pressures. Several phases have been prepared by the reaction of flowing ammonia with Co and Ni powder.

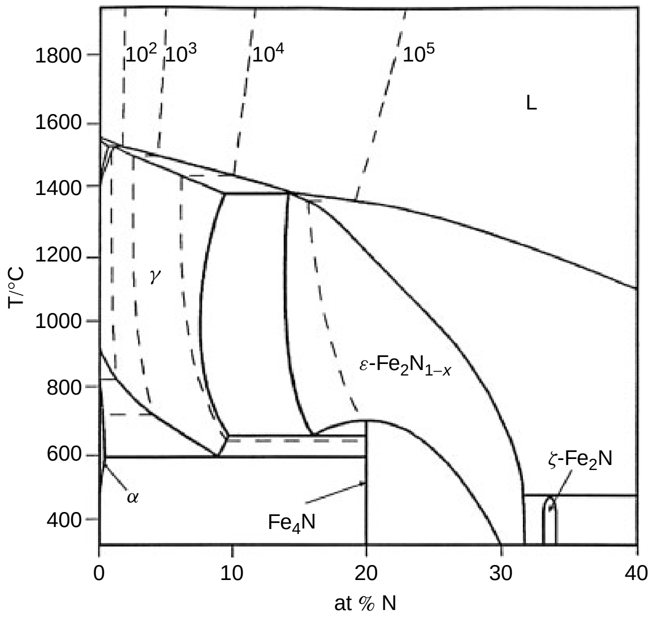

Figure 9 Phase diagram of the Fe–N system: isotherm pressures are in bar; the region around the ζ-Fe_2N phase has been modified. (Ref. 53. Reproduced by permission of Royal Institute of Technology, Stockholm)

5.2.10 Ternary and Higher-order Nitride Systems

Binary transition metal nitrides can form ternary solid solutions with each other if they are isostructural and if their lattice parameters differ by no more than about 10−15%. δ-VN_{1-x} and δ-ZrN_{1-x} do not form extensive solid solutions with each other and the intersolubility of δ-VN_{1-x} and δ-HfN_{1-x} is not complete.

Ternary phases with structures different from those of the phases of the binary boundary systems are more the exception than the rule. Such phases have been reported in the systems Nb–Mo–N, Ta–Mo–N, Nb–Ta–N, Zr–V–N, Nb–Cr–N, and Ta–Cr–N. Information about ternary transition metal-nitrogen systems is often available for specific temperatures only.[55] This is even more the case for quaternary nitride systems, which play a role in the production of carbonitride cermets where quaternary compounds of the types (Ti,Mo)(C,N) and (Ti,W)(C,N) are of interest (*see* ***Carbides: Transition Metal Solid-state Chemistry***), as well as in layer technology where titanium nitride-based coatings of the type Ti(C,B,N) are prepared by magnetron sputtering. Layers consisting of ternary compounds of the type (Ti,Al)N and (Ti,V)N also have favorable properties[56] with respect to abrasion resistance.

A further group of ternary nitrides are of the type $R_2Fe_{17}N_x$ where R is a rare earth element such as Sm, Ce or Nd, and x indicates the variable nitrogen content. These phases have been prepared, by nitridation at relatively low temperatures and up to 15 MPa N_2, under which conditions the nitrogen content can reach $x = 3$. They are closely related to borides and carbides with the similar formula and have attracted considerable interest for hard-magnetic applications.[57] It has been reported that these phases can reach compositions where $x = 6$, using a combination of hydrogen and nitrogen treatments.

Additional generally interesting phases from the crystal chemistry viewpoint are the H-phases,[58] for example, Ti_2AlN, nitrogen perovskites, filled β-manganese-type phases, and Nowotny[6] phases.

6 PROPERTIES OF fcc TRANSITION METAL NITRIDES

For carbonitrides, (*see* ***Carbides: Transition Metal Solid-state Chemistry***).

6.1 Melting Points

Melting points of various nitrides[59] have been measured under nitrogen pressures up to 300 bar. The nitrogen pressure has to be chosen in such a way as to be equal to the nitrogen equilibrium pressure of the nitride at its melting point. The melting point temperatures of the various nitrides can reach more than 3000 °C and can be read from the phase diagrams given in Section 5.2.

6.2 Color

Many mononitrides exhibit vivid colors of a bright metallic appearance that depends on the N/T ratio. Table 1 lists the colors of the mononitrides and gives some idea on their color-composition interdependency. These colors can be observed in bulk samples, and also have an important role when thin films[60] are produced for ornamental purposes.

6.3 Thermal and Electrical Properties

Interestingly, the transition metal carbides and nitrides do not show the expected decrease in heat conductivities with temperature but instead an increase.[61] Figure 10 illustrates this property for the group 4 nitrides and shows a comparison with group 4 carbides and carbonitrides. The substitution of nitrogen by carbon in group 4 transition metal nitrides significantly reduces the heat conductivities.

The electrical conductivities of transition metal carbides and nitrides are greatly influenced by the nonmetal/metal ratio; as this ratio approaches unity the electrical conductivity reaches a maximum. This is shown for δ-TiN_{1-x} in Figure 11.[63] A similar behavior can be observed for other carbides and nitrides. The electrical conductivities of these compounds decrease linearly with increasing temperature.[62]

The phenomenon of superconductivity is common for all fcc transition metal nitrides of groups 4 and 5 and is also observed in fcc MoN_{1-x} and hexagonal MoN. δ-NbN_{1-x}

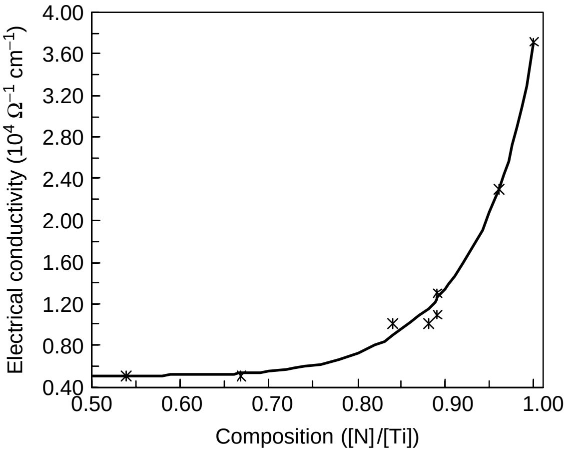

Figure 11 Electrical conductivity at room temperature of δ-TiN_{1-x} as a function of stoichiometry. (Reprinted from Ref. 63. © 1992, with permission from Elsevier)

shows the highest superconducting transition temperature of 17 K, which was the highest known of any material for several decades. It is noteworthy that hexagonal δ-MoN also has one of the highest superconducting transition temperatures (15 K) of these materials,[50] and fcc γ-$MoN_{1.00}$, although never prepared with a stoichiometric composition, was predicted theoretically to have a T_c of up to 30 K. All transition metal nitrides are type II (hard) superconductors. For several fcc nitrides, such as δ-TiN_{1-x}, δ-ZrN_{1-x} and δ-VN_{1-x}, T_c increases linearly with increasing nitrogen content up to [N]/[T] = 1;[64] δ-NbN_{1-x} shows a much weaker increase. The T_c data reported for δ-HfN_{1-x} are contradictory as to whether an increase or a decrease occurs. This is probably due to the fact that δ-HfN_{1-x} can apparently exist with a hyperstoichiometric composition. T_c is expected to be reduced significantly by unoccupied metal sites in the hyperstoichiometric δ-VN_{1+x}. Figure 12 shows the normalized T_c of several fcc nitrides (where the highest T_c of each compound is equal to 1) and Table 1 shows the highest T_c for each compound for the given composition.

6.4 Thermal Expansion

The thermal expansion of various transition metal nitrides has been measured at both low temperatures[65] (8 K) and high temperatures[66] (up to 1500 K). δ-VN_{1-x} exhibits a very low or even negative thermal expansion at temperatures below 70 K. The high-temperature thermal expansion data are summarized in Figure 13.[66] Interestingly, considering its low-temperature

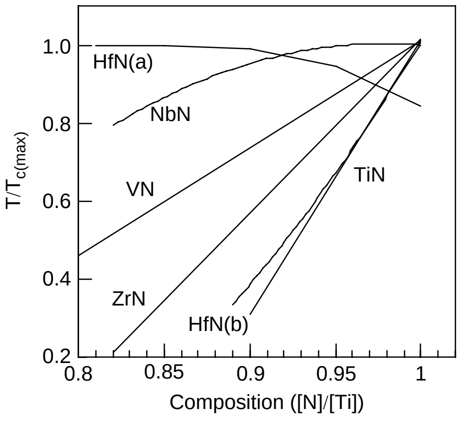

Figure 12 Superconducting transition on temperatures (normalized relative to maximum T_c) as a function of stoichiometry for various transition metal nitrides. For δ-HfN_{1-x}, different functions have been reported (a,b). (Ref. 64. Reproduced by permission of Wiley)

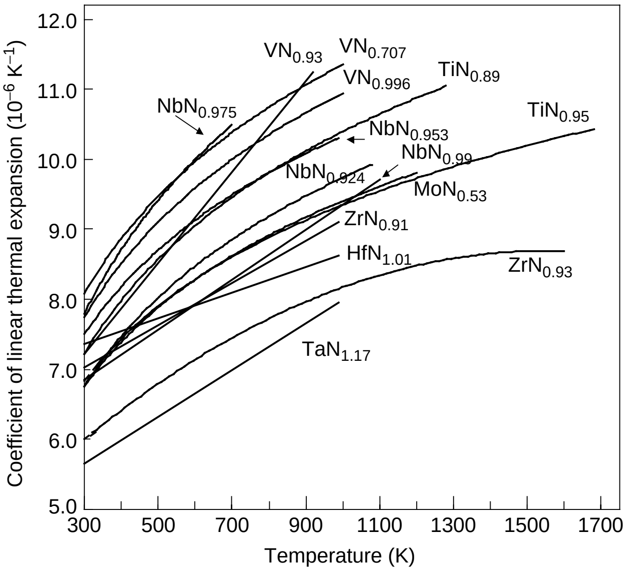

Figure 13 High-temperature thermal expansion of various transition metal nitrides. (Ref. 54. Reproduced by permission of Materials Information Society/ASM International)

thermal expansion behavior, δ-VN_{1-x} has the highest high-temperature expansion coefficient among these compounds, up to $11 \cdot 10^{-6} K^{-1}$ at 1100 K.

6.5 Diffusivities

In transition metal nitrides, nitrogen diffusion proceeds via a vacancy mechanism in the nonmetal sublattice. The vacancy concentration is a function of composition within the homogeneity range of the fcc phases and hence the nitrogen diffusivity is most probably composition-dependent as well. However, this has not been generally investigated in transition metal nitrides.[67] In this respect, the Cr–N system has been investigated in detail.[27] Figure 14 shows the concentration-dependent diffusivity in CrN. Generally, diffusivity studies were conducted by investigating nitride layer growth[62] as a function of time, which gives the average nitrogen diffusivity in the various phases. A parabolic relationship, $d = k \cdot t^{0.5}$, holds for this layer growth, where d is the layer thickness, k is a constant, and t the diffusion time. The parabolic behavior indicates that the nitride layer growth is indeed diffusion controlled. By use of wedge-type samples, the thickness of diffusion layers is increased if the sample thickness increases. Such a deviation from the parabolic law (if different thicknesses are compared) can be used to establish the nitrogen diffusivities in all the phases at a given temperature.[22,24] An example of such a wedge-type sample is shown in Figure 15 for the Hf–N system.[28]

Nitrogen diffusion in nitrides such as δ-TiN_{1-x},[68] δ-ZrN_{1-x} and δ-HfN_{1-x} has an activation energy of 2–3 eV. Although the metal diffusivity in transition metal nitrides has not yet been investigated in detail, the activation energy of that process is probably much higher and can be estimated to be ca. 7–8 eV. Table 2 shows diffusivity data of transition metal nitrides.

The diffusivity versus composition has been investigated for δ-TiN_{1-x}, δ-HfN_{1-x},[28] and δ-NbN_{1-x}.[69] A modified Boltzmann–Matano analysis, carried out on nitrogen diffusion profiles measured by EPMA, yielded a composition-dependent diffusion coefficient for N diffusion expressed as

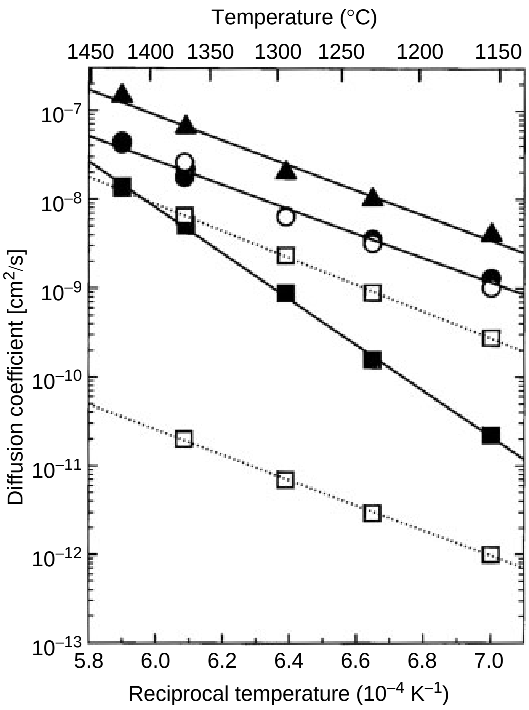

Figure 14 Temperature dependence of diffusion coefficients for the Cr–N system obtained from layer growth and concentration profiles,[27] ■/□: δ-CrN_{1-x}, ○/●: β-Cr_2N, ▲: α-Cr(N)

$$D = f\nu^2 d \exp\left(\frac{-E}{k_B T}\right) \exp(A(c^+ - c))\ \mathrm{cm^2\,s^{-1}} \tag{5}$$

where f = 1/12, for fcc compounds, ν is the jump frequency of the N atom, d is the mean distance between lattice planes, E is the activation energy, k_B is the Boltzmann constant, A is a parameter for the steepness of concentration dependency, c is the concentration and c^+ is the maximum concentration.

6.6 Elastic Properties

Transition metal nitrides exhibit high Young's moduli, appreciably higher than the elastic moduli of the transition

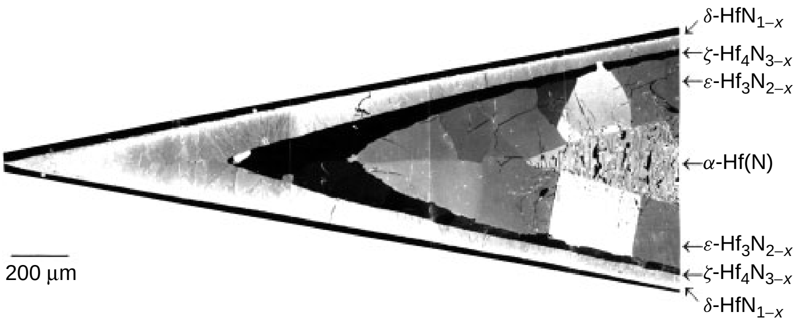

Figure 15 Wedge-type sample of the Hf–N system with various diffusion layers[28]

Table 2 Diffusion data for nitrogen in fcc transition metal nitrides

Compound	D_0 ($cm^2\ s^{-1}$)	E (eV)	A ($cm^3\ mol^{-1}$)

metals. As can be seen from Figure 16,[73] the Young's moduli of δ-TiN_{1-x} and δ-ZrN_{1-x} increase with increasing nitrogen to metal ratio, whereas for δ-HfN_{1-x} the modulus remains approximately constant. Several of these data were obtained from thin layers. It is well known that in layers large deviations from bulk properties (lattice parameter, composition) may occur, due probably to the high concentration of defects particularly in PVD layers, while in bulk samples, pores can drastically influence the results.[72]

The elastic properties were critically reviewed by Kral *et al.*[71]

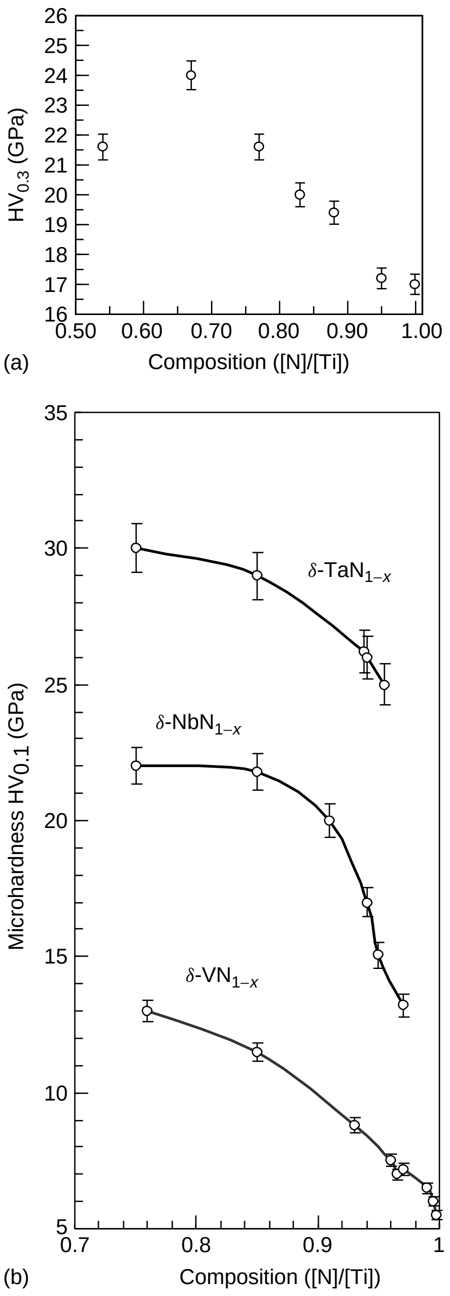

Figure 17 (a) Microhardness of δ-TiN. (Reprinted from Ref. 73. © 1992, with permission from Elsevier) and (b) group 5 transition metal nitrides as a function of composition. (Ref. 5. Reproduced by permission of Wiley VCH)

6.7 Hardness

Some transition metal nitrides are among the hardest materials known. Figure 17 shows hardness versus composition for δ-TiN_{1-x} and for the group 5 transition metal nitrides. The hardness decreases with increasing nitrogen content for the group 5 nitrides.[66,70,74] This behavior can probably be explained by electronically induced lattice softening as a result of the generation of antibonding states. It is known from band structure calculations that in fcc transition metal compounds with more than eight valence electrons, antibonding states are successively occupied. An increasing valence electron concentration arising from increasing nitrogen content would then lead to a decrease in hardness when the number of valence electrons exceeds eight. Indeed, in δ-TiN_{1-x} a maximum in microhardness is found at the composition δ-$TiN_{0.67}$, corresponding to 7.3 valence electrons. For δ-HfN_{1-x}, a smooth

increase in microhardness with increasing nitrogen content is observed. This, however, is probably a result of the difference in electronic states owing to 5f electrons.

7 USES

Nitrides and carbonitrides in form of powders play some role in hardmetals (cemented carbides). The reader is referred to the article on Carbides of this Encyclopedia (*see* ***Carbides: Transition Metal Solid-state Chemistry***). There, also nitrided hardmetals to form functionally graded hardmetals (FGHM) are discussed.

7.1 Wear-resistant and Ornamental Layers

CVD and PVD transition metal nitride layers composed mainly of δ-TiN_{1-x} and Ti(C,N) are produced in order to increase the service life of hardmetal tools for cutting and milling operations. Nitride-coated tool tips result in a better surface finish of the workpiece owing to both a decrease in diffusion welding between tool tip and workpiece and an increase in thermal oxidation resistance. The layer thickness is generally 1–10 µm. Typically, multilayer tools feature layers of TiN, TiC, TiCN, and Al_2O_3.[75] Figure 18 shows a multilayer coating including δ-TiN_{1-x} on a WC-Co hardmetal. Bright golden yellow δ-TiN_{1-x} is also used for ornamental layers, for example, on watch cases where the combination of color with increased scratch resistance is exploited.

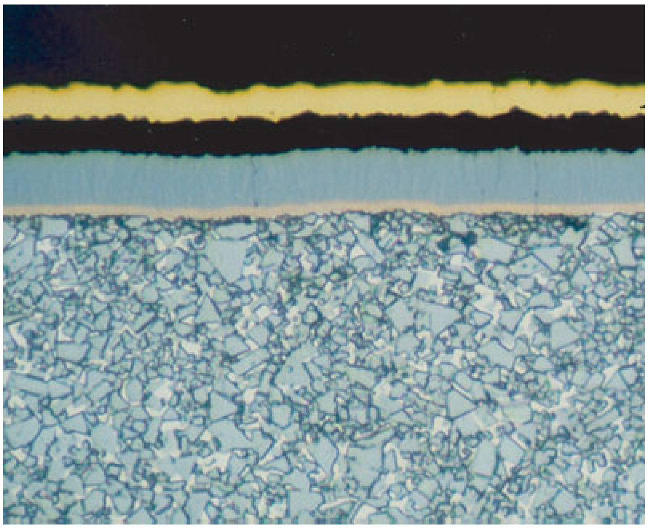

Figure 18 CVD multilayer coating on WC–Co hardmetal with TiN_{1-x} as top and bottom layer

7.2 Cemented Carbonitrides

δ-TiN is used as one of the hard components in sintered hardmetal or cermet compositions containing TiC, Mo_2C, WC, TaC and other compounds. Such cermets can be produced by liquid phase sintering of blends of TiN and TiC with Mo_2C and WC and with Ni and/or Co as a binder phase. The modern titanium carbonitride cermets[76] are characterized microstructurally by a structured hard phase featuring a core-rim structure embedded in a tough Co/Ni binder alloy. In steel-cutting applications, such cermets appear to outperform even nitride-coated hardmetal tools.

7.3 Diffusion Barriers

Because of their chemical inertness, their high electrical conductivities and the ease with which they can be deposited as layers, transition metal nitrides are excellent candidates for use in multilayer metallizations of integrated circuits.[77,78] In these devices, interdiffusion between the different metals, compound layers or thin metal wires during thermal load with soldering and packaging operations must be avoided, otherwise degradation of the multilayer arrangement will occur. In order to protect these layers against interdiffusion, very thin nitride layers ($<$100 nm) can be deposited by PVD methods. These layers are stable up to 600 °C (depending on the time and the substrate) and prevent the layers from undergoing structural changes.

1 INTRODUCTION

Nitrogen, as an element of the first period, has a tendency to form $p_\pi - p_\pi$ double bonds like its neighbors carbon and oxygen. Nitrogen chemistry is therefore different from the chemistry of the heavier homologues (*see* ***Periodic Table: Trends in the Properties of the Elements***). Nitrogen forms element chains (catenation) more easily than its right neighbor oxygen, but less easy than the other neighbors carbon and phosphorus. With the appropriate substituents, nitrogen chains containing up to eight nitrogen atoms are known (see Table 1). Average nitrogen−nitrogen bond distances are 148 pm for single bonds, 120 pm for double bonds, and 110 pm for triple bonds (*see* ***Bond Lengths in Inorganic Solids & Liquids***).

As shown in Scheme 1, nitrogen compounds are known with nitrogen in the oxidation states between −3 and +5:

In compounds with moderately electropositive bonding partners, nitrogen has the coordination number one (N_2, HCN), two (angular in HN=NH, linear in Cl–N=O), three (pyramidal in NH_3; planar in $N(SiMe_3)_3$),[1] and four (tetrahedral in NH_4^+, NF_4^+). With more electropositive bonding partners, the higher coordination numbers five (quadratic-pyramidal in $[Fe_5(CO)_{14}H(\mu_5\text{-}N)]$), six (octahedral in MN, M = Sc, Ti, V, Cr, Th, U; trigonal prismatic in $[Co_6(CO)_{15}(\mu_6\text{-}N)]^-$) and eight (cubic in BeLiN, $AlLi_3N_2$; hexagonal-bipyramidal in Li_3N) are known (*see* ***Coordination Numbers & Geometries***). Nitrogen compounds of all nonradioactive elements except helium, neon, and argon have been isolated, although compounds such as XN^+ with helium, neon, and argon have been detected using mass spectrometry.

Two isotopes of nitrogen are found in nature, ^{14}N (99.634%, magnetic dipole moment $\mu_N = +0.403761$, electrical quadrupole moment 1.60×10^{-30} m^{-2}) and ^{15}N (0.366%, magnetic dipole moment $\mu_N = -0.28319$, no electrical quadrupole moment).[2] The average mass is 14.00674 atomic mass units. The relation between the isotopes may be different by up to 1.5% for nitrogen from other sources than air, for example, in natural gas or in gas pockets in the Earth's crust. ^{15}N is used for labeling in NMR spectroscopy and mass spectrometry. All other nitrogen isotopes have half-lives that are much too short to be of use in labeling experiments (see Table 2).

Fractional distillation of ^{15}NO is an effective method for concentrating ^{15}N. Chemical exchange processes for nitrogen isotope separation include the following:

$$^{15}NH_3(g) + {}^{14}NH_4{}^+(aq) \longrightarrow {}^{14}NH_3(g) + {}^{15}NH_4{}^+(aq) \qquad (1)$$

$$^{15}NO(g) + {}^{14}NO_3{}^-(aq) \longrightarrow {}^{14}NO(g) + {}^{15}NO_3{}^-(aq) \qquad (2)$$

The NO–NO_2 equilibrium can be used in thermal diffusion separation.

$$^{14}NO_2(g) + {}^{15}NO(g) \longrightarrow {}^{15}NO_2(g) + {}^{14}NO(g) \qquad (3)$$

2 DINITROGEN

In 1772, the German Carl Scheele, the Englishman Henry Cavendish, the Scotsman Daniel Rutherford, and Joseph Priestley, who was also English, all independently discovered dinitrogen or studied its equivalent, 'burnt' air or air where the oxygen was removed. A. L. Lavoisier named it azôte (from the Greek word meaning 'lifeless'). After niter (potassium nitrate) and nitric acid were recognized as compounds of the element, the name nitrogenium (Latin, 'niter former') was introduced by the French J. A. C. Chaptal.[3,4]

Nitrogen occurs almost exclusively in nature as dinitrogen N_2. It is the main part of dry air (78.09% by volume, 75.52% by weight), which accounts for more than 99% of the approximately 10^{15} tons of nitrogen on earth. At higher altitudes, dinitrogen is partly dissociated to nitrogen by ultraviolet radiation. Other nitrogen species with very short lifetimes are also formed under stratospheric conditions. The high solubility of nitrogen salts makes minerals containing nitrogen, mainly nitrates, rare. The major minerals are saltpeter KNO_3, occurring in large deposits in India and Chile saltpeter $NaNO_3$, which can be found in the desert sections of northern Chile. Calcium nitrate, ammonium chloride, and several other compounds can occasionally be found in small amounts. Another 10^{13} tons of dinitrogen are

8	N=N–N–N=N–N–N=N	PhN=N–N(Ph)–N=N–N(Ph)–N=NPh

dissolved in the oceans. Like many other gaseous compounds, dinitrogen is also included in water clathrate complexes, for example $(H_2O)_{136}(N_2)_{9.4}$, which was found in Greenland. Extraterrestrially, nitrogen has been detected in the atmosphere of Mars (2.7 vol%), Venus (3.5 vol%), Pluto, and possibly in traces on Mercury. Nitrogen also occurs in proteins and other organic compounds in the biosphere (10^{10} t). It is an essential element for humans; the human body contains about 3% nitrogen, which is found in proteins, DNA, and many coenzymes. There are several processes, referred to as nitrogen fixation, making dinitrogen available to biological species. In lightning, enough energy is set free to activate dinitrogen molecules for the reaction with dioxygen, forming nitrogen oxides. Industrial nitrification is discussed in Section 5.1.1. Some bacteria can form ammonia from dinitrogen (*see* ***Nitrogenase: Metal Cluster Models*** and ***Nitrogenase Catalysis & Assembly***). In the nitrification process, ammonia is converted to nitrate via nitrite by bacteria under aerobic conditions. In anaerobic conditions, bacteria convert nitrate via nitrite to the gaseous compounds NO, N_2O, and N_2.

2.1 Production of Dinitrogen

The technical production of dinitrogen and other nitrogen compounds is discussed in great detail in the literature.[5] A compilation of physical data for many compounds is published.[6] For all technical processes, dinitrogen is obtained from air, where cryogenic (low temperature), adsorption, and membrane separation processes are used. The chemical removal of dioxygen from air is an older method that is of secondary importance. The cryogenic production is based on the fractionized distillation of liquid air. Nitrogen production by pressure-swing adsorption (PSA) employs carbon or zeolitic molecular sieves. Separation of air components with zeolites is based on differences in adsorption capacity; carbon molecular sieves employ differences in diffusion rates. In

Table 2 Properties of nitrogen isotopes

	Mass [amu]	Spin	Mode of decay	$t_{1/2}$	Decay energy [MeV]

carbon molecular sieves, the unadsorbed N_2-rich gas product is withdrawn at the discharge end of the adsorber during the adsorption phase. In the zeolite process, previously adsorbed nitrogen is recovered by lowering the pressure during the regeneration phase. The membrane separation process uses membranes that have different permeabilities for different gases. The total nitrogen production in Europe, the United States, and Japan amounted to $59.6 \times 10^9\,m^3$ in 1996. The production of gaseous nitrogen is growing more rapidly than that of liquid nitrogen. The largest applications need dinitrogen gas and have, therefore, always been most economically served by gas. Today, noncryogenic production technologies such as membranes and PSA are making gas production economical at customer sites.

Nitrogen from the cryogenic distillation of air has an inherent high purity since virtually all bulk gases with higher boiling points (methane, water, carbon dioxide) are removed to less than ppb levels by volume. The very low boiling gases helium, hydrogen, and neon are not removed by standard single-column cryogenic processes, nor is carbon monoxide, which is difficult to separate by cryogenic fractionation because of its boiling point of 81.6 K. CO and H_2 can be removed from the compressed air before distillation by oxidation in an upstream catalytic reactor with a noble metal catalyst. The oxidation products are water and carbon dioxide, which can be removed by the conventional air-purification system. Downstream purifier systems operate by oxidation over metal oxides and chemisorption by transition metals. Thus, nickel at ambient temperature eliminates oxygen as the oxide and hydrogen as the hydride.

In a chemical process, oxygen can be removed from air ($4N_2 + O_2$) by oxidation with carbon, propane gas, or ammonia and successive removal of carbon dioxide and water. Because air also contains noble gases, chemical processes do not yield pure dinitrogen but a mixture of dinitrogen and noble gases.

$$4N_2 + O_2 + C \longrightarrow 4N_2 + CO_2 \quad (4)$$

Partial burning of carbon produces carbon monoxide (see Section 5.1.1):

$$4N_2 + O_2 + 2C \longrightarrow 4N_2 + 2CO \quad (5)$$

In the laboratory, copper can be used to bind oxygen at red heat:

$$4N_2 + O_2 + 2Cu \longrightarrow 4N_2 + 2CuO \quad (6)$$

Pure dinitrogen can be obtained from nitrogen compounds, for example, the oxidation of ammonia with CaCl(OCl) or bromine. More often, nitrous acid is used to include the nitrogen of the acid:

$$NH_3 + HNO_2 \longrightarrow N_2 + 2H_2O \quad (7)$$

The thermal decomposition of azides, especially of sodium azide, is used to produce spectroscopically pure dinitrogen:

$$2NaN_3 \longrightarrow 2Na + 3N_2 \quad (8)$$

The largest-volume of dinitrogen is used for the synthesis of ammonia. As an alloying element in steel, nitrogen serves to improve hardness and corrosion resistance. The inert dinitrogen is used as a blanketing gas to prevent oxidation or fire. It is also used for the processing, cooling, storage, and transportation of food. Liquid nitrogen provides the cryogenic temperature necessary for freezing, and nitrogen vapor as an inert medium inhibits oxygen-dependent ripening and decay processes. Embrittlement of grinding feed, shrink fitting of metal parts, cryosurgery, or the conservation of biological samples are only a few examples of the many uses of liquid nitrogen.

2.2 Physical Properties of Dinitrogen

Dinitrogen is a colorless, odorless, noncombustible gas with a density of $1.2505\,g\,dm^{-3}$ at standard conditions ($C_p = 29.12\,J\,mol^{-1}\,K^{-1}$). The boiling point is 77.36 K (enthalpy of vaporization: $5.577\,kJ\,mol^{-1}$) and the melting point is 63.15 K (enthalpy of fusion: $0.7196\,kJ\,mol^{-1}$) (see Table 3). Two solid phases of dinitrogen exist (see Table 4), the standard β-phase (hexagonal close-packed N_2 molecules) and the α-phase (cubic close-packed N_2 molecules). The standard enthalpy of transition is $228.9\,kJ\,mol^{-1}$. At pressures above 350 Mpa, tetragonal γ-N_2 is formed. Gaseous dinitrogen has a specific heat capacity of $1.040\,J\,g^{-1}\,K^{-1}$, a dynamic viscosity of 15.9×10^{-6} Pa and a thermal conductivity of $25.9\,mW\,m^{-1}\,K^{-1}$ (298).

The bond distance in N_2 is 109.75 pm and the bond dissociation energy of the N–N triple bond is $945.33\,kJ\,mol^{-1}$.

N_2 is soluble in metal melts, for example, 4% dinitrogen can be solved in iron melts. Dinitrogen is only half as soluble as dioxygen in water (see Table 5). This is important for

Table 3 Properties of N_2[7]

	Triple point	Critical point	Boiling point
T [K]	63.15	126.2	77.35
p [MPa]	12.463×10^{-3}	3.39908	0.1013
ρ [$g\,dm^{-3}$]	0.6803 (g) 867.7 (l) 947 (s)	314.03	4.61 (g) 808.6 (l)

Table 4 Properties of solid dinitrogen

	298	100	0.32
Ethanol	293	0.1	6.8×10^{-3}
Blood	311	0.1	6.2×10^{-4}
γ-Iron	1273	0.1	8×10^{-3}

the breathing of marine life. Dinitrogen has no apparent effect on plants, animals, or humans. Suffocation in dinitrogen atmosphere is due to the lack of dioxygen. The higher solubility of dinitrogen in blood at high pressures is responsible for decompression sickness and nitrogen narcosis, known as the 'bends', in divers.

2.3 Chemical Properties of Dinitrogen

Dinitrogen is relatively inert under standard conditions due to the high stability of the nitrogen–nitrogen triple bond. This makes most reactions of dinitrogen endothermic. Exothermic reactions of dinitrogen have high activation barriers. Unlike dioxygen (IE 13.618 eV), dinitrogen cannot be oxidized chemically to the cation N_2^+ because of the high ionization energy of dinitrogen (15.576 eV).[4]

The reactivity of the N_2 molecule increases rapidly as the temperature is increased. At higher temperatures, compounds with many metals and nonmetals are formed. Binary nitrogen compounds, which sometimes cannot be obtained by the direct reaction, have been found for most elements. Binary noble-gas nitrogen compounds have been detected mass spectrometrically (e.g. XN^+, XN_2^+). Among the prominent reactions of dinitrogen are the reaction of dinitrogen with hydrogen to form ammonia (in detail see Section 5.1.1), the reaction of dinitrogen with dioxygen at elevated temperatures to form NO (in details see Section 7.8.1), and the reaction of dinitrogen with calcium carbide at 1300 K ($\Delta H = -296\,\mathrm{kJ\,mol^{-1}}$) to form calcium cyanamide, which is used for nitrogen fixation.

$$CaC_2 + N_2 \longrightarrow CaCN_2 + C \quad (9)$$

While the latter reactions are no longer used for nitrogen fixation, the reaction of dinitrogen with dihydrogen to form ammonia is among the most important industrial processes. The alkaline-earth metals react readily with dinitrogen at elevated temperatures to form nitrides; lithium reacts even at room temperature with dinitrogen.

The nitrides (*see* ***Nitrides: Transition Metal Solid-state Chemistry***) can be divided roughly into ionic nitrides (e.g. alkali and alkaline-earth nitrides), covalent nitrides (e.g. BN (*see* ***Boron: Inorganic Chemistry***), S_4N_4 (*see* ***Sulfur–Nitrogen Compounds***), CN_2 (*see* ***Carbon: Inorganic Chemistry***), S_2N_2 (*see* ***Sulfur–Nitrogen Compounds***), As_4N_4, P_3N_5, Ge_3N_4, Se_4N_4 (*see* ***Selenium: Inorganic Chemistry***), Te_4N_4 (*see* ***Tellurium: Inorganic Chemistry***)), and semimetallic phases (VN, CrN, W_2N). In semimetallic phases, the nitrogen atoms are interstitial or included in more complex structures. The nitride ion, N^{3-}, is only stable with very Lewis basic cations. Even in the alkaline-earth metal nitrides M_2N_3 (M = Be–Ba), the metal–nitrogen bond has a covalent contribution.

Nitrogen can form complexes with compounds of most transition metals. These play an important role in the biological nitrogen fixation process (*see* ***Nitrogenase: Metal Cluster Models*** and ***Nitrogenase Catalysis & Assembly***), where bacteria use dinitrogen complexes to form other nitrogen compounds. Metal complexes of dinitrogen can be synthesized directly from the reaction of dinitrogen with metal salts in a reducing environment (10) or by the oxidation of metal coordinated ammonia (11) or hydrazine (12).

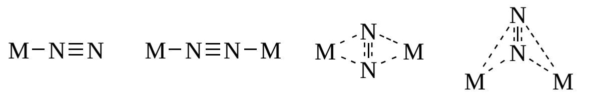
$$[MoCl_4(PR_3)_2] \xrightarrow[-NaCl]{Na,\ N_2} Mo(N_2)(PR_3)_4 \quad (10)$$

$$[C_5H_5Mn(CO)_2(N_2H_4)] + H_2O_2 \longrightarrow [C_5H_5Mn(CO)_2(N_2)] + 4H_2O \quad (11)$$

$$[Os(NH_3)_5(N_2)]^{2+} + HNO_2 \longrightarrow [Os(NH_3)_4(N_2)_2]^{2+} + 2H_2O \quad (12)$$

The dinitrogen ligand is often easily displaced by other ligands. Some dinitrogen complexes can be reduced to ammonia or hydrazine complexes and are model compounds for the biological nitrogen fixation process. Homoleptic metal dinitrogen complexes $M(N_2)_x$ are not stable at standard conditions but can be obtained by the rapid chilling of metal/dinitrogen gas mixtures below 10 K (e.g. $Ti(N_2)_6$, $V(N_2)_6$, $Cr(N_2)_6$, $Rh(N_2)_4$, $Ni(N_2)_4$, $Pd(N_2)_3$, $Pt(N_2)_3$). These compounds are metastable at low temperatures and loose dinitrogen upon warming. $Ti(N_2)_6$ decomposes at 40 K.

As shown in Scheme 2, most dinitrogen complexes show a σ end-on coordination of the dinitrogen molecule (**1**) (e.g. octahedral $[Os(NH_3)_4(N_2)_2]^{2+}$). The end-on coordination (**2**) is also found for bridging dinitrogen ligands (e.g. $[\{Ru(NH_3)_5\}_2N_2]^{2+}$). Side-on coordination via the $N_2\pi$-orbitals has been found in very few complexes. Planar side-on coordinated dinitrogen (**3**) is found in $\{(C_5Me_5)_2Sm\}_2(N_2)$. In some zirconium complexes, for example, $[(i\mathrm{Pr}_2PCH_2SiMe_2)_2N]ZrCl_2(\mu\text{-}\eta^2{:}\eta^2\text{-}N_2)$, a bent coordination (**4**) is found. (*see* ***Nitrogenase: Metal Cluster Models*** and ***Nitrogenase Catalysis & Assembly***).



(1) (2) (3) (4)

Scheme 2 Coordination of dinitrogen in transition metal complexes

3 ATOMIC NITROGEN

An electric discharge in a N_2 atmosphere in the pressure range 1.0–0.1 hPa splits dinitrogen molecules to atomic nitrogen. This is accompanied by a peach–yellow glow that persists for up to 6 h after stopping the discharge.[8]

Atomic nitrogen ($\Delta H_f = 472.7\,\text{kJ mol}^{-1}$) is very reactive. It reacts with many metals to form nitrides at room temperature.

$$3\text{Mg} + 2\text{N} \longrightarrow \text{Mg}_3\text{N}_2 \qquad (13)$$

Atomic nitrogen also reacts with nonmetals like phosphorus and sulfur (*see* ***Phosphorus–Nitrogen Compounds*** and ***Sulfur–Nitrogen Compounds***).

Recombination of the nitrogen atoms to N_2 is a slow process since it requires a three-body collision of the nitrogen atoms with the walls of the container or a termolecular, homogeneous second-order association of the nitrogen atoms. This can result in excited dinitrogen molecules that are responsible for the yellow glow.

$$\text{N}(^4\text{S}) + \text{N}(^4\text{S}) \xrightarrow{(\text{M})} \text{N}_2^* \longrightarrow \text{N}_2 + h\nu(\text{yellow}) \qquad (14)$$

The excited dinitrogen molecules N_2^* can break bonds in other molecules:

$$\text{N}_2^* + \text{CO}_2 \longrightarrow \text{N}_2 + \text{CO} + \text{O}(^3\text{P}) \qquad (15)$$

Nitric oxide NO molecules can be used to determine the concentration of the nitrogen atoms.

$$\text{N}(^4\text{S}) + \text{NO} \longrightarrow \text{N}_2 + \text{O}(^3\text{P}) \qquad (16)$$

This rapid reaction stops the yellow glow. If excess NO is present, the oxygen atoms react with NO to form NO_2 under emission of a green–yellow light:

$$\text{NO} + \text{O}(^3\text{P}) \longrightarrow \text{NO}_2^* \longrightarrow \text{NO}_2 + h\nu(\text{green–yellow}) \qquad (17)$$

whereas a blue light is emitted if not enough nitrogen oxide is present:

$$\text{N}(^4\text{S}) + \text{O}(^3\text{P}) \longrightarrow \text{NO}^* \longrightarrow \text{NO} + h\nu(\text{blue}) \qquad (18)$$

4 POLYNITROGEN

In contrast to the other elements, the homonuclear single-bond energies of nitrogen (159 kJ mol^{-1}) (and oxygen) are significantly less than one-third of their triple (945.33 kJ mol^{-1}) or one-half of their double-bond (466 kJ mol^{-1}) energies (*see* ***Main Group: Multiple Bonding***). Compounds with high nitrogen content are synthesized for use as high-energy materials.[9] The nitrogen–nitrogen double bond energy is also less than two-thirds of the triple bond energy. As a consequence, ordinary nitrogen consists of diatomic molecules, which are very stable and remarkably unreactive and reluctant, in particular, to bind to other N atoms to give N_n species with $n > 2$. Homonuclear polynitrogen species are thermodynamically highly unstable, since invariably their dissociation into N_2 is highly exothermic, and there are only very few compounds known.[10] Owing to the highly endothermic heats of formation, their syntheses and handling present great challenges. No nitrogen compounds are known that can be isolated in bulk, while most other elements can exist in the form of many stable allotropes. Owing to the great experimental difficulties, most polynitrogen species have only been studied theoretically. Molecular nitrogen forms a non-molecular superconductor that exists at equilibrium over a very large range of pressures, from below 100 GPa to at least 240 GPa.

4.1 Trinitrogen

The azide radical $N_3\bullet$ (linear, ground state $^2\Pi_g$, d(N–N) 118.1 pm) is produced in the reaction of HN_3 with fluorine atoms ($\Delta H_r = -180\,\text{kJ mol}^{-1}$):

$$\text{F}\bullet + \text{HN}_3 \longrightarrow \text{N}_3\bullet + \text{HF} \qquad (19)$$

The enthalpy of formation of the azide radical is $467 \pm 8\,\text{kJ mol}^{-1}$. The spin-allowed dissociation to N(^{2}D) and $N_2(X\ ^1\Sigma_g^+)$ is endoergic by 225 kJ mol^{-1}, the dissociation enthalpy to N(^{4}S) $+N_2(X^1\Sigma_g^+)$ is $-0.5 \pm 1\,\text{kJ mol}^{-1}$.[11] The azide radical is only stable because this spin-forbidden decomposition pathway has an appreciable energy barrier. In aqueous solution, it primarily exists as a monomer, in contrast to other halide or pseudohalide radicals that exist as the less reactive dimers (e. g. $Br_2^{-\bullet}$, $(SCN)_2^{-\bullet}$). Reaction of the azide radical with halogen atoms or other small molecules like O_2, NO, CO, and CO_2 produces molecules in electronically excited states because of propensity rules, which can be used for chemically pumped lasers.[12] The azide ion is also formed during high-pressure photolysis of sodium azide.

4.1.1 N_3^+

The trinitrogen cation is produced in nitrogen plasmas through the reaction of energized N_2^+ ions with N_2 molecules. Formation in the atmosphere probably involves ternary

reactions of N^+ and N_2.[13] In the atmosphere, it reacts with H_2O to form H_2NO^+ and with O_2 to form NO^+. N_3^+ ($X\,^1\Sigma g^+$) has a linear, centrosymmetric structure like the azide radical and the azide anion ($D_{\infty h}$, d(N–N) = 119.3 Å). It is quite strongly bound with a dissociation energy of about 3.5 eV:

$$N_3^+(X\,^3\Sigma_g) \longrightarrow N^+(^3P) + N_2(X\,^1\Sigma_g^+) \qquad (20)$$

Attempts to remove the fluorine atom of N_3F with the strong fluorine acceptors AsF_5, SbF_5, or BF_3 only yielded the adducts $N_3F{\cdot}AsF_5$ and $FN_3{\cdot}BF_3$ and explosions in the case of SbF_5. The N_3^+ cation was not observed in this reaction.[14] Electrostatically bound $(N_3)^+$-$(N_2)_n$ clusters have been observed mass spectrometrically.[15]

The azide ion is discussed in Section 5.8.

4.2 Tetranitrogen

The metastable singlet T_4 species tetraazatetrahedrane (**5**) shown in Scheme 3 is the best theoretically investigated N_4 species. The dissociation to N_2 has an activation energy of 54 kJ mol^{-1} to release as much as 800 kJ mol^{-1} of energy. Density functional calculations show the open-chain C_{2h} triplet (**6**), which releases 505 kJ mol^{-1} upon decomposition, to be the global minimum structure whereas a MP4 study shows it to be a transition state and identifies the C_s triplet (**7**) as the global minimum. The metastable D_{2h} singlet (**8**), which releases 766 kJ mol^{-1} upon decomposition, was also found at the B3LYP level.

A van-der-Waals dimer $(N_2)_2$ with a dissociation energy of only about 1 kJ mol^{-1} has been detected experimentally. Another N_4 species, which was prepared by neutralizing N_4^+, was detected mass spectrometrically,[16] and is believed to be the C_s triplet because of its fragmentation pattern. The geometry of the starting material N_4^+ also points to a linear structure.

4.2.1 *N_4^+*

The N_4^+ cation is formed in electric discharges through nitrogen.[17] N_2^+ is formed by interaction of cosmic rays with N_2 in the stratosphere and can, in denser regions of the ionosphere, form N_4^+, which might play a role as an intermediate that reacts very rapidly with other species in the atmosphere. N_4^+ ($X\,^2\Sigma_u^+$) has a linear, centrosymmetric structure. The dissociation energy to N_2 ($X\,^1\Sigma_g^+$) and N_2^+ ($X\,^2\Sigma_u^+$) is only slightly higher than 96 kJ mol^{-1}. The terminal N–N bond is with 110.9 pm slightly longer than in N_2 and slightly shorter than in N_2^+ (111.6 pm). The inner N–N bond is with 200.4 pm rather long. Mass spectrometrically observed $(N_2)_n^+$ clusters contain a N_4^+ core.

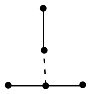
Scheme 3 Connectivity of theoretically predicted N_4 isomers

4.3 Pentanitrogen

While the symmetric, weak complex between a $N_3{\cdot}$ radical and N_2 (**9**) in Figure 1 was shown to be minimum on the potential surface, higher-level computations indicate that this complex is not stable.[18]

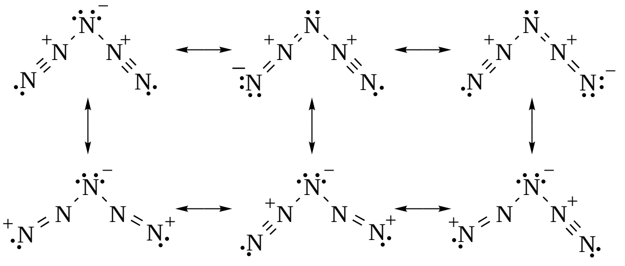
4.3.1 *N_5^+*

The pentanitrogen cation has an essentially planar V-shape structure (C_{2v}). The exceptional stability of N_5^+ is largely due to resonance stabilization shown in Scheme 4, resulting in relatively high bond orders for all the bonds.[19] The additional, higher charged Lewis structures in the second row have to be included to account for the charge distribution of N_5^+.[20] The geometrical parameters of the pentanitrogen cation in $N_5^+Sb_2F_{11}^-$ are shown in Table 6.



(**9**)

Figure 1 Connectivity of N_5 minimum structure



Scheme 4 Mesomeric structures of N_5^+

Table 6 Geometrical parameters of the pentanitrogen cation in $N_5^+Sb_2F_{11}^-$

d(N1-N2) [pm]	110(2)	d(N4-N5) [pm]	111(2)
d(N2-N3) [pm]	130(2)	<(N1-N2-N3) [°]	168(2)
d(N3-N4) [pm]	130(2)	<(N2-N3-N4) [°]	111(1)

The reaction of $N_2F^+MF_6^-$ salts (M = As, Sb) with HN_3 yields the N_5^+ cation (C_{2v}).[21]

$$N_2F^+MF_6^- + HN_3 \xrightarrow[195\,K]{HF} N_5^+MF_6^- + HF \qquad (21)$$

Using the insolubility of $KSbF_6$ in SO_2 and of $CsSbF_6$ in HF, salts of N_5^+ have been prepared in metathetical reactions:

$$N_5^+SbF_6^- + K[B(CF_3)_4] \xrightarrow[214K]{SO_2} N_5^+[B(CF_3)_4]^- + KSbF_6 \qquad (22)$$

$$2N_5^+SbF_6^- + Cs_2SnF_6 \xrightarrow[195\,K]{HF} (N_5^+)_2SnF_6^{2-} + 2CsSbF_6 \qquad (23)$$

$(N_5^+)_2SnF_6^{2-}$ is only marginally stable at room temperature and decomposes at slightly higher temperatures yielding N_5^+ SnF_5^- and FN_5, which has a lifetime of nanoseconds and decomposes instantly to dinitrogen and fluorine azide, whose further decomposition yields several NF compounds (see Section 8.6).

$$(N_5^+)_2SnF_6^{2-} \longrightarrow N_5^+SnF_5^- + N_2 + FN_3 \qquad (24)$$

While $N_5^+AsF_6^-$ and $(N_5^+)_2SnF_6^{2-}$ are only marginally stable at room temperature and decompose at slightly elevated temperatures, the decomposition of N_5^+ $[B(CF_3)_4]$ starts at 323 K and the decomposition of N_5^+ SbF_6^- and $N_5^+Sb_2F_{11}^-$ at 343 K, thus indicating the limits of the thermal stability of the N_5^+ ion.

$N_5^+SbF_6^-$ oxidizes NO, NO_2, and Br_2, but does not oxidize Cl_2, O_2, or Xe, indicating an ionization potential between 10.52 and 11.48 eV.

So far, N_5^+ has not been combined with a polynitrogen anion to form a new modification of nitrogen. Theoretical consideration and experimental investigations agree that $N_5^+N_3^-$ is not stable. However, calculations indicate that the salt $N_5^+N_5^-$ may be stable.[22]

4.3.2 N_5^-

Both pentazole N_5H and the pentazole anion N_5^- consist of a five-membered ring of nitrogen atoms. Huisgen and Ugi synthesized the first pentazole derivatives RN_5 with substituted phenyl rings.[23] Tetrazolylpentazole and imidazolylpentazole, the pentazole derivatives of five-membered aromatic rings, are also known.[24] The geometry of the pentazole ring system was determined from the crystal structures of *p*-dimethylaminophenylpentazole, which decomposes at 340 K, and phenylpentazole (see Table 7). The pentazole ring system is planar with almost equal N–N distances.

Kinetic studies on *p*-substituted phenylpentazoles have demonstrated that electron-donating substituents on the phenyl ring such as NMe_2 and electron-withdrawing substituents such

Table 7 Geometrical parameters of the pentazole ring system in phenylpentazole

d(N1-N2) [pm]	132(1)	N1-N2-N3 [°]	105.3(1)
d(N2-N3) [pm]	130.8(2)	N2-N3-N4 [°]	108.9(1)
d(N3-N4) [pm]	133.7(6)	N3-N4-N5 [°]	109.0(1)
d(N4-N5) [pm]	130.7(8)	N4-N5-N1 [°]	105.3(1)
d(N1-N5) [pm]	132.2(2)	N2-N1-N5 [°]	111.5(1)

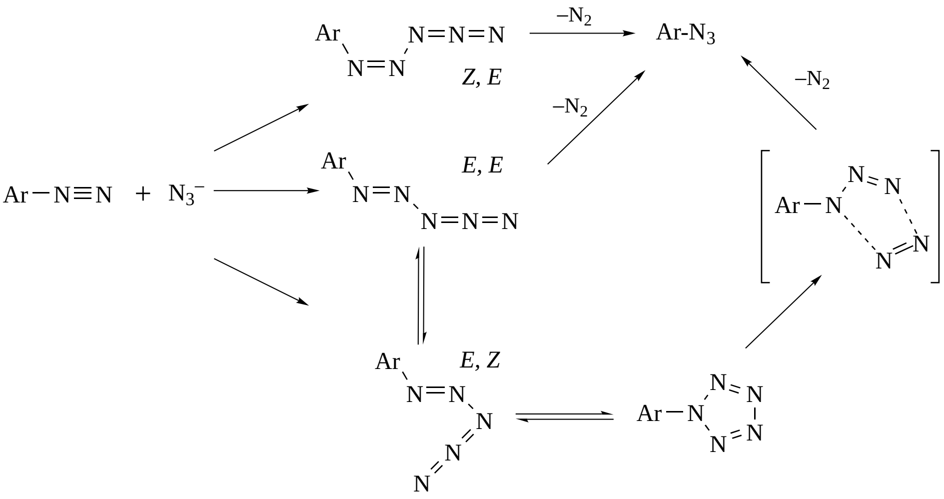
as NO_2, respectively increase and decrease the stability of pentazole with respect to decomposition. Thus, maximum negative charge in the pentazole ring leads to the most stable compounds. Therefore, the pentazole anion N_5^- is the most stable pentazole species with an estimated activation energy of decomposition of 116 kJ mol^{-1}, and a reaction enthalpy of 60 kJ mol^{-1} for the decomposition forming the azide ion and N_2.[25] Pentazole N_5H has an estimated activation energy of 68 kJ mol^{-1} for the decomposition to dinitrogen and hydrazoic acid. NMR spectroscopic studies yielded accurate kinetic data for the decomposition of arylpentazoles (see Scheme 5), and proved that the pentazole ring is relatively stable in solution. On reaction of an azide ion with an aryl diazonium compound, three open-chain ArN_5 compounds are formed.[26] One isomer (Z, E) decomposes instantly to phenylazide and dinitrogen, another (E, E) can rearrange to a third isomer (E, Z), which can also be formed directly and undergoes cyclization to form a pentazole. Decomposition follows a different mechanism: phenylpentazole is involved in a 1,3-dipolar cycloreversion with elimination of dinitrogen to form phenylazide.

With negative ion electrospray ionization of *p*-hydroxyphenylpentazole and laser desorption ionization of *p*-dimethylaminophenylpentazole, it was possible to cleave the C–N bond between the aromatic substituent and the pentazole in $R-N_5$ and to observe the pentazole anion mass spectrometrically.[27]

4.4 Hexanitrogen

Quantum chemical calculations of the N_6 potential-energy hypersurface have shown that the qualitative shape strongly depends on the choice of the theoretical method and basis set. All the geometries represented in Scheme 6 have been shown to be minima on the potential surface, but most of them do not possess minima at all the levels of theories applied. Hexaazabenzene (**13**), for example, has a minimum for a D_{6h} structure at the HF level of theory. However, this geometry is a second-order saddle point with the density functional theory (DFT) and also at the MP2 level of theory. D_2 hexaazabenzene has a minimum structure at DFT, but at the CCSD(T)/aug-cc-pVDZ level, the D_2 geometry resembles a van der Waals complex of two N_3 units, whereas it is a minimum structure at the CCSD(T)/cc-pVTZ level of theory. Similar behavior has been observed for most of the other isomers.

Only the first two compounds, an open-chain diazide (**10**)[28] and hexaazadewarbenzene (**11**) have minima at all levels of



Scheme 5 Formation and decomposition of the pentazole ring system

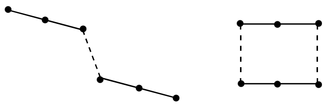
theory applied. The diazide (**10**) has a planar *trans*- C_{2h} structure and is the global minimum structure for N_6, the C_{2v} hexaazadewarbenzene (**11**) is 230 kJ mol^{-1} higher in energy. The diazide (**10**) decomposes with a concerted elimination of two N_2 molecules. The decomposition barrier is estimated to be about 70–80 kJ mol^{-1}.[18]

4.4.1 N_6^-

The reaction of the azide radical N_3• with excess azide ions in solution forms the hexanitrogen radical anion ($\Delta H = 18\,\text{kJ mol}^{-1}$).[29]

$$N_3\bullet + N_3^- \rightleftharpoons N_6^{-}\bullet \tag{25}$$

The hexanitrogen radical anion is more stable in acetonitrile solution compared to water. In the absence of added quenchers, it decays with approximately second-order kinetics with a half-life of 10 µs. During the high-pressure photolysis (1.1 GPa) of sodium azide, N_6^- ions have also been detected.



(**19**) (**20**)

Scheme 7 Connectivity of calculated N_6^- isomers

Using quantum chemical calculations, the two minima in Scheme 7 have been found for N_6^-. Both are formal dimers of N_3 with large distances between the azide units.

At the highest level of theory applied, the *trans* form (**19**) was calculated to be more stable than the rectangular form (**20**) by about 2 kJ mol^{-1}.[18]

(**21**) C_{2v}

Figure 2 Connectivity of N_7 minimum structure

4.5 Heptanitrogen

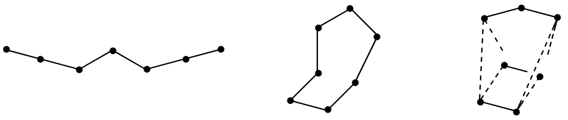
A C_{2v} open-chain structure (**21**) in Figure 2 was found to be the global minimum structure for N_7, but complications of the calculations suggest that neutral N_7 does not have a significant dissociation barrier similar to N_5.[30]

For $N_7{}^+$, an open-chain structure (**22**) shown in Figure 3 and similar to (**21**), which was found for N_7, was calculated. The decomposition of the open-chain $N_7{}^+$ to the $N_5{}^+$ cation and dinitrogen has a calculated activation barrier of 13 kJ mol^{-1}.[31]

For $N_7{}^-$, the open-chain C_2 structure (**23**) in Scheme 8 is the global minimum. It is favored by 36 kJ mol^1 over the complex C_s structure (**25**) and 45 kJ mol^{-1} over the C_s ring structure (**24**). The activation energy for the decomposition was calculated to be 5 kJ mol^{-1} for the open-chain structure (**23**), which decomposes to the azide anion and two molecules of dinitrogen and to 18 kJ mol^{-1} for the ring structure (**24**).[31]

(**22**) C_{2v}

Figure 3 Connectivity of $N_7{}^+$ minimum structure



(**23**) C_2 (**24**) C_s (**25**) C_s

Scheme 8 Connectivity of calculated $N_7{}^-$ isomers

4.6 Octanitrogen

Several isomers of N_8 have been studied theoretically (see Scheme 9).[32] Azidopentazole (**26**) is the global minimum structure (964 kJ mol^{-1} above 4 N_2). Octaazapentalene (**27**) is 72 kJ mol^{-1} higher in energy, *cis*-(**29**) and *trans*-(**28**) diazidodiimide (N_3–N=N–N_3) are 58 kJ mol^{-1} and 63 kJ mol^{-1} higher in energy and octaazacubane (**30**) is 939 kJ mol^{-1} higher in energy.

Azidopentazole (**26**) is believed to decompose forming four dinitrogen molecules (activation energy 59 kJ mol^{-1}). The violently explosive tetrazolylazide, which is derived from azolylpentazole by the exchange of one nitrogen with a carbon atom and the addition of a hydrogen atom, shows the high-energy content of these systems.[33] Octaazapentalene (**27**) decomposes by rearrangement to azidopentazole (**26**) (activation energy 37 kJ mol^{-1}) and the diazodiimides (**28**) and (**29**) decompose via elimination of a dinitrogen molecule (activation energies: *cis* 80 kJ mol^{-1}, *trans* 91 kJ mol^{-1}). The least motion unimolecular decomposition of octaazacubane (**30**) to four dinitrogen molecules is spin forbidden, as is the case also for its hydrocarbon analogue cubane C_8H_8. However, a non-least-motion pathway was found that reduces the activation barrier to less than 80 kJ mol^{-1}.

4.7 Nonanitrogen

For the decomposition of the C_{2v} open-chain nonanitrogen N_9 (**31**), in Figure 4 to open-chain N_7 (**28**) and N_2, a dissociation barrier of 69 kJ mol^{-1} was calculated.[34] Bearing in mind that no true minimum structures for N_5 and N_7 have been found, the calculated dissociation barrier for N_9 seems to be too high.

4.8 Decanitrogen

The C_{3v} triazidoamine (**33**) in Scheme 10 represents a minimum structure at lower levels of theory; at the MP2 level, however, it does not represent a minimum. Dipentazole (D_{2d}) (**32**) decomposes to azidopentazole (**26**) and dinitrogen

(**31**)

(**32**) D_{2d} (**33**) C_{3v} (**34**) C_{2h} (**35**) C_s

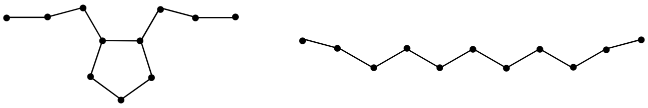
Scheme 10 Connectivity of calculated N_{10} isomers

with an activation barrier of 21.2 kJ mol^{-1}.[25] It is very improbable that dipentazole (**32**) can be isolated, because the activation energy for the decomposition of the experimentally known tetrazolylpentazole, where one nitrogen atom is exchanged by carbon, was calculated by the same method to be 48 kJ mol^{-1}, and tetrazolylpentazole decomposes at temperatures above 220 K.[24] Calculations have shown that the activation energy for the decomposition of azolylpentazoles decreases with an increasing number of nitrogen atoms in the five-membered ring. Imidazolylpentazole, which has two nitrogen atoms, decomposes above 248 K. Therefore, dipentazole could only be observed at temperatures that are below 200 K, maybe much below 200 K. The activation energy for the decomposition of open-chain C_{2h} N_{10} (**34**) to open-chain N_8 (**28**) and dinitrogen was calculated to be 64 kJ mol^{-1}. The C_s pentazole isomer (**35**) has an activation energy of 49 kJ mol^{-1} for the decomposition to open-chain N_8 (**28**) and dinitrogen. Calculations also indicate that salts of the type $N_5^+N_5^-$ with the experimentally known N_5^+ and N_5^- ions are stable against charge transfer reactions between the ions. A $N_5^+N_5^-$ salt is the most likely candidate for the synthesis of solid nitrogen.[22]

4.9 Undecanitrogen

The C_s isomer (**36**) containing two pentazole ring systems in Scheme 11 was calculated to be 180 kJ mol^{-1} lower in energy than the C_2 isomer (**37**) and 312 kJ mol^{-1} lower than the open-chain C_{2v} isomer (**38**). For the decomposition of the C_{2v} open-chain undecanitrogen (**38**) a dissociation barrier of 59 kJ mol^{-1} to open-chain N_9 (**31**) and N_2 was calculated.[34] As remarked for the dissociation barrier of nonanitrogen, this activation barrier for the decomposition of (**38**) also seems to be too high.

The open-chain N_{11}^+ cation (**40**) in Scheme 12 is 30 kJ mol^{-1} higher in energy than the pentazole derivative (**39**), which is the lowest energy N_{11}^+ structure reported.



(**39**) C_{2v} (**40**) C_{2v}

Scheme 12 Connectivity of calculated N_{11}^+ isomers

For N_{11}^-, an open-chain global minimum structure with the connectivity of (**40**) was reported.[35]

4.10 Dodecanitrogen

Several minima have been found on the N_{12} energy hypersurface (see Scheme 13).[36] The azobispentazole C_{2h} structure (**41**) is the global minimum structure. It has an activation energy of 17 kJ mol^{-1} for the decomposition to the N_{10} pentazole isomer (**35**) and dinitrogen.[37] The C_s pentazole derivative (**42**) decomposes to open-chain N_{10} (**34**) and N_2 with an activation energy of 39 kJ mol^{-1} and the open-chain C_{2h} N_{12} (**43**) decomposes to the open-chain N_{10} (**34**) and dinitrogen with an activation energy of 61 kJ mol^{-1}. Further reported N_{12} isomers have activation energies of less than 5 kJ mol^{-1}. The azobistetrazolate dianion, where one nitrogen atom of each pentazole ring of (**41**) is formally exchanged with C^-, is a remarkably stable species that is used in high-energy materials.[38]

Higher polynitrogen species have also been calculated, but only at lower levels of theory because of computational cost. As was discussed above for the hexanitrogen isomers, the results of the calculation on polynitrogen energy hypersurfaces are heavily dependant on the method employed and the basis set used. Lower level calculations of the structures and properties of polynitrogen species have not given accurate results in the past. Therefore, polynitrogen species larger than dodecanitrogen are not discussed here.

5 BINARY COMPOUNDS OF NITROGEN AND HYDROGEN

Nitrogen forms several binary compounds with hydrogen (see Table 8). A review of binary nitrogen–hydrogen compounds can be found in the literature.[39,40] Substitution of hydrogen atoms by organic substituents leads to organic derivatives that are often more stable than the binary nitrogen–hydrogen compounds. Ammonia, hydrazine, diazene (diimine), hydrazoic acid, and tetrazene have been isolated so far. Ammonia and hydrazine also form salts with hydrazoic acid, that is, ammonium azide and hydrazinium azide. Hydrazinium azide forms an adduct with another hydrazine molecule, resulting in hydrazinium azide hydrazinate. Other binary nitrogen compounds, which have not been isolated but have been detected experimentally include nitrene, triazane, *cyclo*-triazane, tetrazane, and triazene. Hydrogenpentazole is discussed in Section 4.3.2.

5.1 Ammonia

Ammonia is a colorless, diamagnetic gas with a characteristic, penetrating odor that is irritating to the eyes and mucous membranes at concentrations higher than 100 ppm. At higher concentrations, ammonia paralyzes the breathing organs which may be fatal.[4,40] Some physical properties of ammonia are given in Table 9.

The ammonia molecule has a pyramidal structure (see (26)) with C_{3v} symmetry (d(N–H) 101.1 pm, <(H–N–H) 106.18°). Solid ammonia crystallizes in a distorted cubic close packed structure, where every nitrogen atom is surrounded by six other nitrogen atoms with N–N distances of 338 pm, thus every nitrogen atom is involved in six hydrogen bonds. Upon melting, about 27% of the hydrogen bonds are broken. Another 7% are broken while heating to the boiling point (see Table 10). The high vaporization enthalpy is the result of breaking the remaining hydrogen bonds, and it allows the use of ammonia as a refrigerant. Ammonia shows anomalies in its melting and boiling point as well as in the enthalpies of fusion and vaporization compared to the heavier homologues PH_3, AsH_3, SbH_3, and BiH_3. As for H_2O and HF, which show similar anomalies in their periodic group, these anomalies are explained by hydrogen bonding.

The ammonia molecule can undergo inversion of configuration with a planar transition state (activation energy

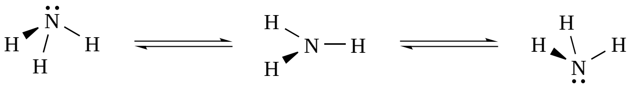
24.5 kJ mol^{-1}).



(26)

The observed microwave frequency of $2.387 \times 10^{10}\ s^{-1}$ for the inversion of ammonia is higher than the frequency calculated from the inversion barrier. The reason is quantum chemical tunneling through the inversion barrier. Because tunneling is proportional to the weight of the atoms, the inversion of ND_3 with the heavier deuterium atoms has a frequency of $1.591 \times 10^9\ s^{-1}$, roughly 1/15 of the frequency of ammonia. Derivatives of ammonia are also subject to this inversion with higher or lower activation energies depending on the substituent. Highly electronegative substituents increase the inversion barrier (250 kJ mol^{-1} in NF_3), π-bonding of the nitrogen lone pair to the substituent decreases the activation barrier (5.6 kJ mol^{-1} in H_2NCN).

Ammonia is stable at ambient conditions, but decomposes to the elements in the presence of catalysts at higher temperatures ($\Delta H = 92.28$ kJ mol^{-1}). This decomposition also takes place under UV irradiation or in electric discharges.

$$2NH_3 \rightleftharpoons N_2 + 3H_2 \quad (27)$$

In the presence of catalysts, ammonia reacts with oxygen to form nitrogen oxide at relatively low temperatures of 500–700 K ($\Delta H = -906.1$ kJ mol^{-1}).

$$4NH_3 + 5O_2 \longrightarrow 4NO + 6H_2O \quad (28)$$

This reaction is used for the synthesis of nitric acid in the Ostwald process (see Section 7.8.1). Without catalysts, and at higher temperatures, ammonia burns in an oxygen atmosphere with a pale yellow flame forming the thermodynamically favorable products dinitrogen and water ($\Delta H = -1267$ kJ mol^{-1}). At high pressures, mixtures of ammonia and oxygen are explosive.

$$4NH_3 + 3O_2 \longrightarrow 2N_2 + 6H_2O \quad (29)$$

Strong oxidants like H_2O_2, $KMnO_4$, HOCl, HNO_2, or Cl_2 oxidize ammonia to dinitrogen ($E° = 0.27$ V at pH 1, see Scheme 26).

$$2NH_4^+ \rightleftharpoons N_2 + 8H^+ + 6e^- \quad (30)$$

If chlorine is passed through a concentrated solution of ammonia or through ammonia gas, ammonia starts to burn and dinitrogen and HCl are formed.

$$2NH_3 + 3Cl_2 \longrightarrow N_2 + 6HCl \quad (31)$$

The reaction of dilute chlorine with dilute ammonia yields chloramine, which can, under the right conditions, react with excess ammonia to form hydrazine (see Section 5.2.1). Fluorine reacts more vigorously than chlorine with ammonia. Bromine shows about the same reactivity and iodine reacts less vigorously. Ammonia reacts with phosphorus to form PH_3 and N_2 (*see* ***Phosphorus–Nitrogen Compounds***), with sulfur to form H_2S and S_4N_4 (*see* ***Sulfur–Nitrogen Compounds***) and with red-hot carbon to form NH_4CN and H_2 (*see* ***Carbon: Inorganic Chemistry***).

Ammonia and all other amines, NR_3, are bases. A solution of ammonia in water is mildly alkaline ($pK_b = 4.75$). Ammonia dissolves readily in water (1.176 m^3 at 273 K, 0.702 m^3 at 298 K in 1 L of water) under evolution of heat ($\Delta H = -37.1$ kJ mol^{-1}). Hydrogen bonds are formed between water and ammonia. Two hydrogen-bonded ammonium hydrates have been isolated, $NH_3 \cdot H_2O$ (m.p. 194.15 K) and $2NH_3 \cdot H_2O$ (m.p. 194.32 K). In the solid state, both compounds have a three-dimensional extended hydrogen bond network.

$$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^- \quad (32)$$

The equilibrium (32) lies to the left side, a 0.1 mol L^{-1} solution of ammonia in water is less than 1% dissociated into ions. The undissociated ammonia forms hydrogen-bonded hydrates $NH_3 \cdot xH_2O$. For comparison, a potassium hydroxide solution is dissociated quantitatively. Ammonium hydroxide NH_4^+ OH^- is only found dissociated in solution, the undissociated form does not exist. Addition of stronger acids than water, for example, hydrochloric acid, sulfuric acid, or nitric acid, shifts the equilibrium (32) to the right side, that is, the side of the salts. The reaction of ammonia with hydrochloric acid vapors forms a white nebula in humid air, and white smoke in dry air.

$$NH_3 + HCl \longrightarrow NH_4Cl \quad (33)$$

Heating of the ammonium salts shifts the formation equilibrium to the ammonia side, the ammonium salts sublime under dissociation. Ammonium salts with oxidizing anions (NO_2^-, NO_3^-, $Cr_2O_7^{2-}$) decompose under oxidation of the ammonium nitrogen to N_2 or N_2O.

Ammonia also has a low acidity (34) and a very slight oxidizing character (35).

$$NH_3 \longrightarrow NH_2^- + H^+ \quad (34)$$

$$NH_3 + e^- \longrightarrow NH_2^- + 0.5H_2 \quad (35)$$

Step-by-step replacement of the hydrogen atoms in ammonia with metal atoms according to (34) or (35) leads to the amides MNH_2, the imides M_2NH, and the nitrides M_3N. The alkali and alkaline-earth amides can be obtained from the reaction of the hot metals with ammonia.

$$2Na + 2NH_3 \longrightarrow 2NaNH_2 + H_2 \quad (36)$$

Imides are formed during heating of the amides, further heating results in the nitrides.

$$M(NH_2)_2 \longrightarrow MNH + NH_3 \quad (37)$$

$$3MNH \longrightarrow M_3N_2 + NH_3 \quad (38)$$

The alkali and alkaline-earth amides, imides, and nitrides are immediately decomposed by water to ammonia and the metal hydroxides.

Ammonia and its organic, H_2NR, HNR_2, and NR_3, derivatives have a lone pair and can act as Lewis bases. The trialkylated derivatives of ammonia form the well-known trialkylammonium oxides R_3NO with the Lewis acid oxygen. Ammonia oxide H_3NO is less stable than the alkylated compounds, it rearranges to the more stable hydroxylamine NH_2OH. Two H_3NO^+ species have been identified mass spectrometrically.[41] Neutralization of the ion beam and subsequent reionization of the H_3NO^+ cations have shown that the neutral ammonia oxide H_3NO also has an inherent stability.

Lewis acids like boron trifluoride form Lewis acid–Lewis base complexes such as $H_3N{\cdot}BF_3$ with ammonia. Ammonia also forms metal complexes, the aminocomplexes (*see* ***Ammonia & N-donor Ligands***).[42] Deprotonation leads to amido, imido, and nitridocomplexes (see Scheme 14).

The nitrogen lone pair can be included in the metal–nitrogen bonds, decreasing the bond length and increasing the bond angle at the nitrogen atom.

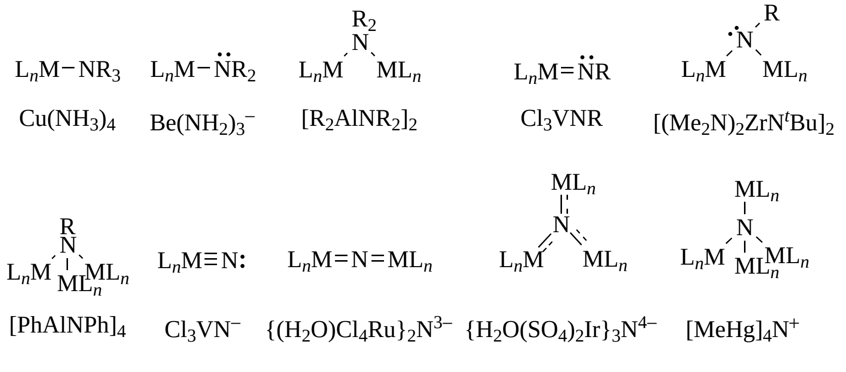
5.1.1 Production of Ammonia

Ammonia is the second largest synthetic chemical product by mass and the largest by molar units.[5] Almost all the world consumption is manufactured from the elements nitrogen and hydrogen in a catalytic process originally developed by Fritz Haber and Carl Bosch using a promoted iron catalyst discovered by Alwin Mittasch. This process has remained largely unchanged since its discovery. A hydrogen–nitrogen mixture reacts over the iron catalyst at an elevated temperature in the range of 673–773 K and pressures above 10 MPa ($\Delta H = -46.22\,\text{kJ mol}^{-1}$). The unreacted portion of the synthesis gas is recycled and the ammonia product separated under high pressure.

$$0.5N_2 + 1.5H_2 \longrightarrow NH_3 \quad (39)$$

Even though this reaction is exothermic, the dinitrogen molecule, which has a very high dissociation energy of $945.33\,\text{kJ mol}^{-1}$, has to be activated. A purely thermal activation would require temperatures well above 800–1200 K under the most favorable conditions to achieve measurable reaction rates. However, at such high temperatures and industrially reasonable pressures, the theoretically possible ammonia yield is extremely small because of the unfavorable position of the thermodynamic equilibrium. At pressures above 200 MPa, the synthesis of ammonia proceeds even in the absence of specific catalysts, here the vessel walls appear to catalyze the formation of ammonia. Electrical energy or ionizing radiation, so-called plasma processes, can also be employed to provide the activation energy. The principal difficulty is that a great part of the supplied energy is transformed either into heat, which is undesirable, or unusable incidental radiation.

In the catalytic combination of nitrogen and hydrogen, the molecules lose their translational degrees of freedom by fixation on the catalyst surface. This drastically reduces the required energy of activation. The reaction may then proceed in the temperature range 520–670 K. Electron donor–acceptor complexes allow the synthesis of ammonia at room temperature with a measurable reaction rate. Since the beginning of commercial ammonia synthesis, iron catalysts that are composed in an unreduced form of iron oxides (mainly magnetite) and a few percent of Al, Ca, and K, are generally used. Other elements such as Mg and Si may also be present in small amounts. The catalysts are usually activated in situ by reduction with synthesis gas. The added elements perform different functions. Structural stabilizers like Al_2O_3 produce high inner surfaces during reduction and stabilize it under thermal stress by restraining iron crystallite growth.



Scheme 14 Connectivity of amido, imido, and nitridocomplexes (R = H or organyl substituent)

Electronic promoters, for example, the alkali oxides, enhance the specific activity of iron–alumina catalysts. However, they reduce the inner surface or lower the thermal stability and the resistance to oxygen-containing catalyst poisons. Promoter oxides that are reduced to the metal during the activation process, and form an alloy with the iron, are a special group in which cobalt is an example that is in industrial use. Oxygen-containing compounds such as H_2O, CO, CO_2, and O_2 only temporarily poison the iron catalysts in low concentrations. Sulfur, phosphorus, arsenic, and chlorine compounds poison the catalyst permanently.

Ruthenium on a graphite or basic oxide support is also used as a catalyst in industrial synthesis. A Co–Mo–N system has also been investigated as a potential catalytic material, however, it has to be improved to compete with the already available catalysts.[43]

The mechanism of the ammonia synthesis by the Haber–Bosch process includes the following steps:

1. transport of the reactants by diffusion and convection out of the bulk gas stream, through a laminar boundary layer, to the outer surface of the catalyst particles, and further through the pore system to the inner surface;
2. adsorption on the inner surface;
3. reaction of the adsorbed species, if necessary with participation by hydrogen from the gas phase, to form activated intermediate compounds;
4. desorption of the formed ammonia into the gas phase;
5. transport of the ammonia through the pore system and the laminar boundary layer into the bulk gas stream.

The nitrogen adsorption and dissociation is the rate-determining step for the intrinsic reaction for iron catalysts. The mechanism of the catalytic reaction includes adsorption of dinitrogen in the molecular state followed by chemisorption in the atomic state. Hydrogen has a direct transition from the gaseous H_2 molecule into the chemisorbed atoms. The chemisorbed nitrogen atoms are then stepwise hydrogenated via N, NH, NH_2 species to NH_3. After the ammonia synthesis, ammonia is recovered from the synthesis loop by cooling the synthesis gas to condense the ammonia under synthesis pressure. The liquid ammonia product is separated from the gas, which is again fed into the synthesis loop.

Industrial ammonia production contains the following steps:

1. Synthesis gas production
   (a) Feedstock pretreatment and gas generation
   (b) Carbon monoxide conversion
   (c) Gas purification
2. Compression
3. Synthesis and purge gas management

Over the years, the most fundamental changes were made in the synthesis gas production and gas compression. These steps still have the highest potential for improvement. Some progress has been made in the synthesis section, especially in converter design and optimization of heat recovery.

The goal of synthesis gas production is a pure mixture of nitrogen and hydrogen in the stoichiometric ratio of 1:3. The raw materials are water, air, and a carbon-containing reducing medium that may contain hydrogen (natural gas, CH_4, naphtha, petroleum) and nitrogen. Normally natural gas and sometimes naphtha is used as a reducing medium. Depending on special economic circumstances, other media are used, for example, coal, which is used for most of the ammonia production in China. The capital cost and the specific energy requirement (i.e. feed and fuel) largely depend on the raw material employed. Both are lowest for natural gas. The term feedstock is often applied to the total consumption of fossil fuel, although strictly speaking a distinction should be made between gasification feed and fuel for energy generation. The chemical reaction of hydrocarbons with water, oxygen, air, or any combination of these is generally referred to as gasification. It produces a gas mixture of CO and H_2 in various proportions along with carbon dioxide and, where air is used, some nitrogen. Any carbon-containing feedstock reacts according to (40) ($\Delta H > 0$) or (41) ($\Delta H < 0$) or both simultaneously.

$$[CH_x] + H_2O \rightleftharpoons CO + H_2 + \frac{x}{2}H_2 \quad (40)$$

$$[CH_x] + 0.5O_2 \rightleftharpoons CO + \frac{x}{2}H_2 \quad (41)$$

Light hydrocarbons from natural gas (methane) to naphtha (max. C_{11}) are reacted with steam over a catalyst according to (40), a process usually called steam reforming. In (40), the proportion of hydrogen supplied by the feedstock increases with its hydrogen content with a theoretical maximum of 66% for methane. The higher bond energy of a hydrogen–oxygen bond compared to a carbon–hydrogen bond decreases the positive reaction enthalpy of (40) with increasing hydrogen content. Natural gas consists predominantly of methane and is therefore the most hydrogen-rich and energetically the best raw material for the steam-reforming route. In the partial-oxidation route, less hydrogen is produced in the primary gasification step and the raw synthesis gas has a rather high CO content. The catalytic steam-reforming technology can only be applied to light hydrocarbon feedstock (up to naphtha) but not for heavy hydrocarbons such as fuel oil or vacuum residue. These materials contain a substantial amount of sulfur and also minor quantities of heavy metals, which would poison the sensitive reforming catalyst, thus heavy feedstocks are processed by partial oxidation.

In the steam-reforming process, any sulfur compounds present in the hydrocarbon feedstock have to be removed because the nickel-containing catalysts are sensitive to poisons. This is either achieved by hydrodesulfurization (*see* ***Hydrodesulfurization & Hydrodenitrogenation***), generally with a combination of cobalt–molybdenum and zinc oxide

catalysts, or by adsorption on activated carbon when the feed is natural gas with a rather low sulfur content.

The primary reformer consists of a multitude of reformer tubes loaded with the nickel catalyst (15–25% NiO on aluminum oxide, calcium aluminate, or magnesium aluminum spinel support) in a furnace box, in which the heat needed for the reaction is transferred to the tubes by radiation. The heat is generated in burners, generally gas-fired in the furnace box.

While only light hydrocarbons can be used for the steam-reforming process, all carbon-containing feedstocks can be processed in a noncatalytic reaction with oxygen according to (41), which is referred to as partial oxidation or coal gasification for coal feedstocks. A minor amount of water is added for process reasons and gives rise to a simultaneous reaction according to (40).

For the exothermic reaction no external heat supply is necessary.

As the synthesis of ammonia needs only nitrogen and hydrogen, all carbon oxides must be removed from the raw synthesis gas of the gasification process. Depending on feedstock and process technology, this gas contains 10–50% carbon monoxide and also varying amounts of carbon dioxide. In the water gas shift reaction, traditionally known as carbon monoxide shift conversion, the carbon monoxide serves as a reducing agent for water, to yield hydrogen and carbon dioxide ($\Delta H = -41\,\text{kJ}\,\text{mol}^{-1}$). In this way, not only is the carbon monoxide converted to readily removable carbon dioxide but also additional hydrogen is produced:

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \quad (42)$$

This reaction is without volume change and is therefore independent of pressure. As an exothermic process, it is favored by lower temperatures, which shift the equilibrium to the right side. Even with a low excess of steam in the gas, the equilibrium concentrations of CO are low, for example, 0.2 vol% at 220 °C and 0.12 vol% at 200 °C for a steam/gas ratio of 0.4. The heat formed in the reaction has to be removed to keep the temperature low, and effective catalysts have to be applied to achieve a sufficient reaction rate. The process is therefore performed in steps. Heat is removed between the individual catalyst beds in which the reaction runs adiabatically. Quasi-isothermal reactors with cooling tubes through the catalyst layers are used. The process configuration and catalysts of steam reforming and partial oxidation are somewhat different. The raw synthesis gases from the partial oxidation of heavy hydrocarbons and coal differ mainly in two aspects from that produced from light hydrocarbons by steam reforming. First, depending on the feedstock composition, the gas may contain a rather high amount of sulfur compounds (mainly H_2S with smaller quantities of COS); second, the CO content is much higher, in some cases in excess of 50%. The high initial carbon monoxide concentration means that the reaction has to be performed in steps with intermediate cooling. In steam-reforming plants, the gas from the secondary reformer enters the high-temperature shift reactor loaded with an iron–chromium catalyst at 600–630 K. After a temperature increase of around 50–70 K, depending on the initial CO concentration, the process gas has a residual CO content of around 3%. It is then cooled to 470–480 K for the low-temperature shift, which is carried out on a copper–zinc–alumina catalyst in a downstream reaction vessel and achieves a carbon monoxide concentration of 0.1–0.3 vol%.

After shift conversion, carbon dioxide, residual carbon monoxide, and sulfur compounds (only present in the synthesis gas from partial oxidation) have to be removed as they are not only a useless ballast but, more importantly, can poison the ammonia synthesis catalyst.

CO_2 is removed by scrubbing the synthesis gas under pressure with a solvent capable of dissolving carbon dioxide in sufficient quantity and at a sufficient rate, usually in countercurrent in a column equipped with trays or packings. The CO_2 saturated solvent is flashed, often in steps, to around atmospheric pressure, and the spent scrubbing liquid is subsequently heated and regenerated in a stripping column before being recycled to the pressurized absorption column. Today, physical or chemical solvents are used. In physical solvents, carbon dioxide dissolves without forming a chemical compound, allowing a recovery by flashing. In chemical solvents, carbon dioxide becomes fixed as a chemical compound. Heat is needed for its decomposition. In the first ammonia plants, water was used for scrubbing. Today ethyl or diethyl amine as well as potassium carbonate solutions are used. As the acidic gases CO_2 and H_2S are both soluble in the solvents applied, special process configurations are required to recover a separate pure CO_2 fraction and an H_2S-rich fraction suitable for sulfur disposal from partial-oxidation gases.

After this bulk removal of the carbon oxides, the typical synthesis gas still contains 0.2–0.5 vol% CO and 0.005–0.2 vol% CO_2. All oxygen-containing compounds have to be reduced to a very low ppm level, as they are poisonous toward the ammonia synthesis catalysts. Methanation is the simplest method to reduce the concentrations of the carbon oxides well below 10 ppm, and is widely used in steam-reforming plants.

$$CO + 3H_2 \rightleftharpoons CH_4 + H_2O \quad (43)$$

$$CO_2 + 4H_2 \rightleftharpoons CH_4 + 2H_2O \quad (44)$$

The advantages of simplicity and low cost more than outweigh the disadvantages of hydrogen consumption and production of additional inert gases in the makeup gas to the synthesis loop. Water is absorbed on molecular sieves. Other final purification methods are pressure-swing adsorption, or washing with liquid nitrogen.

Of the world energy consumption, 1.6% is used for the production of ammonia. In 2000, 108 megatons of ammonia were produced. About 85% is used for fertilizer production as urea, which accounts for 40% of the fertilizer production, and

ammonium nitrate, phosphate, and sulfate. Ammonia is also used as a solvent, for the nitriding of steel, and as a refrigerant, due to its low boiling point and high heat of evaporation.

5.1.2 Ammonia as a Solvent

Ammonia possesses similar physical properties to that of water, which is similarly highly associated.[44] It is a good solvent for many compounds. Owing to the lower dielectric constant (NH_3: 16.9, H_2O: 78.3 at 298 K) of ammonia in comparison with water, less polar compounds are more soluble in ammonia and polar compounds, for example, salts, are more soluble in water. Organic compounds tend to have a higher solubility in ammonia than in water. Ammonium salts, nitrates, nitrites, cyanides, and thiocyanates dissolve readily in ammonia. The solubility increases from fluorides to chlorides, bromides, and iodides. Salts with higher charged ions dissolve only poorly in ammonia. This results in the reversal of some precipitation reactions in ammonia compared to water.

$$Ba(NO_3)_2 + 2AgBr \xrightarrow{NH_3} BaBr_2 + 2AgNO_3 \quad (45)$$

As a hard base, water prefers to coordinate to the harder acid Ba^{2+}, the softer base ammonia prefers to coordinate the softer acid Ag^+ to form $Ba(OH_2)_n{}^{2+}$ and $Ag(NH_3)_2{}^+$, respectively. Sulfates, sulfites, carbonates, phosphates, arsenates, oxides, and sulfides are virtually insoluble in ammonia. Hydroxides and amides are also very poorly soluble.

In ammonia, the $NH_4{}^+$ ion is the strongest available acid and the $NH_2{}^-$ ion the strongest available base. Compounds of the type HX that produce $NH_4{}^+$ ions are acids in this system, MR compounds such as $LiCH_3$ or $NaSiH_3$ are bases as they produce $NH_2{}^-$ ions.

$$NH_3 + HX \longrightarrow NH_4{}^+ + X^- \quad (46)$$

$$NH_3 + MR \longrightarrow NH_2{}^- + M^+ + RH \quad (47)$$

Ammonia is an attractive solvent if strong bases are required, since $NH_2{}^-$ is more basic than OH^-, but is less useful for reactions requiring strong acids. Acids like acetic acid that are weak acids in water are strong acids in ammonia and dissociate fully to form ammonium ions. Strong bases like $C{\equiv}C^{2-}$, Ph_3Ge^-, or R_2P^-, that are immediately hydrolyzed in water, can be handled in ammonia. Complexation is an important factor for the solution of metal salts in ammonia. $Zn(NH_2)_2$, which is insoluble in ammonia, is like the hydroxocomplex $Zn(OH)_2$, which is insoluble in water, amphoteric. It dissolves in acidic solution to form $Zn(NH_3)_4{}^{2+}$ or in basic solution to form $Zn(NH_2)_4{}^{2-}$.

Elements that are above H_2/H^+ are oxidized under evolution of dihydrogen, elements below NH_3/N_2 are reduced under evolution of dinitrogen (see Table 11). This leaves a range of only +0.04 V in which oxidizing agents more powerful than N_2, and reducing agents more powerful than H_2 are thermodynamically stable. However, kinetic effects leading to overvoltages of H_2 and N_2 extend the range from +1.0 V to −1.0 V in basic solution and from −2.05 V to +0.6 V in acidic solution. Therefore, even strong reductants like $[M^0(CN)]^{4-}$ (M = Ni, Pd, Pt) and strong oxidizers like $O_2{}^-$ or $O_3{}^-$ can be handled in liquid ammonia.

Alkali and alkaline-earth metals dissolve in ammonia, in contrast to water, without the evolution of dihydrogen, forming intensely colored solutions that are strong reducing agents. The solutions, which have lower densities than ammonia, are metastable in the absence of water and dioxygen. Over time, or in the presence of catalysts such as $FeCl_2$, these solutions decompose to the metal amides and dihydrogen. Beryllium and magnesium do not dissolve because metal ionization and lattice energies are too high, but solutions of these metals in ammonia can be prepared by the electrochemical reduction of solutions of their salts in ammonia. The color of the solutions depends on concentration; dilute solution are intense blue and salt-like, concentrated solutions bronze–gold and truly metallic. At intermediate concentrations, there is a concentration-dependent metal–nonmetal transition, which is associated with a remarkable liquid–liquid phase transition and unusual critical properties. In one mol of ammonia, the following amounts of metals are dissolved at 223 K: Li 0.27 mol, Na 0.19 mol, K 0.20 mol, Rb 0.3 mol, Cs 0.43 mol.

Saturated solutions of lithium in ammonia have the lowest density ($\rho = 0.48\,g\,cm^{-1}$) of any known liquid at room temperature and provide the lowest-temperature liquid metals with a deep pseudoeutectic extending to 88 K.[45] Dissolution of lithium atoms in ammonia produces a rich variety of solvated electronic and ionic species. At very low concentrations (c < 0.01 mole percent metal, MPM),

Cd/Cd^{2+}	−0.2 (−2.84)	Ag/Ag^+	+0.83 (+0.80)	F^-/F_2	+3.50 (+3.05)

the solutions are essentially electrolytic, and contain solvated ions and isolated electrons. The latter are localized within polaronic solvent cavities with an approximate radius of 3 Å, causing the decrease in density of the metal solutions compared to ammonia and the paramagnetism of the solutions. At intermediate concentrations (0.01 MPM to 2 MPM), the electronic and magnetic properties are dominated by spinpaired species, for example, peanut-shaped bipolarons. These species account for about 90% of the excess electrons at 1 MPM. A metal–nonmetal transition takes place at around 4 MPM, with the onset of liquid–liquid phase separation below 210 K. At higher concentrations, the excess electronic states become more extended and itinerant, forming solutions that are good metals. Saturated solutions of lithium in ammonia have a concentration of 22 MPM, and an electrical conductivity that exceeds that of liquid mercury. The lithium cations are strongly solvated by four ammonia molecules, forming $Li(NH_3)_4{}^+$. This suggests that the excess electrons are almost fully dissociated from lithium and trapped in polaronic cavities formed by free-solvent molecules. The nonmetal-to-metal transition is explained as the lack of enough free-solvent molecules to fully solvate all excess electrons and the resulting overlap of the solvation shells of different electrons. The alkaline-earth metal solutions in ammonia contain hexacoordinated cations $M(NH_3)_6{}^{2+}$.

5.1.3 Ammonium Salts

The ammonium ion $NH_4{}^+$ has a tetrahedral structure and is slightly acidic ($pK_a = 9.25$). If no strong hydrogen bonds are present, like in NH_4F, the properties of ammonium salts, for example, the solubility and the structure, are similar to the corresponding potassium and rubidium salts. The reasons are similar ionic radii of the ammonium (143 pm), potassium (137 pm), and rubidium ions (148 pm). The oxonium salts $H_3O^+X^-$, which have lower melting points, are also similar to the ammonium salts. The similar properties of element-hydrogen compounds have been rationalized by the hydride displacement law shown in Table 12.

Table 12 Hydride displacement law

C	N	O	F	Ne	Na
	CH	NH	OH	FH	NeH
		CH_2	NH_2	OH_2	FH_2
			CH_3	NH_3	OH_3
				CH_4	NH_4

Accordingly, the isoelectronic FH_2, OH_3, NH_4, as well as Na form cations, for example, in $Na^+ClO_4{}^-$, $FH_2{}^+ClO_4{}^-$, $OH_3{}^+ClO_4{}^-$, and $NH_4{}^+ClO_4{}^-$. NeH has only been observed in the gas phase. The saturated molecules HF, H_2O, NH_3, and CH_4 correspond to the noble gas neon and OH, NH_2, and CH_3 are found either single bonded or anionic like the fluorine atom. Examples are the ionic compounds Na^+F^-, Na^+OH^-, $Na^+NH_2{}^-$, $Na^+CH_3{}^-$ or the covalent compounds CH_3F, CH_3OH, CH_3NH_2, and CH_3CH_3. The ammonium radical NH_4•, which is isosteric to the alkali metals, has so far not been isolated.

Ammonium ions can coordinate up to four ammonia molecules via hydrogen bonds, for example, $NH_4I{\cdot}4NH_3$ (m.p. 268). The ionic, hydrogen-bonded structure $NH_4\cdots X$ shifts to an adduct structure $NH_3\cdots HX$ with weaker acids HX. For an explanation of hydrogen bonds, *see* ***Hydrogen Bonding & Dihydrogen Bonding***. Some properties of important ammonium salts are given in Table 13.

Ammonium Chloride. Ammonium chloride, which occurs naturally in volcanic material, forms two solid phases. The α-modification (cubic, CsCl type), which is stable at room temperature, changes reversibly to the β-modification (cubic, NaCl type) at 457.6 K. The slightly hygroscopic ammonium chloride sublimes easily, the dissociation to ammonia and HCl is complete at 520 K. It is very soluble in water.[5]

Ammonium chloride is produced in a modified Solvay process, which is used for the production of sodium carbonate.

$$2NH_3 + CO_2 + H_2O + 2NaCl \longrightarrow 2NH_4Cl + Na_2CO_3 \quad (48)$$

If HCl is available cheaply, ammonium chloride can also be produced from ammonia and HCl. Ammonium chloride as gas, solid, or in solution is corrosive because it is acidic, it complexes metal ions and it contains the corrosive chloride ion.

The 150 kilotons of ammonium chloride that are produced per year are mostly used as fertilizer and, in order of importance, for solid electrolytes in dry cell batteries, a component of quarrying explosives, hardeners for formaldehyde-based adhesives, one component of etching solutions in the manufacture of printed circuit boards, and a component, along with zinc chloride, of fluxes in tin and zinc plating.

Table 13 Properties of important ammonium salts

	NH_4Cl	$(NH_4)_2SO_4$	NH_4NO_3	NH_4HCO_3
m.p. [K]	dissoc. 520	decomp. > 575	442.8	decomp. 309–333
ΔH_f [kJ mol^{-1}]	−314.6	−1180.9	−365.1	−849
ρ [g cm^{-3}]	1.530	1.77	1.725	1.58
C_p [J g^{-1} K^{-1}]	1.63	1.423	1.70	1.53

Ammonium Sulfate. The colorless, crystalline ammonium sulfate cannot be melted at atmospheric pressure without decomposition at 508 K, releasing ammonia and forming NH_4HSO_4. After cleavage of water, ammonium bisulfate $(NH_4)_2S_2O_7$ is left. However, the ammonia vapor pressure of pure, anhydrous ammonium sulfate is effectively zero up to 350 K. Above 573 K, decomposition yields N_2, SO_2, SO_3, and H_2O in addition to ammonia.[5]

Ammonium sulfate is synthesized from ammonia, which stems from either coke oven gas or the Haber–Bosch process, and sulfuric acid.

$$2NH_3 + H_2SO_4 \longrightarrow (NH_4)_2SO_4 \quad (49)$$

Ammonium sulfate is a coproduct in the production of synthetic-fiber intermediates, such as caprolactam, acrylonitrile, and methyl methacrylate, and in the production of formic acid and acrylamide. The recovery of ammonium sulfate form these syntheses has gained importance in the last thirty years. Almost all of the 2.8 megatons of ammonium sulfate produced annually is used as fertilizer. In industrial countries, ammonium sulfate is almost always a coproduct or by-product in other processes and can only be sold as fertilizer, mostly in developing countries. In these countries, its low nitrogen content makes the transportation cost per unit of nitrogen higher than for other nitrogen fertilizers.

Ammonium Nitrate. Ammonium nitrate is a colorless, deliquescent crystalline salt. At standard pressure, five modifications of ammonium nitrate exist (Table 14). The phase change at 305.5 K is of particular importance for the handling of ammonium nitrate fertilizer. On passing through the phase change repeatedly, granules of ammonium nitrate lose strength and finally disintegrate because of the differing densities.[5]

Ammonium nitrate dissolves readily in water; in addition, the salt is hygroscopic. Therefore, care must be taken to avoid moisture during transportation and storage. When the salt dissolves in water, heat is absorbed ($\Delta H = 26\,\text{kJ mol}^{-1}$). Therefore, ammonium nitrate can be used in freezing mixtures, for example, in mixtures with sodium chloride and ice.

In the synthesis of ammonium nitrate from the neutralization of 45–65% HNO_3 with gaseous NH_3, the considerable heat of the reaction is used for the partial or complete evaporation of the water.

$$NH_3 + HNO_3 \longrightarrow NH_4NO_3 \quad (50)$$

Table 14 Modifications of ammonium nitrate

Modification	Existence range [K]	Crystal system
α	<256.2	tetragonal
β	305.5–256.2	orthorhombic
γ	357.5–305.5	orthorhombic
δ	398.4–357.4	tetragonal
ε	442.8–398.4	cubic

Depending on the reaction conditions, 95–97% solutions of ammonium nitrate can be obtained. Quick and thorough mixing of the compounds is necessary to avoid local overheating, losses of nitrogen, and decomposition of the ammonium nitrate. Ammonium nitrate has to be prevented from caking during storage by a final surface treatment (coating). The earlier practice of powdering with inorganic substances to separate the grains mechanically has mostly been replaced by treatment of the grain with effective organic surfactants, such as cationic long-chain fatty amines or anionic alkylarylsulfonates.

Ammonium nitrate undergoes several decomposition processes. At 442.8 K, ammonium nitrate starts to melt and at 443.2 K endothermic dissociation takes place ($\Delta H = +175\,\text{kJ mol}^{-1}$):

$$NH_4NO_3 \xrightarrow{442.8\,K} HNO_3 + NH_3 \quad (51)$$

On careful heating to 473 K, N_2O is eliminated ($\Delta H = -37\,\text{kJ mol}^{-1}$).

$$NH_4NO_3 \xrightarrow{473\,K} N_2O + 2H_2O \quad (52)$$

Above 503 K, dinitrogen and NO_2 are eliminated ($\Delta H = -102\,\text{kJ mol}^{-1}$).

$$4NH_4NO_3 \xrightarrow{503\,K} 3N_2 + 2NO_2 + 8H_2O \quad (53)$$

Further heating results in the formation of dinitrogen and dioxygen accompanied by detonation ($\Delta H = -118.5\,\text{kJ mol}^{-1}$).

$$NH_4NO_3 \xrightarrow{>>503\,K} N_2 + 0.5O_2 + 2H_2O \quad (54)$$

Hydrogen ions, chlorides, and heavy metals catalyze the decomposition of ammonium nitrate.

Pure ammonium nitrate, highly concentrated hot solutions of ammonium nitrate, various mixtures of ammonium nitrate, and ammonium nitrate fertilizer can be detonated by shock waves unless stabilized. Several times, huge amounts of ammonium nitrate have exploded, causing severe damage. One of the latest accidents happened in Toulouse in 2001, where 200 to 300 tons of ammonium nitrate exploded in a warehouse. The blast blew out windows in the city center 3 km away and created a crater with a diameter of 50 meters and more than 10 meters deep.

For safety reasons, solidified ammonium nitrate should not be broken up by blasting. Products containing ammonium nitrate must be stored separately from oxidizable and inflammable materials and, if ammonium nitrate must be heated (during production, evaporation, etc.), the quantity must be kept small and catalysts avoided. In several countries, inert materials such as limestone powder, dolomite, or precipitated calcium carbonate, are added to ammonium

nitrate for fertilizer use (calcium ammonium nitrate). Such fertilizers, containing no more than 80% ammonium nitrate, no more than 0.4% combustible constituents, and no less than 18% magnesium or calcium carbonate, are considered nondetonatable.

The 15 megatons of ammonium nitrate produced annually are used mainly as fertilizer, either pure, diluted, or in multinutrient mixtures. It is used in liquid fertilizers with urea.

Safety explosives for mining are produced from ammonium nitrate. Owing to its low explosion temperature in mixtures with NaCl, the temperature is not high enough to set off the much-feared firedamp. For greater explosive power, for example, for mining (rock explosives), porous-prilled ammonium nitrate containing approximately 6% diesel oil is used.

Ammonium Carbonates. In the ternary system, $NH_4^+/H_2O/CO_2$ four compounds are found: ammonium hydrogencarbonate NH_4HCO_3 ($\rho = 2.4\,g\,cm^{-3}$), ammonium carbonate $(NH_4)_2CO_3 \cdot H_2O$ (m.p. 316.2 K), ammonium sesquicarbonate $(NH_4)_2CO_3 \cdot 2NH_4HCO_3 \cdot H_2O$, and ammonium carbamate $NH_4CO_2NH_2$ (m.p. 402 K).[5] Ammonium hydrogencarbonate, also called ammonium bicarbonate is the only compound soluble in water without decomposition. $(NH_4)_2CO_3 \cdot H_2O$ is only formed under precisely defined conditions, which are difficult to achieve in production. Therefore, usually equimolar mixtures of ammonium carbamate and ammonium hydrogencarbonate are used and sold as ammonium carbonate. In the presence of air, ammonium carbonate $(NH_4)_2CO_3$ forms ammonium bicarbonate NH_4HCO_3, which decomposes at temperatures higher than 333 K to ammonia and CO_2. Owing to this decomposition, ammonium bicarbonate is mainly used as an expanding agent for baked goods. It is also used in buffer solutions for the neutralization of acids when additional anions are undesirable. Further uses include an ammonization agent for the humic acid in turf, a nitrogen source for yeast cultures, and blowing agents for foam rubber and poly(vinyl chloride). Ammonium carbamate is used as an insecticide for cereals, a neutralization agent in the chemical industry, and as feedstock for ammonium carbonate production. Ammonium carbonate is used in the manufacture of catalysts, as a blowing agent in foam rubber and foam plastic, and as an additive in photographic developers. In a number of countries, it is also used as an expanding agent in certain baked goods.

5.2 Hydrazine

Hydrazine is a colorless, viscous liquid that fumes in air. A comprehensive review of the chemistry, properties, and production of hydrazine can has been produced.[46] The toxic substance has an odor reminiscent of ammonia and forms a hydrate $N_2H_4 \cdot H_2O$. A $2s2p^3$ hybridization of the nitrogen atoms in hydrazine leads to a tetrahedral arrangement similar to that of saturated carbon atoms, where a lone pair of electrons replaces one ligand of the carbon atom. The repulsion of these lone pairs destabilizes the N–N single bond. Rotation of one-half of the hydrazine molecule around the N–N bond leads to three different conformations, which are shown in Scheme 15.

The unsymmetrical *gauche* conformation (**46**) is the most stable structure. The staggered (anti) chair structure (**45**) is about 3 kJ mol^{-1} higher in energy, and the eclipsed (syn) boat structure (**44**) represents a transition state that was found to be 25–41 kJ mol^{-1} higher in energy by spectroscopic and dipole measurements. The high rotation barrier compared to ethane (10.7–13.8 kJ mol^{-1}) was explained by the repulsion of the nitrogen lone pairs. Hydrogen peroxide (*see* ***Oxygen: Inorganic Chemistry***) is another example of this lone pair interaction. At room temperature, hydrazine does not rotate freely in the gas phase, the NH_2 groups only twist and oscillate against each other.

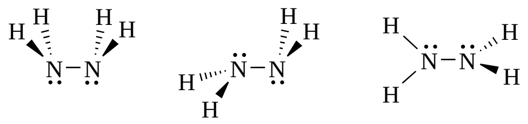
The bonding parameters of hydrazine as obtained by various experimental investigations are in the expected range for an sp^3 hybridized nitrogen atom (see Table 15).

In liquid hydrazine, hydrogen bonding occurs between the hydrazine molecules similar to the hydrogen bonding in liquid water. In solid hydrazine, the hydrogen bonds have NH-N distances between 319 and 367 pm. In hydrazine hydrate, each hydrazine molecule is linked via six hydrogen bonds to surrounding water molecules so that the hydrazine molecules are separated from each other by water molecules.[47] Some physical properties of hydrazine and hydrazine hydrate are shown in Table 16.

5.2.1 Production of Hydrazine

For a long time, the Raschig process, which was discovered in 1907, was used for the production of hydrazine.[5] Here, ammonia is oxidized with sodium hypochlorite in alkaline solution (pH = 8–11). In the initial rapid reaction, (55) sodium hypochlorite reacts with ammonia, forming chloramine. Chloramine then reacts with ammonia in a slower second reaction.[5,46]

$$NaOCl + NH_3 \longrightarrow H_2NCl + NaOH \qquad (55)$$



(**44**) eclipsed (**45**) staggered (**46**) gauche

$$NH_2Cl + NH_3 + NaOH \longrightarrow N_2H_4 + NaCl + H_2O \qquad (56)$$

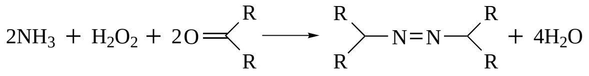
Chloramine reacts preferentially with the produced hydrazine, thus limiting the stationary hydrazine concentration in solution.

$$2NH_2Cl + N_2H_4 \longrightarrow 2NH_4Cl + N_2 \qquad (57)$$

To avoid this decomposition, an excess of ammonia has to be present. Transition metal ions, which are generally present as contaminants in the starting materials and the process water, catalyze this reaction and have to be removed by complexation with glue, gelatin, or albumin. One of the main disadvantages of the Raschig process is the high dilution of the obtained hydrazine (3% solution in water). To obtain hydrazine hydrate, an energy-intensive multistage distillation is necessary. The Bergbau–Bayer–Whiffen or ketazine process solves some of these disadvantages. Here a ketone, typically acetone, reacts with hydrazine forming a ketazine $Me_2C{=}N{-}N{=}CMe_2$ or acetone hydrazone $Me_2C{=}NNH_2$. In contrast to hydrazine, ketazines are not oxidized by chloramine, thus improving the yield. The liberation of hydrazine from the ketazine is dependant on further use. For hydrazinium(I) sulfate, the azine is hydrolyzed with dilute sulfuric acid; for hydrazine hydrate, a high-pressure steam hydrolysis is used.

In anhydrous systems, the low hydrazine concentration is avoided.[48] Chlorine and ammonia can react in the gas phase to form chloramine, which then reacts with ammonia to form hydrazine. As in the Raschig process, the reaction (57) of chloramine with hydrazine limits the yields. Substituted hydrazines can be prepared using this process with the appropriate substituted amines.

In the PCUK process (introduced by Produits Chimiques Ugine Kuhlmann), ammonia is oxidized with hydrogen peroxide in the presence of a ketone. A ketazine is formed as in the ketazine process, which is then processed similarly. Ketones with many different substituents, even aldehydes, have been examined for this reaction. Normally acetone, methylethylketone, or diethylketone are employed.



(58)

The PCUK process is used for most of the newly built hydrazine plants. Its main advantages are higher yield (close to 90% compared to 60–70% with Raschig technology) and lower energy consumption. Furthermore, no sodium chloride has to be disposed off.

The production of hydrazine from urea by treatment with sodium hypochlorite is no longer used. Here urea was oxidized with sodium hypochlorite followed by hydrolysis and decarboxylation to yield hydrazine.

$$(H_2N)_2CO + NaOCl \xrightarrow[-NaCl\ -CO_2]{H_2O} N_2H_4 \qquad (59)$$

Many other processes have been investigated. Attempts to synthesize hydrazine from nitrogen and hydrogen gave only traces of hydrazine. In the biological nitrogen fixation process (*see* ***Nitrogenase Catalysis & Assembly***), hydrazine is an intermediate. The oxidation of ammonia has been investigated by photolysis, γ-radiolyses, glow discharge, arc plasma electrolysis, chemonuclear processes, and chemical oxidation. Also, other starting materials such as semicarbazide, nitramide, nitrosamines, nitroso compounds, and nitrogen oxides were used. These processes are not used on an industrial scale. About 74 kilotons of hydrazine hydrate were produced in 2000.

Hydrazine is mostly sold as an aqueous solution; anhydrous hydrazine is only used as a rocket fuel or as a mono- or bipropellant for satellites and spacecrafts. About 80–90% of the hydrazine produced is converted into organic derivatives. Other applications are based on its use as a reducing agent, as an energy-rich compound, or on its hydrogen storage capacity.

5.2.2 *Anhydrous Hydrazine*

All technical processes for the synthesis of hydrazine yield either hydrazine in aqueous solution or hydrazine hydrate. Most applications can use hydrazine hydrate, but for some applications, for example, rocket propulsion, anhydrous hydrazine is necessary. The water can be removed by a chemical reaction followed by distillation or by azeotropic distillation with an auxiliary fluid. As water binding chemicals, calcium carbide, sodium hydroxide, calcium oxide, calcium hydride, barium oxide, barium hydroxide, and barium pernitride Ba_3N_4 have been used. The use of sodium or calcium metal and sodium amide is best avoided because of the formation of explosive hydrazides. Starting from hydrazine hydrate (64% hydrazine), sodium hydroxide is generally used

to obtain 90% hydrazine. The rest of the water can be removed by repeated treatment with barium oxide and recondensation. The separation of the drying agent and hydrazine by distillation has resulted in many explosions in the past and is, if possible, best avoided. In technical processes, hydrocarbons with similar boiling points as hydrazine, for example, *n*-heptane, are used as blanketing fluids to dilute the hydrazine vapor and prevent explosions. Upon recondensation, they are immiscible with hydrazine and are easily siphoned off. Another approach for drying hydrazine uses an entrainer, a fluid that forms an azeotrope with water, boiling at a temperature different from hydrazine or hydrazine hydrate. Aniline is ideally suited for this purpose.[46]

For liquid–liquid extraction, fluids that have a high affinity for hydrazine and are immiscible with water were found. Fluoroalcohols, typically $H(CF_2)_6CH_2OH$, are ideally suited for this purpose. Anhydrous hydrazine can also be prepared by reacting hydrazinium salts with strong bases.

$$N_2H_5HSO_4 + 2NH_3 \longrightarrow N_2H_4 + (NH_4)_2SO_4 \qquad (60)$$

The equilibrium of the reaction of hydrazinium hydrogensulfate with liquid ammonia (60) is shifted to the product side by the precipitation of $(NH_4)_2SO_4{\cdot}3NH_3$. Organic amines that are weaker bases than hydrazine but have higher boiling points than hydrazine can also be used for the production of anhydrous hydrazine. In a mixture with these bases, hydrazine always has a small equilibrium concentration and can be distilled off under reduced pressure. It is also possible to thermally decompose some hydrazinium salts, yielding anhydrous hydrazine. Here hydrazinium tetraborate $(N_2H_5)_2(B_4O_7)_3$, the hydrazinium salt of carbazic acid $N_2H_5{}^+H_2NNHCO_2{}^-$, and the hydrazinium salt of cyanuric acid have been used. Further purification by fractional crystallization, sublimation, or distillation at low pressure is possible.

5.2.3 *Chemical Properties of Hydrazine*

Hydrazine is an endothermic compound that decomposes at higher temperatures, sometimes explosively, to form dinitrogen and ammonia.[46]

$$3N_2H_4 \longrightarrow 4NH_3 + N_2 \qquad (61)$$

Hydrazine and aqueous solutions of hydrazine are strong reducing agents. Depending on the oxidizing agent, catalysts, pH, and temperature, hydrazine can react in different ways. In aqueous solution, hydrazine can be oxidized in a one, two, or four electron oxidation to form dinitrogen, a mixture of dinitrogen and ammonia or ammonium azide.[49] Hydrazoic acid (63) is only formed in a highly acidic solution with strong oxidants like H_2O_2, $ClO_3{}^-$, or $S_2O_8{}^2$. The oxidation potentials are given in Table 17.

$$N_2H_5{}^+ \longrightarrow 0.5N_2 + NH_4{}^+ + H^+ + e^- \qquad (62)$$

$$N_2H_5{}^+ \longrightarrow 0.5HN_3 + 0.5NH_4{}^+ + 2.5H^+ + 2e^- \qquad (63)$$

$$N_2H_5{}^+ \longrightarrow N_2 + 5H^+ + 4e^- \qquad (64)$$

Reactions (63) and (65) often occur simultaneously. For example, iodate or iodine in acidic conditions and cyanoferrate(III) in alkaline solutions prefer reaction (62), while iron(III) or manganate prefer reaction (64). The oxidation to dinitrogen either takes place directly or stepwise in a one-electron oxidation with hydrazyl radicals $N_2H_3{\bullet}$ ($\Delta H_f = 231\,kJ\,mol^{-1}$) as intermediates.

$$N_2H_4 \longrightarrow N_2H_3{\bullet} + H^+ + e^- \qquad (65)$$

The hydrazyl radicals either dimerize to form tetrazane, which then decomposes to form dinitrogen and ammonia (62), or are oxidized further to diazene, which disproportionates to dinitrogen and hydrazine, thus yielding (64).

$$N_2H_3{\bullet} \longrightarrow N_2H_2 + H^+ + e^- \qquad (66)$$

Under atmospheric conditions, an autoxidation of hydrazine takes place:[50]

$$N_2H_4 + O_2 \longrightarrow N_2 + 2H_2O \qquad (67)$$

While autoxidation is undesirable during storage, it limits the environmental damage after spillage and is the driving force in hydrazine-air fuel cells, which have a standard potential of 1.56 V, which is split into 1.16 V for the oxidation of hydrazine (68) and 0.4 V for the reduction of dioxygen (69).

$$N_2H_4 + 4OH^- \longrightarrow N_2 + 4H_2O + 4e^- \qquad (68)$$

$$O_2 + 2H_2O + 4e^- \longrightarrow 4OH^- \qquad (69)$$

Hydrazinium salts do not show autoxidation. When ignited in air, hydrazine burns rapidly and completely with a high-energy release ($\Delta H = -625.1\,kJ\,mol^{-1}$).

When hydrazine is combined with strong oxidizers (N_2O_4, HNO_3, and $HClO_4$), spontaneous ignition takes place. These hypergolic mixtures are used for rocket propulsion. The end stage of the European Ariane 5, for example, uses a bipropellant mixture of methylhydrazine and N_2O_4.[51]

Reaction with CO_2 gives hydrazinocarboxyclic acid (carbazidic acid) H_2NNCO_2H and ammonia. The reaction of hydrazine with carbon monoxide at high pressure and temperature in the presence of iron pentacarbonyl leads

Table 17 Oxidation potentials of hydrazine

	pH = 0	pH = 14
(62)	$E° = -1.74\,V$	$E° = -2.42\,V$
(63)	$E° = +0.11\,V$	$E° = -0.92\,V$
(64)	$E° = -0.23\,V$	$E° = -1.16\,V$

to semicarbazide $H_2NCONHNH_2$. Thiocarbonohydrazide $S{=}C(NHNH_2)_2$ is prepared by reacting carbon disulfide with excess hydrazine in aqueous solution. Hydrazine also reacts with many nitrogen compounds, where it is almost always oxidized.[52] Nitrite, nitrite esters, and occasionally also nitrates can oxidize hydrazine to azides, which are often unwanted because of their explosive hazards. The reaction of hydrazine and its derivatives with many organic compounds are used for analytical purposes.[53]

Pure hydrazine undergoes an autionization according to the following equation

$$N_2H_4 \rightleftharpoons N_2H_5^+ + N_2H_3^- \qquad (70)$$

with an equilibrium constant $K = 2 \times 10^{-25}$.

This is nine orders of magnitude less than the corresponding constant of water and eight orders of magnitude larger than the self-ionization constant of ammonia. Each nitrogen atom of hydrazine can accept one proton, thus two series of salts can be formed ($pK_1 = 6.07$, $pK_2 = 15.1$). With a pK_1 of 6.07, hydrazine is a weaker base than ammonia. The second nitrogen atom is only protonated by strong bases like H_2SO_4 or $HClO_4$. The diprotonated salts are not stable in aqueous solution; they hydrolyze with water acting as a base according to equation (71).

$$N_2H_6^{2+} + H_2O \longrightarrow N_2H_5^+ + H_3O^+ \qquad (71)$$

A solution of hydrazinium(2+) chloride in water is thus equivalent to a solution of hydrazinium(1+) chloride with an equimolar excess of HCl. Hydrazinium salts are similar to ammonium salts, they are colorless and crystallize well. The difference is their lower stability due to the lower basicity of hydrazine and their reducing nature. Salts with strong oxidizing acids like nitric or perchloric acid may be explosive and require careful handling. The salts are characterized by strong hydrogen bonding between the hydrazinium ions and the anions. Some hydrazinium salts crystallize as hydrates.

Hydrazine only acts as a base with very strong bases, for example, sodium amide or sodium hydride.

$$N_2H_4 + NaNH_2 \longrightarrow Na^+N_2H_3^- + NH_3 \qquad (72)$$

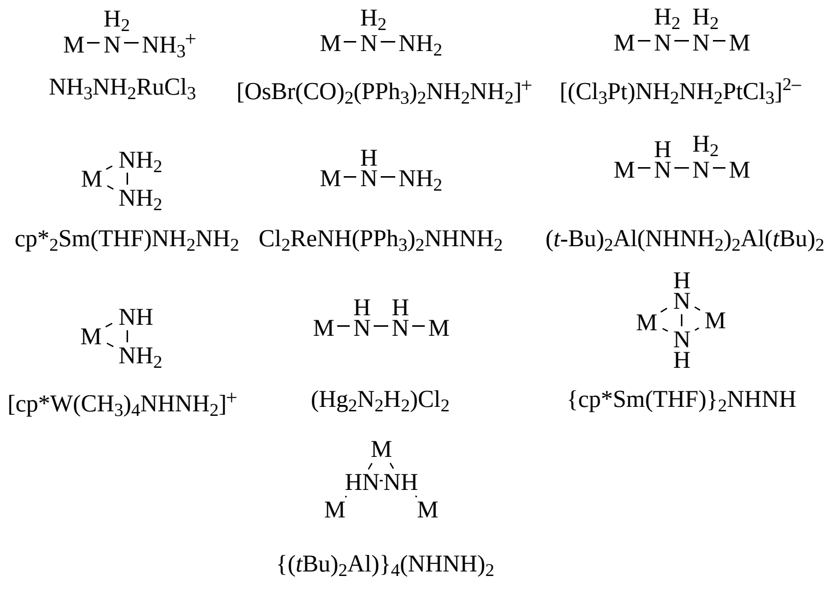
Hydrazine can occupy the space commonly occupied by water in crystallization. These compounds are sometimes called hydrazinates in analogy to hydrates. This addition is reversible. Hydrazinium salts and their hydrazine adducts can be used as gas generators, for example, $(N_2H_5)_2(N_2H_4)_2C_2N_{10}$ as they release huge amounts of gas upon decomposition.[54]

The two lone electron pairs of the nitrogen atoms make hydrazine a good ligand for complex formation.[55] One or both nitrogen atoms of hydrazine can be bound to a metal center (*see* ***Ammonia & N-donor Ligands***). Complexes of deprotonated hydrazine are also known, thus giving hydrazine a great structural variety as shown in Scheme 16.

Hydrazine forms Lewis acid–Lewis base adducts with electron-deficient compounds, for example, $BF_3{\cdot}N_2H_4$.

5.3 Triazane and Tetrazane

Triazane and *cyclo*-triazane form in the capillaries of fully Ag^+-exchanged zeolite after exposure to NH_3 gas at ambient temperature. The N_3H_5 molecules (d(N–N) 160(10) pm, <(N–N–N) 107(8)°) form triple bridges via the terminal



Scheme 16 Coordination of hydrazine ligands in complexes

nitrogen atoms in the complex $Ag(N_3H_5)_3^{2+}$.[56] *Cyclo*-triazane acts as a η^3 ligand in $Ag(N_3H_5)^+$ (d(N–N) 149(8) pm). The triazane molecules are further stabilized by hydrogen bonds to the oxygen atoms of the surrounding zeolite framework. Weak $N_3H_5^+$ and $N_3H_4^+$ peaks were observed in the mass spectrum of the zeolite crystal. Organic derivatives of *cyclo*-triazane (triaziridine) are known, for example, *trans*-diisopropyltriaziridine.[39]

Triazane and tetrazane ($\Delta H_f = 293(10)\,kJ\,mol^{-1}$) were observed mass spectrometrically in a continuous-flow microwave plasma discharge excited in hydrazine gas in helium.[57] Tetrazane is formed from the dimerization of N_2H_3 radicals and decomposes to dinitrogen and ammonia.

$$2N_2H_3\bullet \longrightarrow N_4H_6 \quad (73)$$

$$N_4H_6 \longrightarrow N_2 + 2NH_3 \quad (74)$$

Otherwise the free bases have not yet been observed. In the case of triazane, only the decomposition products were observed.

$$H_2NNHNH_2 \longrightarrow HN{=}NH + NH_3 \quad (75)$$

Substitution of the hydrogen atom of the central nitrogen atom leads to more stable organyltriazanes H_2NNRNH_2.[58]

5.3.1 Triazanium Salts

The Raschig hydrazine synthesis can be extended one further step. Reaction of chloramine with hydrazine in ether yields triazanium chloride, which decomposes instantaneously.[39] This is responsible for hydrazine decomposition during the Raschig synthesis (see Section 5.2.1):

$$H_2NNH_2 + NH_2Cl \longrightarrow H_2NNHNH_2{\cdot}HCl \quad (76)$$

Hydroxylamine-*O*-sulfonic acid reacts with hydrazine to form a precipitate of triazanium hydrogensulfate $(H_2NNH_2\ NH_2)^+$ HSO_4^-. Reaction of this solution with an appropriate barium salt in 0.1 M aqueous solution yielded solutions of the nitrate, perchlorate, chlorate, acetate, cyanide, bromide, and hydroxide salts.[59] The stability of the salts decreases in the order hydrogen sulfate > nitrate > perchlorate > chlorate > acetate > azide > cyanide > bromide > hydroxide. The stability of the solutions decreases with decreasing H^+ concentration, thus stronger acids form more stable salts.

5.4 Nitrene

Nitrene ($\Delta H_f = 357(1)\,kJ\,mol^{-1}$, $S^\circ = 181.253\,J\,mol^{-1}\,K^{-1}$), also called imidogen radical, nitrogen monohydride, and azene has a triplet ground state ($X^3\Sigma^-$).[39] The reactivity of the first excited singlet state ($a^1\Delta$) is different from ground-state nitrene because of the difference in its electronic structure. In thermal systems below 1000 K, the ground state is the dominant state. At very high temperatures or in nonthermal systems (photolytic, radiolytic), higher electronic states can be populated. The controlled formation of NH in the electronic ground state is difficult. Thermal decomposition of NH_3, NH_2Cl, N_2H_4, and HNCO yields NH in different electronic states. Photolysis of NH_3 and HN_3 produces NH in the first excited state ($a^1\Delta$). Ground-state nitrene is formed in the multiphoton dissociation of NH_3 at 193 nm. A two-step process also produces ground-state nitrene: first UV photolysis of HN_3 or HNCO that yields NH ($a^1\Delta$) followed by quenching in a Xe or N_2 matrix to yield NH ($X^3\Sigma^-$).

Ground-state nitrene decomposes to dinitrogen and dihydrogen ($\Delta H = -331\,kJ\,mol^{-1}$)

$$NH(X^3\Sigma^-) \longrightarrow 0.5N_2 + 0.5H_2 \quad (77)$$

Nitrene can be stored for some time below 40 K. At room temperature, nitrene dimerizes very quickly to diimine according to (77).

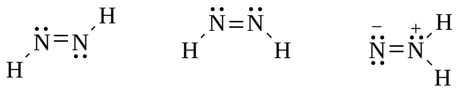
$$2NH \longrightarrow N_2H_2 \quad (78)$$

Nitrene reacts with dioxygen to form nitrous acid and has been observed in a variety of environments including astrophysical studies. It is a key for understanding the fate of nitrogen in combustion systems regardless of the source of nitrogen: dinitrogen, air, or fuel.

5.5 Diazene

At low-pressure diazene ($\Delta H_f = 219.2(8)\,kJ\,mol^{-1}$), also called diimine, is a moderately stable, yellow compound with a lifetime of several minutes at room temperature. It is metastable as a solid below 93 K and very light sensitive.[39]

Evidence for both *cis*-(**47**) and *trans*-(**48**) diazene shown in Scheme 17 has been found in IR studies. *Trans*-diazene (**48**) (d(N–N) 124.7(1) pm, d(N–H) 102.9(1) pm, <(H–N–N) 106.3(2)°) is the dominant structure in the gas phase and has been unambiguously identified. There is evidence that the *cis* isomer (**47**) is the reactive species in many reactions, for example, in the hydrogenation of organic compounds. A third isomer, the blue–violet, photolabile 1,1-diazene or isodiazene (**49**) has been detected in matrix-isolation studies at 12 K. It was prepared from aminoisocyanate. Irradiation



(**47**) C_{2h} (**48**) C_{2v} (**49**) C_{2v}

Scheme 17 Isomers of diazene

of isodiazene (**49**) at 80 K leads to quantitative formation of dihydrogen and dinitrogen.

The major decomposition path of solid *trans*-diazene (**48**) is the disproportionation to dinitrogen and hydrazine:

$$2N_2H_2 \longrightarrow N_2 + N_2H_4 \quad (79)$$

The dissociation to dinitrogen and dihydrogen, the dimerization to ammonium azide, and the cleavage to ammonia and dinitrogen are only of minor importance.

$$N_2H_2 \longrightarrow N_2 + H_2 \quad (80)$$

$$2N_2H_2 \longrightarrow NH_4N_3 \quad (81)$$

$$3N_2H_2 \longrightarrow 2NH_3 + 2N_2 \quad (82)$$

Below 400 K, dissolved or gaseous diazene decomposes according to (79). Above 400 K, (80) is the major decomposition path. Gaseous diazene can be stored for some time at room temperature at very low pressures because the decomposition reaction is a bimolecular reaction. The photolytic decomposition of *trans*-N_2H_2 occurs according to (80) with a radical mechanism via NNH•.

Diazene can be prepared by a microwave discharge of hydrazine at low pressures. It is accompanied by an excess of NH_3 and can be frozen out with ammonia at lower temperatures. Diazene is more stable in ammonia than in the gas phase at room temperature.

The thermal decomposition of tosylhydrazides H_2NNXM($X = p$-CH_3-$C_6H_4SO_2$, M = alkali metal) at temperatures between 373 and 393 K, and trapping at 77 K produces diazene, which is almost free of ammonia.[60]

$$H_2N-N\begin{smallmatrix}M\\X\end{smallmatrix} \xrightarrow[-MX]{373-393\,K} N_2H_2 \quad (83)$$

In solution, diimine can be conveniently generated by the protolysis of azodicarbonate:

$$^{-}OOC{-}N{=}N{-}COO^{-} \xrightarrow[-2CO_2]{H^+} N_2H_2 \quad (84)$$

Diazene is a reducing agent. In the absence of reactive substances, solid or dissolved diazene decomposes in a self-reduction (79). At 77 K, it reacts with dioxygen to form H_2O_2 and with CCl_4 to form $HCCl_3$, H_2CCl_2, and HCl. At 173 K, it reduces sulfuric acid to SO_2 and P_2O_5 to P_4. It does not react with SiO_2, therefore, glass equipment can be used for the handling of N_2H_2. In organic chemistry, solutions of diazene are used for the hydrogenation of unsaturated compounds, N=N, C≡N, C=N, S=O, and C=O bonds.

Trans-diazene can be stabilized in complexes (see Scheme 18), where it is normally found as a bridging ligand (**51**). Only one complex is known where it has a monodentate configuration, as in (**50**) (*see* ***Ammonia & N-donor Ligands***). Diazene complexes are intermediates in biological nitrogen fixation (*see* ***Nitrogenase: Metal Cluster Models*** and ***Nitrogenase Catalysis & Assembly***).[61]

5.6 Triazene

Triazene HN=N–NH_2 is formed in the pulse radiolysis of aqueous solutions of hydrazine.[62] In the radiolysis, hydrazyl radicals N_2H_3• are formed that dimerize to tetrazane, which decomposes under elimination of ammonia to form triazene.[39]

$$N_4H_6 \longrightarrow HN{=}N{-}NH_2 + NH_3 \quad (85)$$

Triazene has only a limited lifetime, milliseconds in an acidic medium and up to 100 seconds in a basic environment. It decomposes to form ammonia and dinitrogen.

$$HN{=}N{-}NH_2 \longrightarrow N_2 + NH_3 \quad (86)$$

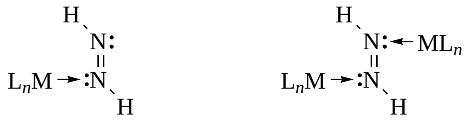
The amphiprotic triazene forms both $N_3H_4^+$ ($pK_1 = 4.95$) and $N_3H_3^-$ ($pK_2 = 11.35$).

$$N_3H_3 + H^+ \rightleftharpoons N_2H_4^+ \quad (87)$$

$$N_2H_3 \rightleftharpoons N_2H_2^- + H^+ \quad (88)$$

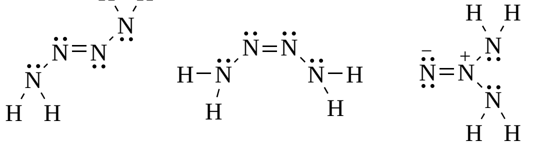
5.7 Tetrazene

Trans-2-tetrazene (**52**), which is shown in Scheme 19, forms colorless needles that decompose, sometimes explosively, at 273 K to form dinitrogen and a liquid phase



(**50**) $[Co(CO)_5]_2HNNH$ (**51**) $[PPh_3)_2(CO)_2NO\ W(HNNH)]^+$

Scheme 18 Coordination of diazene in complexes



(**52**) C_{2h} (**53**) C_{2v} (**54**)

Scheme 19 N_4H_4 isomers

containing hydrazine and ammonium azide. At temperatures below 243 K, tetrazene can be stored indefinitely.[39] It is soluble in methanol, less soluble in dichloromethane, THF, or trimethylamine. The density of 1.40 g cm^{-3} is higher than the density of hydrazine (1.00 g cm^{-3}) and is similar to the density of ammonium azide, another N_4H_4 isomer. In the solid state, *trans*-2-tetrazene (**52**) is found in a gauche conformation. The nitrogen atoms belong to one plane, the lone pairs of all nitrogen atoms are orthogonal to each other (d(N=N) 121(2) pm, d(N–N) 142.9(5) pm, <(H–N–H) 109.8°, <(H1–N–N) 101(4)°, <(H2–N–N) 118(3)°, <(N–N=N) 109(2)°).[63] Hydrogen bonds with NH···N distances of 303–342 pm form a three-dimensional network of tetrazene molecules.

Gaseous 2-tetrazene decomposes only slowly at low pressures to form hydrazinium azide. In solution, 2-tetrazene decomposes above 253 K. It can disproportionate to form dinitrogen and hydrazine or to ammonium azide.

$$N_4H_4 \longrightarrow N_2 + N_2H_4 \quad (89)$$

$$N_4H_4 \longrightarrow NH_4N_3 \quad (90)$$

Tetrazene can be obtained from the reaction of tetrazenium salts $N_4H_7{}^+X^-$ with bases. The tetrazenium salts are formed in small amounts in the decomposition of diazene, which is catalyzed by acids. For the bulk preparation of *trans*-2-tetrazene, the trimethylsilylderivative of tetrazene is reacted with trifluoroacetic acid at 195 K.[64]

$$(Me_3Si)_2N–N=N–N(SiMe_3)_2 + 4F_3CCOOH \longrightarrow H_2N–N=N–NH_2 + 4F_3CCOOSiMe_3 \quad (91)$$

Tetrazene can be purified by sublimation at 253 K. Tetrazenes with organic substituents can be obtained by oxidation of organically substituted hydrazines.

Tetrazene is a weaker base than hydrazine and forms salts $N_4H_5{}^+X^-$ with strong acids. The salts decompose at temperatures above 253 K to the respective ammonium salt and hydrazoic acid.

$$N_4H_5{}^+X^- \longrightarrow NH_4X + HN_3 \quad (92)$$

Tetrazene is a strong reducing agent that readily forms dinitrogen.

$$N_4H_4 \longrightarrow N_2 + 4H^+ + 4e^- \quad (93)$$

cis-2-tetrazene (**53**), the product of protolysis of a cyclic silyl derivative of tetrazene, decomposes instantly at 195 K to form ammonium azide. 1-Tetrazene HN=N–NH–NH_2 is known in form of some unstable organic derivatives that can be synthesized from the reaction of diazonium salts with organic hydrazine derivatives $RNHNH_2$. Isotetrazene $(H_2N)_2N$=N (**54**) is only known in the form of the complex $[(Cl_5WN)_2NN]^-AsPh_4{}^+$ (*see* ***Ammonia & N-donor Ligands***) (d(N–N) 148(2), 159(2), 123(2) nm, <(N–N–N) 125(2) and 126(1)°).

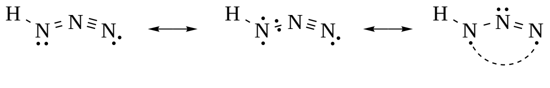
5.8 Hydrazoic Acid and Azide Salts

Hydrazoic acid is a volatile, endothermic liquid of unbearably acrid odor. Some of its properties are given in Table 18. Hydrazoic acid and its salts are very toxic. Inhalation of small quantities causes the blood pressure to drop and damages the mucous membranes. Exposure to HN_3 vapors can be recognized by reddening of the eyes. Pure, liquid hydrazoic acid is very sensitive and explodes with slight mechanical stress.[39] It is completely miscible with water and soluble in alcohols and ethers. Tests have shown that aqueous solutions with less than 20% hydrazoic acid do not detonate. Diethylether, which has almost the same boiling point (307.7 K) as HN_3 can be used as a blanketing fluid.

The N_3 unit of HN_3 (C_s) is angular (d(H–N_α)101 pm, d(N_α–N_β)124 pm, d(N_β–N_γ)113 pm, <(H–N–N) 109°, <(N–N–N) 171°). The unsymmetrical structure of covalent azides can be explained by mesomeric resonance, the triple bond structure is the more important Lewis structure.

(94)

The bond distances of hydrazoic acid suggest a bond order greater than one for the N_α–N_β bond. This fact is explained better by the extended valence bond theory.[65] In (95), two different mesomeric structures are used to explain the bonding properties of HN_3.[66] The middle structure describes a three-electron bond between N_α–N_β, whereas the right (Dewar) structure describes a long bond.



(95)

The azide anion, which has a symmetric, linear arrangement of the nitrogen atoms ($D_{\infty h}$, d(N–N) 118 pm, <(N–N–N) 180°), is a pseudohalide (*see Pseudohalide*).

HN_3 was first obtained as a product of the oxidation of hydrazine by nitrous acid in aqueous solution:

$$N_2H_4 + HNO_2 \longrightarrow HN_3 + 2H_2O \quad (96)$$

Today, hydrazoic acid is obtained by the reaction of sodium azide, which is the precursor for all azide compounds, with a stronger acid. Several procedures have been developed for this reaction. Hydrazoic acid has been generated by the reaction of ion-exchange resins, mineral acids, or stearic acid. A convenient way to synthesize anhydrous HN_3 solutions is the reaction of HBF_4 with sodium azide in diethylether followed by recondensation of the HN_3 solution.[67]

$$HBF_4 + NaN_3 \xrightarrow[200\,K]{Et_2O} HN_3 + NaBF_4 \quad (97)$$

5.8.1 *Production of Azides*

For the synthesis of sodium azide, precursors with two nitrogen atoms, hydrazine N_2H_4 and N_2O, are used.[5] In the technical process, sodium azide is obtained from dry N_2O, which is passed through a sodium amide melt.

$$NaNH_2 + N_2O \xrightarrow{460\,K} NaN_3 + H_2O \quad (98)$$

Water reacts with a second molecule of sodium amide to form sodium hydroxide and ammonia.

$$NaNH_2 + H_2O \longrightarrow NaOH + NH_3 \quad (99)$$

Since N_2O is formed from sodium amide and sodium nitrate, sodium azide can also be obtained from the reaction of sodium amide and sodium nitrate in liquid ammonia under pressure at 370 K.

$$3NaNH_2 + NaNO_3 \longrightarrow NaN_3 + 3NaOH + NH_3 \quad (100)$$

5.8.2 *Chemical Properties of Hydrazoic Acid and Azide Salts*

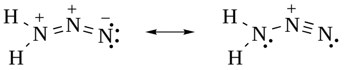
Hydrazoic acid is a weak acid, comparable in strength to acetic acid ($pK_a = 4.64$).

$$HN_3(aq) \rightleftharpoons H^+(aq) + N_3^-(aq) \quad (101)$$

HN_3 only acts as a base with very strong acids, for example:

$$HN_3 + HF/SbF_5 \longrightarrow H_2N_3^+SbF_6^- \quad (102)$$

The C_s $N_3H_2^+$ ion (d(N_α–N_β) 1.295(5) pm, d(N_β–N_γ) 1.101(6) pm, <(H–N–N) 107(6)°, <(N–N–N) 175.3(5)°) has a pyramidal NH_2 group. The N–N bond distances show that the mesomeric formula with an N–N triple bond is the dominant mesomeric structure.



(103)

The weak acid HN_3 can also react with another azide ion to form the hydrogendiazide anion $N_3HN_3^-$.[68] The second azide ion is bound to hydrazoic acid via hydrogen bonding with a short NH···N distance of 272(1) pm.

The sometimes explosive decomposition of HN_3 releases huge amounts of heat ($\Delta H = -528\,kJ\,mol^{-1}$):

$$HN_3(l) \longrightarrow 0.5H_2 + 1.5N_2 \quad (104)$$

At high temperatures and low pressures, HN_3 decomposes to form nitrene.

$$HN_3 \longrightarrow HN + N_2 \quad (105)$$

Hydrazoic acid is a strong oxidant ($E° = 1.96\,V$):

$$HN_3 + 3H^+ + 2e^- \longrightarrow N_2 + NH_4^+ \quad (106)$$

It dissolves some metals (M = Zn, Fe, Mn, and Cu) without evolution of dihydrogen:

$$M + 3HN_3 + H^+ \longrightarrow M(N_3)_2 + N_2 + NH_4^+ \quad (107)$$

In the presence of oxidants, hydrazoic acid is a strong reducing agent ($E° = -3.09\,V$).

$$2HN_3 \longrightarrow 2H^+ + 3N_2 + 2e^- \quad (108)$$

Iodine and Ce(IV) salts reduce HN_3 to dinitrogen. Nitrous acid oxidizes hydrazoic acid to dinitrogen and dinitrogen oxide:

$$HN_3 + HNO_2 \longrightarrow N_2O + N_2 + H_2O \quad (109)$$

Hydrazoic acid can be reduced electrochemically to hydrazine and ammonia.

$$HN_3 + 6H^+ + 6e^- \longrightarrow N_2H_4 + NH_3 \quad (110)$$

The salts of hydrazoic acid, the azides, have similar properties as the respective chlorides, for example, AgN_3, $Hg_2(N_3)_2$, $Pb(N_3)_2$, CuN_3, TlN_3 have only low solubility in water. The alkali- and alkaline earth azides have ionic structures. With the exception of CsN_3 (m.p. 483 K), they do not melt without decomposition. Upon heating, they decompose under evolution of dinitrogen.

$$3Ba(N_3)_2 \xrightarrow[-7N_2]{473\,K} Ba_3N_4 \xrightarrow[-N_2]{523\,K} Ba_3N_2 \quad (111)$$

$$2NaN_3 \xrightarrow{573\,K} 2Na + 3N_2 \quad (112)$$

The thermal decomposition of sodium azide is used for the preparation of spectroscopically pure dinitrogen.

Heavy metal azides have more covalent structures and detonate upon heating or mechanical stress. Lead diazide $Pb(N_3)_2$ is used as an initiator for explosives. Like chlorine, azide can act as a ligand in complexes. The complex azido anions are often more stable than binary azide complexes (*see* ***Ammonia & N-donor Ligands***).[69] Dinuclear azide complexes are found with two coordination modes of the azide ion, (**56**) and (**57**) depicted in Scheme 20.

Anhydrous azide salts or moisture sensitive azides can easily be prepared by the reaction of HN_3 with the respective metal hydrides, of sodium azide with the respective metal chlorides, or of trimethylsilyl azide with the respective metal fluorides:

$$n\mathrm{HN_3} + \mathrm{MH}_n \longrightarrow \mathrm{M(N_3)}_n + \frac{n}{2}\mathrm{H_2} \quad (113)$$

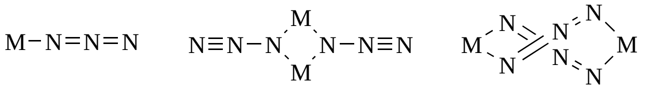
$$n\mathrm{NaN_3} + \mathrm{MCl}_n \longrightarrow \mathrm{M(N_3)}_n + n\mathrm{NaCl} \quad (114)$$

$$n\mathrm{(CH_3)_3SiN_3} + \mathrm{MF}_n \longrightarrow \mathrm{M(N_3)}_n + n\mathrm{(CH_3)_3SiF} \quad (115)$$

5.8.2 Covalent Azides

In covalent azides, the pseudohalogen azide RN_3 has an angular structure as in HN_3.[70] Triazidoborazine $[H_3N_3B_3(N_3)_3]$ and other boron azides, for example, salts of the tetraazidoborate ion $B(N_3)_4{}^-$[67] have been considered as boron nitride precursors (*see* ***Boron–Nitrogen Compounds***). The $M(N_3)_3$ azido complexes of the other group 13 elements (Al, Ga, In, Tl) and their $M(N_3)_4{}^-$ tetraazido anions are all known. They and their derivatives are also used as precursors for the nitrides.

In group 14, the triazidocarbenium ion $C(N_3)_3{}^+$ and cyanuric azide $C_3N_3(N_3)_3$ are molecules with a high-energy content. The triazidocarbenium dinitramide and perchlorate have high positive heats of formation. Nitrophenylazides like 1,3,5-trinitro-2,4,6-triazidobenzene were recently reinvestigated as high-energy materials that produce only gaseous products (CO and N_2).[71] While $Si(N_3)_4$ has been reported,[72] no other tetraazides of group 14 are known. The hexaazides $M(N_3)_6{}^{2-}$ of Si–Pb are remarkably stable when accompanied by large cations, for example, $AsPh_4{}^+$.[73] Organic derivatives of germanium, tin, and lead diazides and triazides are known, but only lead diazide, which is used as a primary explosive, has been isolated. Silicon and tin azides have been reported as versatile reagents in main group element and organic chemistry.[74]



(**55**) $As(N_3)_6{}^-$ (**56**) $[Cu_2(N_3)_6]^{2-}$ (**57**) $[(PPh_3)_2Cu]_2(\mu N_3)_2$

Scheme 20 Coordination of the azide ion in complexes

Table 19 Physical properties of ammonium azide

	NH_4N_3
m.p. [K]	433

ΔH_{sub} [kJ mol^{-1}]	73.6

The phosphorus azides $P(N_3)_3$, $P(N_3)_4{}^+$, $P(N_3)_5$, and $P(N_3)_6{}^-$ have long been known (*see* ***Phosphorus–Nitrogen Compounds***). More recently, the binary arsenic, antimony, and bismuth $M(N_3)_3$, the cations $As(N_3)_4{}^+$ and $Sb(N_3)_4{}^+$, and the arsenic and antimony $M(N_3)_4{}^-$ and $M(N_3)_6{}^-$ anions have been synthesized.[75] While the cations and binary azides are very sensitive(the bismuth compound has not been isolated), the anions, in combination with sufficiently large cations such as $As(Ph)_4{}^+$, are less sensitive. Attempts to prepare the As(V) and Sb(V) pentaazides resulted in explosions.

In group 16, the intermediate existence of $O(N_3)_2$ as an intermediate in the reaction of OF_2 with CsN_3 has been proposed.[76] Many sulfur azides are known, for details see (*see* ***Sulfur: Inorganic Chemistry***). Binary selenium and tellurium azides are not known, but several organic derivatives of the azides have been synthesized.[77,78] For a description of the halogen azides, see Section 8.6.

5.9 Ammonium Azide

Ammonium azide is a colorless, crystalline substance. Some of its properties are given in Table 19. No phase transitions are found between 90 and 348 K. Sublimation of ammonium azide begins at 406 K, recondensation of the vapors at 418 K. Ammonium azide vapors decompose, similar to other ammonium salts, to ammonia and HN_3 at 418 K ($\Delta H = +67.7$ kJ mol^{-1}). In the solid state, all ammonium ions are tetrahedrally connected to azide ions via hydrogen bonds with an NH···N distance of 297.5(4) and 296.7(3) pm.[39]

Ammonium azide is synthesized either by reacting solutions of HN_3 with ammonia:

$$\mathrm{NH_3} + \mathrm{HN_3} \longrightarrow \mathrm{NH_4{}^+N_3{}^-} \quad (116)$$

or by dry heating of sodium azide with ammonium nitrate, whereby the produced ammonium azide sublimes to colder parts of the reaction vessel. Great care has to be taken in this reaction because of the thermal sensitivity of ammonium nitrate.

$$\mathrm{NH_4NO_3} + \mathrm{NaN_3} \longrightarrow \mathrm{NH_4{}^+N_3{}^-} + \mathrm{NaNO_3} \quad (117)$$

The reaction of sodium azide with ammonium sulfate or ammonium chloride in dimethylformamide at 358–393 K under reduced pressure also leads to ammonium azide:

$$NH_4Cl + NaN_3 \xrightarrow{\text{DMF}} NH_4^+N_3^- + NaCl \quad (118)$$

The detonation of ammonium azide produces a huge amount of gas ($\Delta H = -158\,\text{kJ mol}^{-1}$).

$$NH_4N_3 \longrightarrow NH_3(g) + 0.5H_2(g) + 1.5N_2(g) \quad (119)$$

An activation energy of $110\,\text{kJ mol}^{-1}$ was found for the explosion of ammonium azide. Irradiation at wavelengths <300 nm results in decomposition to ammonia and dinitrogen:

$$3NH_4N_3 \xrightarrow{h\nu} 4NH_3 + 4N_2 \quad (120)$$

5.10 Hydrazinium Azide

Hydrazinium azide ($\Delta H_f = +246.6\,\text{kJ mol}^{-1}$, $\Delta H_{\text{fusion}} = +15.8\,\text{kJ mol}^{-1}$, $\rho = 1.40\,\text{g cm}^{-3}$) is the salt of the weak acid HN_3 with the weak base hydrazine. It is a colorless, hygroscopic solid (m.p. 348 K, b.p. 443 K) that easily sublimes.[38] A phase change between 268 and 273 K has been detected. The hydrazinium ions in the crystal structure have a staggered configuration, and every hydrogen atom of the hydrazinium ions is involved in hydrogen bonding with azide ions. The NH···N distances of the hydrogen bonds between hydrazinium ions and azide ions are between 282.4 and 291.8 pm. There is also a weak hydrogen bond between the hydrazinium ions with an NH···N distance of 338 pm. Table 20 shows a comparison of the bonding parameters between ammonium azide, hydrazinium azide, and its hydrazine adduct.

Hydrazinium azide is prepared by the reaction of hydrazine with hydrazoic acid. To avoid the handling of the hazardous HN_3, which is generally synthesized by the reaction of sodium azide with an acid, several procedures have been developed for this reaction. Hydrazoic acid has been generated by the reaction of ion-exchange resins, mineral acids, or stearic acid. It was then either passed through a solution of hydrazine in an inert gas stream or a solution of hydrazoic acid was added to a solution of hydrazine. Especially pure hydrazinium azide can be obtained by the reaction of anhydrous solutions of HN_3 in diethyl ether with a suspension of anhydrous hydrazine in diethyl ether (97). Hydrazinium azide was also observed in the decomposition of 5-aminotetrazole and *trans*-2-tetrazene.

Table 20 Bonding parameters of $N_2H_5N_3$ and $N_2H_5N_3{\cdot}N_2H_4$

	NH_4N_3	$N_2H_5N_3$	$N_2H_5N_3{\cdot}N_2H_4$
d(N–N) [pm]	–	144.5	145.3(2)
d(N1=N2) [pm]	118.6(4)	117.4	118.0(2)
d(N2=N3) [pm]	118.6(4)	116.4	117.4(2)
<(N1=N2=N3) [°]	180.0	179.21	179.5(2)

The first step in the decomposition of liquid hydrazinium azide is the dissociation to hydrazine and HN_3.

$$N_2H_5N_3 \longrightarrow N_2H_4 + HN_3 \quad (121)$$

HN_3 reacts with hydrazinium azide to form NH_3 and N_2.

$$N_2H_5N_3 + HN_3 \longrightarrow 2NH_3 + 3N_2 \quad (122)$$

The overall equation for the decomposition of hydrazinium azide between 400 and 570 K was found to be:

$$N_2H_5N_3 \longrightarrow 0.25N_2H_4 + 1.33NH_3 + 1.58N_2 \quad (123)$$

Detonation of hydrazinium azide in an argon atmosphere under 3 MPa pressure produces ammonia, dinitrogen, and dihydrogen.

$$N_2H_5N_3 \xrightarrow{\text{3MPa}} 2.18N_2 + 1.52H_2 + 0.65NH_3 \quad (124)$$

Both hydrazinium azide and its hydrazinate have been tested in explosive mixtures and as gas generators, but so far they are not in use.

5.11 Hydrazinium Azide Hydrazinate

The hydrazine adduct of hydrazinium azide, hydrazinium azide hydrazinate ($\Delta H_f = +294(3)\,\text{kJ mol}^{-1}$, $\rho = 1.320\,\text{g cm}^{-3}$) is a colorless solid (m.p. 338 K).[79] Every hydrogen atom of the hydrazine molecules is involved in hydrogen bonding. The NH···N distances are between 294.5(2) and 313.5(2) pm. The hydrazinium ion and the hydrazine molecule are connected by a long hydrogen bond with an NH···N distance of 313.5(2) pm, forming a formal $(N_2H_4)_2H^+$ cation.

Hydrazinium azide hydrazinate can be synthesized by heating a mixture of hydrazinium azide and an equimolar amount of hydrazine to 333 K for several days.

$$N_2H_5N_3 + N_2H_4 \xrightarrow{\text{333 K}} N_2H_5N_3{\cdot}N_2H_4 \quad (125)$$

The detonation of hydrazinium azide hydrazinate under pressure produces ammonia, dinitrogen, and dihydrogen.

$$N_2H_5N_3{\cdot}N_2H_4 \xrightarrow{\text{3MPa}} 2.63N_2 + 1.91H_2 + 1.73NH_3 \quad (126)$$

6 NITROGEN OXIDES

The nitrogen oxides, shown in Table 21, except N_2O_4 (l) and N_2O_5 (s), are endothermic compounds and all nitrogen

Table 21 Binary nitrogen oxides

Ox. state	NO_x	N_2O_{2x}	N_3NO_x
+1	N_2O		
+2	NO	N_2O_2	N_3NO
+3		N_2O_3	
+4	NO_2	N_2O_4	N_3NO_2
+5		N_2O_5	
+5	NO_3		

compounds are endergonic compounds ($\Delta G_f > 0$) and should therefore decompose to the elements at room temperature.[5] Owing to kinetic barriers, decomposition begins only at higher temperatures. The monomeric nitrogen oxides NO, NO_2, and NO_3 are radicals.[65] Some properties of the nitrogen oxides are summarized in Table 22.

The nitrogen oxides NO_x are important in globally relevant tropospheric and stratospheric processes. Their life and fate is related to the ozone molecule due to manifold interactions both between the neutral and charged species. The anthropogenic emission of nitrogen oxides is now in the same order of magnitude as the natural emission of nitrogen oxides. Bacteria produce dinitrogen oxide from NH_4^+ during nitrification, and from NO_3^- in the denitrification process. N_2O ($t_{1/2}$ about 100 years) is inert under tropospheric conditions, but reacts in the stratosphere under the influence of oxygen radicals and ultraviolet radiation.

$$N_2O \xrightarrow[\lambda\,<\,240\,\text{nm}]{h\nu} NO\bullet + O\bullet \qquad (127)$$

$$N_2O + O\bullet \longrightarrow 2NO\bullet \qquad (128)$$

Nitric oxide radicals ($t_{1/2}$ about 2–3 years) destroy ozone in a catalytic process. In the stratosphere, they also stem from emissions from planes and rockets, and reactions of N_2O with solar protons

$$NO\bullet + O_3 \longrightarrow NO_2\bullet + O_2 \qquad (129)$$

$$NO_2\bullet + O\bullet \longrightarrow NO\bullet + O_2 \qquad (130)$$

The overall reaction of this process is:

$$O_3 + O\bullet \longrightarrow 2O_2 \qquad (131)$$

Ozone is formed by the photolytic decomposition of NO_2 yielding oxygen radicals and by the reaction sequence $NO_2 \rightarrow HNO_3 \rightarrow NO_3 \rightarrow O_3$. In particular, the reaction of NO_2 with hydroxyl radicals to form HNO_3 increases ozone concentration because two radicals, $NO_2\bullet$ and •OH, which catalyze ozone decomposition, are removed. Other radicals are also important for ozone destruction in the stratosphere, especially chlorine oxides (*see* ***Chlorine, Bromine, Iodine, & Astatine: Inorganic Chemistry***). The mechanism of ozone destruction is complicated as there many compounds involved. Chlorine nitrate and dinitrogen pentoxide can act as reservoir species for ClO•, $NO_2\bullet$, and $NO_3\bullet$ radicals.

Nitric oxide in the troposphere ($t_{1/2}$ about 1 day) stems from bacteria, lightning and for the main part from emissions of combustion engines.

The oxidation of nitric oxide in small concentrations in the troposphere by dioxygen is very slow. As shown in Scheme 21, nitric oxide is oxidized to nitrogen dioxide ($t_{1/2}$ several days) either by HOO• radicals or by ozone. Reaction of nitrogen dioxide with hydroxide radicals forms nitric acid ($t_{1/2}$ several days). Rain washes nitric acid out, thus acidic rain is formed.

$$CO + HO\bullet \longrightarrow CO_2 + H\bullet \qquad (132)$$

$$H\bullet + O_2 \xrightarrow{(M)} HO_2\bullet \qquad (133)$$

$$HO_2\bullet + NO\bullet \longrightarrow NO_2\bullet + HO\bullet \qquad (134)$$

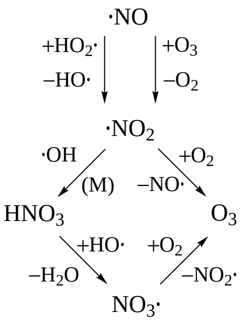
[a]Dissociation to NO and NO_2.



Scheme 21 Reactions of tropospheric nitrogen oxides

$$NO_2\bullet + O_2 \xrightarrow{h\nu} NO\bullet + O_3 \quad (135)$$

$$HO_2\bullet + O_3 \longrightarrow HO\bullet + 2O_2 \quad (136)$$

Carbon monoxide is oxidized in the troposphere ((133) and (134)). With a high concentration of nitric oxide in the troposphere, reactions (135) and (136) take place. This sequence is a formation of ozone catalyzed by nitric oxide. If the nitric oxide concentration is too low, the perhydryl radicals decompose ozone to form hydroxyl radicals (136). Ozone and peroxyacylnitrates PAN are the major toxins of smog. Peroxyacylnitrates are formed from aldehydes in a reaction catalyzed by nitric oxide.

6.1 Nitrosyl Azide

Nitrosyl azide is formed in the reaction of an excess of activated sodium azide with nitrosyl chloride at 218 K.[80]

$$NOCl + NaN_3 \xrightarrow{218\,K} NaCl + ONN_3 \quad (137)$$

Nitrosyl azide can be sublimed under partial decomposition at low temperatures to form a pale yellow solid. Upon warming, it decomposes to form dinitrogen oxide and dinitrogen.

$$ONN_3 \longrightarrow N_2O + N_2 \quad (138)$$

Calculations indicate the formation of a cyclic N_4O isomer as an intermediate during this decomposition.[81] A N_3O^+ cation has been detected mass spectroscopically in the detonation products of nitromethane.[82]

6.2 Nitryl Azide

The reaction of nitronium hexafluoroantimonate with sodium azide at 223 K in carbon dioxide yields nitryl azide.[83]

$$NO_2{}^+SbF_6{}^- + NaN_3 \xrightarrow[223\,K]{CO_2} NaSbF_6 + O_2NN_3 \quad (139)$$

On warming up to room temperature, nitryl azide decomposes to dinitrogen oxide.

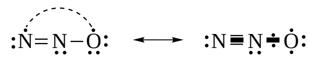
$$O_2NN_3 \longrightarrow 2N_2O \quad (140)$$

6.3 Dinitrogen Monoxide

Dinitrogen monoxide ($\Delta H_f^\circ = +82.10\,kJ\,mol^{-1}$), also called nitrous oxide, is a colorless, diamagnetic gas with a weak, pleasant odor, and a sweet taste. The melting point of N_2O is 182.3 K; its boiling point is 184.7 K. It is insoluble in water.[4]

(141)

N_2O has a linear geometry with an N–O distance of 118.6 pm and an N–N distance of 112.6 pm. The N–N bond can be regarded to be between a double and triple bond, the N–O bond is between a single and a double bond. The extended valence bond structures in (142) describe the observed N–N and N–O bond lengths in N_2O better. The right structure gives is the best representation of the actual bonding situation.[84]



(142)

A cyclic N_2O isomer has not been detected yet,[81] but theoretical calculations indicate its formation in the decomposition of nitrosyl azide and in the reaction of OF_2 with cesium azide. Dinitrogen monoxide is only metastable at lower temperatures, at temperatures above 870 K it decomposes to the elements ($\Delta H = +82.10\,kJ\,mol^{-1}$):

$$N_2O \longrightarrow N_2 + 0.5O_2 \quad (143)$$

Dinitrogen monoxide is relatively unreactive at room temperature; it does not react with alkaline metals, ozone, chlorine, bromine, or iodine. Easily flammable materials (phosphorus (*see* ***Phosphorus–Nitrogen Compounds***), sulfur (*see* ***Sulfur–Nitrogen Compounds***), coal (*see* ***Carbon: Inorganic Chemistry***)) burn in a dinitrogen oxide atmosphere as in an oxygen atmosphere, though it is more difficult to start the combustion in dinitrogen monoxide. A mixture of N_2O and dihydrogen (*see* ***Hydrogen: Inorganic Chemistry***) explodes with slightly less force than a dioxygen/dihydrogen mixture because of the formation of dinitrogen ($\Delta H = +1012.1\,kJ\,mol^{-1}$).

$$3N_2O + 2NH_3 \longrightarrow 4N_2 + 3H_2O \quad (144)$$

Under UV irradiation, N_2O reacts with difluorine to form nitrosodifluoramine (see Section 9.4). Dinitrogen monoxide is synthesized by the thermal decomposition of ammonium

nitrate or mixtures of sodium nitrate and ammonium sulfate at about 500 K:

$$NH_3 + HNO_3 \longrightarrow N_2O + 2H_2O \quad (145)$$

At first, this process used solid ammonium nitrate and great care had to be taken to avoid an explosive decomposition of ammonium nitrate (54), which starts at higher temperatures. Now aqueous solutions of ammonium nitrate are used. By-products in this reaction are N_2 and NO.

Laboratory syntheses of nitrous oxide include the decomposition of hyponitrous acid (236) or nitramide (314), the reaction of nitrous acid with hydroxylamine (146) or hydrazoic acid, (147) and the reaction of amidosulfonic acid with concentrated nitric acid (148):

$$HNO_2 + NH_2OH \longrightarrow N_2O + 2H_2O \quad (146)$$

$$HNO_2 + HN_3 \longrightarrow N_2O + H_2O + N_2 \quad (147)$$

$$H_2NSO_3H + HNO_3 \longrightarrow N_2O + H_2SO_4 + H_2O \quad (148)$$

Dinitrogen monoxide can act as a Lewis base in complexes (monodentate in $[Ru(NH_3)_5(N_2O)]^{2+}$). It can also act as a Lewis acid with strong Lewis bases, for example, in the reaction with amides to form azides.

$$NH_2^- + N_2O \longrightarrow N_3^- + H_2O \quad (149)$$

Dinitrogen monoxide is used in medicine as an anesthetic because, when inhaled, it can bring about a spasmodic inclination to laugh and a condition resembling drunkenness, which explains its historic name, laughing gas. It is also used as a propellant in the munitions industry and a foaming agent for whipped cream in the food industry.

6.4 Nitrogen Monoxide and Dinitrogen Dioxide

Nitrogen monoxide ($\Delta H_f = +90.25\,kJ\,mol^{-1}$), also called nitric oxide, is a colorless, paramagnetic, and toxic gas. Impurities of N_2O_3 can cause a blue color of the liquid (b.p. 121.38 K, m.p. 115.5 K). It is only slightly soluble in water. Nitrogen monoxide is the simplest known, thermally stable molecule (d(N–O) 114 pm) with an odd number of electrons (*see* ***Electronic Structure of Main-group Compounds***) and is a chemical messenger in biological systems. NO helps to regulate a diverse array of physiological processes, such as neurotransmission and blood pressure, and prevents blood clots (*see* ***Nitrogen Monoxide (Nitric Oxide): Bioinorganic Chemistry***).

(150)

The structure with the three electron bond between nitrogen and oxygen is the best description of the bonding situation in nitric oxide.

Nitrogen monoxide partly dimerizes upon condensation. At room temperature the dimerization equilibrium is on the side of NO ($\Delta H = -10.5\,kJ\,mol^{-1}$).

$$2NO \rightleftharpoons N_2O_2 \quad (151)$$

In the liquid and especially in the solid state (diamagnetic), the equilibrium is on the side of the diamagnetic dimer.

As the MO scheme (Scheme 22) shows, the unpaired electron in nitric oxide is in an antibonding MO, thus the bond order is 2.5 and the ionization energy is rather low compared to dinitrogen, dioxygen or carbon monoxide (IE(NO) = 9.25 eV, IE(N_2) = 15.6 eV, IE(CO) = 14.0 V, IE(O_2) = 12.1 eV). The two antibonding $\pi*$ orbitals of NO form a bond in the dimer (see Figure 5). The antibonding $\pi*$ orbital is closer to nitrogen, thus explaining the shorter nitrogen–nitrogen bonds.[65]

While both the *cis* (**58**) and the *trans* (**59**) isomer in Scheme 23 have been observed, the *cis* isomer (**58**) (d(N–O) 112(2) pm, d(N–N) 218(3) pm, d(O–O) 2.62(3) pm)[85] is more stable. A red asymmetric dimer (**60**) has been detected when NO is condensed in the presence of Lewis acids like BX_3 (X = Hal), SiF_4, $SnCl_4$, $TiCl_4$, SO_2, or HCl.

NO can form a molecule with an even number of electrons either by oxidation to the NO^+ cation (d(N–N) 106 pm), which is isoelectronic with CO and N_2 and has a nitrogen–oxygen triple bond or by reduction to form the nitroxyl anion NO^-, which is isoelectronic to dioxygen O_2.

The highly endothermic nitric oxide can be synthesized from the elements dinitrogen and dioxygen in an electric arc ($\Delta H = 180.6\,kJ\,mol^{-1}$). This also takes place in the natural nitrogen fixation by lightning.

$$N_2 + O_2 \rightleftharpoons 2NO\bullet \quad (152)$$

Nitric oxide is only formed at very high temperatures (equilibrium concentration about 10^{-7} vol% NO (500 K), 0.04% (1000 K), 0.1% (1500 K), 0.5% (1800 K), and 1% at 2100 K). Around 2300 K, the NO concentration reaches a maximum; at higher temperatures the NO decomposition is faster than the NO formation. The nitric oxide formation has a radical mechanism, starting with the homolytic dissociation of dioxygen to form oxygen radicals.

$$O_2 \xrightleftharpoons{(M)} 2O\bullet \quad (153)$$

The chain reaction consists of oxygen radicals reacting with dinitrogen molecules to form NO and nitrogen radicals, which

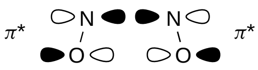


Figure 5 Bonding in the NO dimer

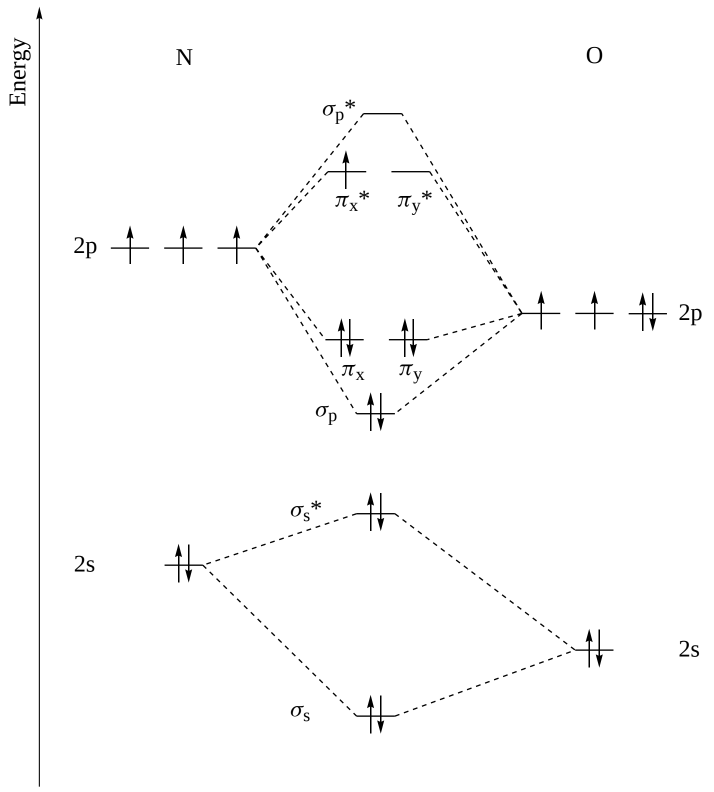


Scheme 22 MO scheme of nitric oxide

react with dioxygen to form NO and oxygen radicals.

$$\text{O}\bullet + \text{N}_2 \underset{}{\overset{(\text{M})}{\rightleftharpoons}} \text{NO}\bullet + \text{N}\bullet \quad (154)$$

$$\text{N}\bullet + \text{O}_2 \underset{}{\overset{(\text{M})}{\rightleftharpoons}} \text{NO}\bullet + \text{O}\bullet \quad (155)$$

The process stops on the combination of nitrogen and oxygen radicals.

$$\text{O}\bullet + \text{N}\bullet \underset{}{\overset{(\text{M})}{\rightleftharpoons}} 2\text{NO}\bullet \quad (156)$$

In former technical processes for the synthesis of nitric oxide, the reaction gases had to be rapidly cooled below 725 K. Slow cooling would give the equilibrium concentration of nitric oxide at the appropriate temperature. At temperatures lower than 725 K, nitric oxide is metastable and does not decompose to dinitrogen and dioxygen. Careful control of the reaction conditions can yield nitric oxide concentrations of about 3%. Nitric oxide is a side product in all combustion processes that employ air and has to be disposed off to avoid pollution of air and the detrimental effects of nitric oxide in the atmosphere (see Section 6). Owing to the preventive energy consumption, the process was only ever practiced in countries with cheap waterpower like Norway and Switzerland and has been completely replaced by the catalytic combustion of NH_3 in the Ostwald process (see Section 7.8.1).[5]

$$4\text{NH}_3 + 5\text{O}_2 \longrightarrow 4\text{NO} + 6\text{H}_2\text{O} \quad (157)$$

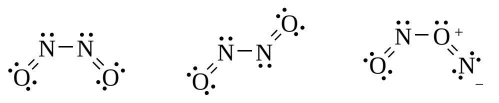
Nitric oxide can be obtained conveniently in the laboratory by the reduction of nitric acid with copper, mercury, or iron(II) salts.

$$\text{NO}_3^- + 4\text{H}^+ + 3e^- \rightleftharpoons \text{NO} + \text{H}_2\text{O} \quad (158)$$

A very pure nitric oxide is available from the reduction of acidic nitrite solutions with iodide or iron(II) salts.

$$\text{HNO}_2 + \text{H}^+ + e^- \longrightarrow \text{NO} + 2\text{H}_2\text{O} \quad (159)$$

Nitric oxide decomposes at temperatures higher than 725 K in the reverse of its formation (152) to dinitrogen and dioxygen.



(**58**) *cis* C_{2v} (**59**) *trans* C_{2h} (**60**)

Scheme 23 N_2O_2 isomers

Compressed, liquid, and nitric oxide included in zeolites decompose slowly in an exothermic process:

$$4NO \longrightarrow N_2O_3 + N_2O \tag{160}$$

At higher pressures and temperatures above 323 K it decomposes to:

$$3NO \longrightarrow NO_2 + N_2O \tag{161}$$

In the presence of air or dioxygen, nitric oxide is oxidized to the brown nitrogen dioxide ($\Delta H = 114.2\,\mathrm{kJ\,mol^{-1}}$).

$$NO + 0.5O_2 \longrightarrow NO_2 \tag{162}$$

The equilibrium of this exothermic reaction is shifted to the left side at higher temperatures. At temperatures higher than 925 K, almost all nitrogen dioxide has decomposed to nitric oxide and dioxygen. The mechanism of the oxidation of NO with dioxygen is assumed to have an ONOONO intermediate that isomerizes to the nitrite isomer of N_2O_4. It has not been proven whether a ONOO intermediate is formed in the first step.[86]

Nitric oxide forms nitrosyl halides in the reaction with chlorine and bromine (see Section 9.1); in the reaction with fluorine, both nitrosyl fluoride and trifluoramine oxide are formed (see Section 9.3).

$$NO + 0.5X_2 \longrightarrow XNO \quad X = Cl, Br \tag{163}$$

Strong oxidizing agents such as $KMnO_4$, HOCl, or K_2CrO_4 oxidize nitric oxide to nitrate (158) in acidic solution ($E° = 0.96\,\mathrm{V}$). Strong reducing agents reduce nitric oxide to dinitrogen or ammonia. Coal, phosphorus, and magnesium burn vigorously in nitric oxide atmosphere.

Nitric oxide, in contrast to nitrogen dioxide, does not react with water. It reacts with concentrated solutions of strong bases or with alkali metal oxides at 373 K to form nitrite and hyponitrite, which decomposes under these conditions forming N_2O and Na_2O.

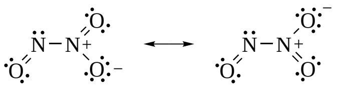
$$4NO + 2Na_2O \longrightarrow 2NaNO_2 + N_2O + Na_2O \tag{164}$$

In coordination compounds, NO is more electronegative than CO and a weaker σ-donor than CO, but a stronger π-acceptor. In mononuclear complexes, NO is found either in a linear geometry (**61**) (which can still have small deviations) or in an angular geometry (**61**). In the linear geometry, the NO ligand coordinates as NO^+ and is considered a three-electron donor. In the angular geometry, the NO ligand coordinates as NO^- and is considered a one-electron donor. Scheme 24 summarizes different modes of no coordination.

In multinuclear complexes, NO can act as a bridging ligand, bridging two (**63**) or three metal atoms (**64**). NO has one electron more than CO, therefore the atomic number of the metal centers of NO complexes are lower than in similar CO complexes (*see* ***Carbonyl Complexes of the Transition Metals***), for example, $Ni(CO)_4$, $Co(CO)_3NO$, $Fe(CO)_2(NO)_2$, $Mn(CO)(NO)_3$, and $Cr(NO)_4$. For more information on nitrosyl complexes, see Reference 87.

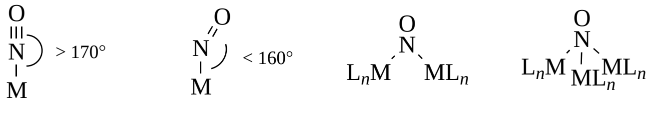
6.5 Dinitrogen Trioxide

Pure dinitrogen trioxide ($\Delta H_f = +86.6(1)\,\mathrm{kJ\,mol^{-1}}$) is a pale blue solid ($\rho = 1.781\,\mathrm{g\,cm^{-3}}$) that melts at 172.6 K to form an intensively blue liquid. N_2O_3 partially decomposes in the range of 233 K to 270 K. At 233 K, the vapor phase contains NO and N_2O_3, while the liquid phase contains N_2O_3 and the equilibrium mixture of NO_2 and N_2O_4. The liquid assumes a green hue due to the mixed colors of blue N_2O_3 and brown NO_2. At higher temperatures, NO_2 is also found in the vapor phase and at ambient temperatures N_2O_3 vapors only contain about 10% undissociated N_2O_3. Solutions of N_2O_3 in organic solvents also have a blue color.



(165)

Dinitrogen trioxide has a planar C_s structure.[88] The nitrogen–nitrogen bond in N_2O_3 of 186 pm in the gas phase and 189 pm in the solid state is significantly longer than the bond distances found for N–N single bonds, for example, in hydrazine. It corresponds to a Pauling bond order of 0.2. N_2O_3 can be described as nitrosyl nitrite $NO^+NO_2^-$. The N1–O1 distance is with 112 pm between the N–O distance of NO of 115 pm and NO^+ with 106.5 pm. The N–O bond length of 121 pm and the O–N–O bond angle of 129° of the NO_2 group are in good agreement with N_2O_4 (d(N–O) =



(**61**) (**62**) (**63**) (**64**)

$[Fe(CN)_5(NO)]^{2-}$ $[Co(NH_3)_5NO]^{2-}$ $\{cpCo\}_2NO$ $\{cp(NO)Mn\}_3NO$

Scheme 24 Coordination of NO in nitrosyl complexes

118 pm, <(O–N–O) = 134°) and NO_2^- (d(N−O) = 124 pm, <(O–N–O) = 115°). A comparison between solid-state and gas-phase bonding parameters is shown in Table 23.

A second isomer (**65**) of N_2O_3 shown in Figure 6 with the connectivity ONONO was detected in matrix-isolation experiments.

It is assumed to be an intermediate in the nitration of organic compounds in solution. After irradiation at 380 nm, it reverts to the $ONNO_2$ structure.

Nitric oxide and nitrogen dioxide form N_2O_3 upon cooling ($\Delta H = +40.6(1)$ kJ mol^{-1}).

$$NO\bullet + NO_2\bullet \rightleftharpoons N_2O_3 \quad (166)$$

Therefore, dinitrogen trioxide can be synthesized by adding an equimolar amount of NO to liquid NO_2 or by adding a stoichiometric amount of dioxygen to NO_2.[5]

$$2NO + 0.5O_2 \longrightarrow N_2O_3 \quad (167)$$

The equilibrium (166) is easily shifted to either side, therefore an equimolar mixture of NO and NO_2 has the same reactivity as N_2O_3, the anhydride of nitrous acid:

$$N_2O_3 + H_2O \rightleftharpoons 2HNO_2 \quad (168)$$

In basic solutions, NO and NO_2 are absorbed to form nitrites. N_2O_3, which is responsible for the nitrite formation, is formed according to the equilibrium (166).

$$NO + NO_2 + 2NaOH \longrightarrow 2NaNO_2 + H_2O \quad (169)$$

In strong acids, the nitrosyl cation NO^+ is formed from N_2O_3.

$$HONO + HClO_4 \longrightarrow NO^+ClO_4^- + H_2O \quad (170)$$

Table 23 Bonding parameters of N_2O_3

(**65**)

Figure 6 ONONO Isomer of N_2O_3

N_2O_3 is used as a powerful nitrosating agent in organic chemistry. It is also used for preparing high-purity alkali nitrites.

6.6 Nitrogen Dioxide and Dinitrogen Tetroxide

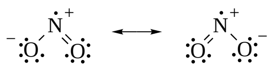
Nitrogen dioxide ($\Delta H_f = +34.2(5)$ kJ mol^{-1}) is a brown, paramagnetic, corrosive, and highly toxic gas with a characteristic pungent odor. Below the melting point of 262 K, it forms a brown liquid that loses its intensity upon cooling, until at 258 K a colorless solid is formed. The color change is due to the equilibrium of the NO_2 radical (brown) with its dimer N_2O_4 (colorless).

$$N_2O_4 \rightleftharpoons 2\bullet NO_2 \quad (171)$$

The dissociation enthalpy in the gas phase is 57.3(1) kJ mol^{-1}. Below the freezing point, only N_2O_4 exists. The pale yellow liquid at the freezing point contains 0.01% NO_2. At the boiling point, the liquid changes to an intense red–brown color with 0.1% NO_2, the vapor phase contains 20% NO_2. At 373 K, the vapor phase contains 90% NO_2 and at 413 K N_2O_4 is completely dissociated. At temperatures higher than 423 K, NO_2 starts to decompose ($\Delta H = +114.2$ kJ mol^{-1}), and decomposition is complete at 873 K.

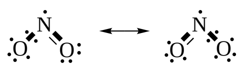
$$2NO_2 \longrightarrow 2NO + O_2 \quad (172)$$

Paramagnetic nitrogen dioxide is, like nitric oxide, a molecule with an odd number of electrons (*see* ***Electronic Structure of Main-group Compounds***) and has an angular structure (C_{2v}, d(N−O) = 119.5(3) pm (GED), 119.455(3) (MW); <(O−N−O) = 133.7(2)° (GED), 133.852(2) (MW)).[89] The repulsive interaction of lone pairs of electrons can be observed in the bond angles of NO_2^+, NO_2, and NO_2^-. NO_2^+, which has no lone electrons and has a linear structure; NO_2, which has one lone electron has a O–N–O angle of 133.7° and NO_2^-, which has a lone pair, has a O–N–O angle of 115.4°.



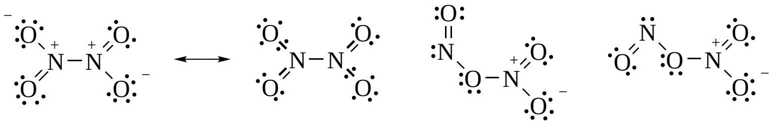
(173)

A better bonding description is given by the extended valecence bond structures:



(174)

Diamagnetic dinitrogen tetroxide ($\Delta H_f(g) = +11.1(1)$ kJ mol^{-1}) has a planar (D_{2h}) geometry (**66**). The activation energy for internal rotation is estimated to be 40 kJ mol^{-1}, the twisted isomer has been detected under nonequilibrium conditions. Table 24 shows a comparison of the bonding parameters of N_2O_4 in the solid state and in the gas phase.



(**66**) D_{2h} (**67**) *syn* (**68**) *anti*

				119.6(3)
				120.4(3)

N_2O_4 forms two phases in the solid state, a cubic and a monoclinic phase.[90] The monoclinic phase is only formed during crystallization from liquid N_2O_4 with small impurities and can transform to the standard cubic phase, whereas the cubic phase does not transform to the monoclinic phase The *syn* (**67**) and *anti* (**68**) nitrite isomers of N_2O_4 shown in Scheme 25 were identified in low-temperature matrices of N_2 and O_2.[91] The less stable of these forms converts to the ionic form of N_2O_4 and $NO^+NO_3^-$ upon warming. Self ionization of N_2O_4 has been implicated in the solution chemistry of N_2O_4, and occurs as a reversible phase transition at 2.5 GPa for solid N_2O_4, although the molecular form O_2NNO_2 is metastable to very high pressures when compressed as a single crystal.[92] Self oxidation of NO at 80 K also results in a red solid that is described as $NO^+NO_3^-$ on the basics of its IR spectrum. If N_2O is compressed to 10–30 GPa at temperatures of 1000–2000K, $NO^+NO_3^-$ is formed in the following reaction:

$$4N_2O \longrightarrow NO^+NO_3^- + 3N_2 \quad (175)$$

Once formed, $NO^+NO_3^-$ is stable below 180 K. At room temperature, it is stable with a pressure greater than 1.0 GPa. At higher temperatures/lower pressures, NO^+ NO_3^- transforms to molecular N_2O_4 (**66**).[93] Weak electron donor solvents can form complexes of the type D-N_2O_4 and strong electron donor solvents stabilize the ionic form of N_2O_4: $NO^+NO_3^-$. N_2O_4 dissolves in IF_5 with a yellow color, forming an adduct of the type $NO^+NO_3^-\cdot IF_5$.[94] An ONOONO isomer of N_2O_4 is assumed to be an intermediate in the oxidation of NO with dioxygen, and isomerizes to the nitrite isomers of N_2O_4, (**67**) and (**68**).

In nitrogen dioxide, one electron is in a $\pi*$ antibonding orbital like in nitric oxide. A bonding interaction between two dinitrogen oxide molecules with partly filled $\pi*$ antibonding orbitals leads to a six center three-electron interaction (see Figure 7), explaining the planar structure and the long N–N bond of 176 pm in dinitrogen tetroxide.

NO_2/N_2O_4 is produced industrially by the Ostwald process (see Section 7.8.1),[5] by the catalytic oxidation of ammonia to NO, and oxidation of NO with dioxygen.[5] Other commercial processes for producing NO_2/N_2O_4 are the oxidation of nitrosyl chloride yielding chlorine as by-product and the treatment of sodium nitrite with nitric acid followed by oxidation of the liberated nitrogen monoxide to nitrogen dioxide. High-purity NO_2/N_2O_4 is obtained in the production of sodium nitrate from sodium chloride and nitric acid. In the laboratory, NO_2 is accessible by the reduction of concentrated nitric acid with copper:

$$2NO_3^- + 4H^+ + Cu \longrightarrow 2NO_2 + Cu^{2+} + 2H_2O \quad (176)$$

Even more convenient is dry heating of heavy metal nitrates, especially lead(II)nitrate to 620–850 K:

$$Pb(NO_3)_2 \xrightarrow{>620\,K} PbO + 2NO_2 + 0.5O_2 \quad (177)$$

Dinitrogen oxide is a strong oxidizing agent ($E° = 1.03$ V) (see Scheme 26 and Scheme 27) with a similar oxidation potential to Br_2.

$$NO_2 + 2H^+ + 2e^- \rightleftharpoons NO + H_2O \quad (178)$$

Potassium, sulfur (*see* ***Sulfur–Nitrogen Compounds***), phosphorus (*see* ***Phosphorus–Nitrogen Compounds***), coal (*see* ***Carbon: Inorganic Chemistry***), and dihydrogen (*see* ***Hydrogen: Inorganic Chemistry***) burn in an NO_2 atmosphere more intensively than in an NO or N_2O atmosphere. NO_2 forms explosive mixtures with hydrogen; mixtures with ammonia

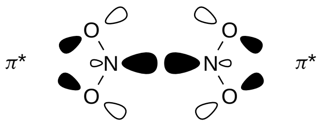

Figure 7 Bonding in dinitrogen tetroxide

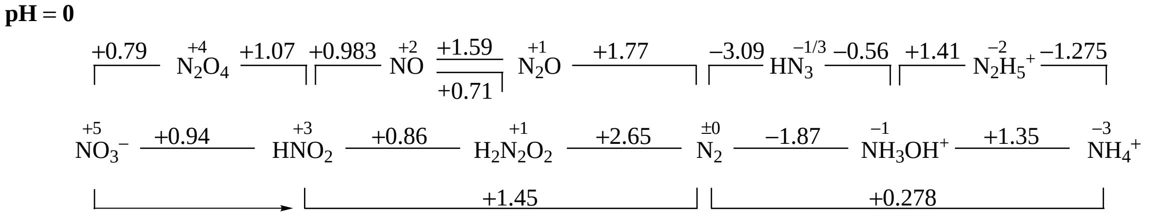
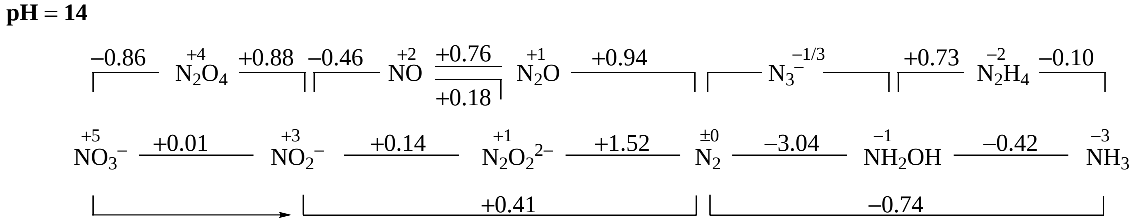


Scheme 26 Standard potentials for nitrogen compounds at pH = 0



Scheme 27 Standard potentials for nitrogen compounds at pH = 14

explode even at low temperature. It can also react explosively with organic compounds in a radical chain reaction with the first step:

$$\bullet NO_2 + RH \longrightarrow ONOH + R\bullet \quad (179)$$

NO_2 can also act as a reducing agent with powerful oxidizing agents like O_3 or H_2O_2.

$$NO_2 + H_2O \longrightarrow NO_3^- + 2H^+ + e^- \quad (180)$$

The reaction of NO_2 with fluorine or chlorine yields nitryl halides (see Section 9.2).

N_2O_4 is between the anhydride of nitrous acid, N_2O_3, and the anhydride of nitric acid, N_2O_5, and is the anhydride of both nitrous and nitric acid:

$$N_2O_4 + 2H_2O \longrightarrow HNO_2 + HNO_3 \quad (181)$$

In the reaction with bases, nitrates and nitrites are formed.

Liquid N_2O_4 can be used as a nonaqueous solvent.[95] The low electric conductivity $1.3 \times 10^{-13}\ \Omega^{-1}\ cm^{-1}$ indicates that autodissociation to nitrosonium and nitrate ions does not take place in liquid N_2O_4.

$$N_2O_4 \rightleftharpoons NO^+ + NO_3^- \quad (182)$$

Weak electron donor solvents can form complexes of the type D-N_2O_4 and strong electron–donor solvents stabilize the ionic form of N_2O_4:$NO^+NO_3^-$. N_2O_4 dissolves in IF_5 with a yellow color, forming an adduct of the type $NO^+NO_3^-\cdot IF_5$. It consists of double chains of alternating NO^+ and NO_3^- ions separated by layers of IF_5 molecules. Distillation of the IF_5 adduct returns covalent N_2O_4.

The nitrosonium cations in liquid N_2O_4 react as oxidizing agents, for example, for the oxidation of metals.

$$NO^+ + e^- \longrightarrow NO \quad (183)$$

Nitrosonium ions also react as Lewis bases with Lewis acids like halides or oxides.

$$NO^+ + X^- \longrightarrow XNO \quad (184)$$

$$ZnCl_2 + 2N_2O_4 \longrightarrow 2NOCl + Zn(NO_3)_2 \quad (185)$$

$$CaO + 2N_2O_4 \longrightarrow Ca(NO_3)_2 + N_2O_3 \quad (186)$$

The nitrate ions remaining from the dissociation of N_2O_4 react as Lewis bases with metal cations.

$$M^{n+} + nNO_3^- \longrightarrow M(NO_3)_n \quad (187)$$

Many metal salts dissolve in N_2O_4. Sn, Cu, and Zn dissolve in N_2O_4 to form the metal dinitrates.

$$M + 2N_2O_4 \longrightarrow M(NO_3)_2 + 2NO \quad (188)$$

These reactions are a convenient preparation of anhydrous nitrates, especially if the metal bromides or iodides are dissolved in N_2O_4.

$$TiI_4 + 4N_2O_4 \longrightarrow Ti(NO_3)_4 + 4NO + 2I_2 \quad (189)$$

Often nitrato complexes with nitrosonium cations $(NO^+)_m$ $M(NO_3)_n{}^{(n-m)-}$ are formed.

$$Zn(NO_3)_2 + 2N_2O_4 \longrightarrow (NO)^+{}_2[Zn(NO_3)_4]^{2-} \quad (190)$$

Another example is the intriguing $[(NO^+)_3NO^-]^+$ $[Fe(NO_3)_4]_2^-$. Here the cation consists of a nitrate anion surrounded by three NO^+ cations.

N_2O_4 is a donor for nitronium and nitrite ions:

$$N_2O_4 \rightleftharpoons NO_2^+ + NO_2^- \quad (191)$$

An example is the reaction with BF_3, where NO_2^+ $[NO_2^- \cdot BF_3]^-$ is formed.

$$BF_3 + N_2O_4 \longrightarrow NO_2^+[NO_2 \cdot BF_3]^- \quad (192)$$

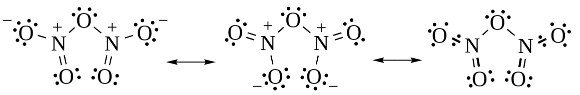
The strong oxidizing agent dinitrogen tetroxide is used for many applications. It is employed as a catalyst in oxidation reactions and as an inhibitor in the distillation of acrylates. It is also used in the manufacture of explosives and as bleach. In rocket propellants, it is used in a hypergolic mixture with hydrazine derivatives.[51] The command module of the Apollo mission used a 1:1 mixture of hydrazine and *N,N′*-dimethylhydrazine with N_2O_4 as the oxidant.

6.7 Dinitrogen Pentoxide

Dinitrogen pentoxide ($\Delta H_f = -43.1\,kJ\,mol^{-1}$) is a colorless, light, and heat sensitive solid that is deliquescent in air and sublimes at 305.5 K. It melts under pressure at 314 K and decomposes at room temperature. The decomposition is sometimes explosive, especially at higher temperatures.

$$N_2O_5 \longrightarrow 2NO_2 + 0.5O_2 \quad (193)$$

In the gas phase and in unpolar solvents like CCl_4, N_2O_5 consists of two NO_2 groups linked by a bridging oxygen atom with a nonlinear N–O–N group.[96] The equilibrium structure has a torsion angle of 30° (C_2); the rotation along the N–O single bonds has an activation barrier of about $4-8\,kJ\,mol^{-1}$.



(194)

In the solid state, ($\rho(78\,K) = 2.175\,g\,cm^{-3}$; $\rho(288\,K) = 2.05\,g\,cm^{-3}$) and when dissolved in strong acids like nitric acid, N_2O_5 has an ionic nitronium nitrate $NO_2^+NO_3^-$ structure. When gaseous N_2O_5 is rapidly cooled below 80 K, the molecular structure is conserved. Upon reheating to 200 K, the ionic structure is formed. Table 25 shows a comparison of the bonding parameters of N_2O_5 in the solid state and in the gas phase.

In the gas phase, N_2O_5 dissociates ($\Delta H = 95.6(1.5)\,kJ\,mol^{-1}$) to nitrogen dioxide and nitrogen trioxide, which can decompose further according to (202) and (203). This makes N_2O_5 an important nighttime reservoir in atmospheric chemistry for the reactive $NO_2\bullet$ and $NO_3\bullet$ species.[97]

Table 25 Bonding parameters of N_2O_5

	X-ray	GED
d(N–O) [pm]	123.4	1.505(4) 1.495(4)
d(N=O) [pm]	115.4	1.188(1) 1.188(2)
<(N–O–N) [°]	–	112(2) 112(2)
<(N–O=N) [°]	–	134.2(4) 133.2(6)

$$N_2O_5 \rightleftharpoons NO_3\bullet + NO_2\bullet \quad (195)$$

Dinitrogen pentoxide is the anhydride of nitric acid, and was industrially prepared by the careful dehydration of nitric acid with phosphorus pentoxide.

$$6HNO_3 + P_2O_5 \xrightarrow{263\,K} 3N_2O_5 + 2H_3PO_4 \quad (196)$$

A newer synthesis produces 10–20% solutions of N_2O_5 in nitric acid by electrolysis of nitric acid in the presence of N_2O_4.

$$2HNO_3 + 2e^- \xrightarrow{N_2O_4} N_2O_5 + H_2O \quad (197)$$

Pure and almost acid free N_2O_5 is obtained from the oxidation of dinitrogen tetroxide with ozone.

$$N_2O_4 + O_3 \longrightarrow N_2O_5 + O_2 \quad (198)$$

N_2O_5 is a strong oxidant and reacts violently with many types of reductants, including metals, nonmetals, and numerous organic compounds.

$$N_2O_5 + I_2 \longrightarrow I_2O_5 + N_2 \quad (199)$$

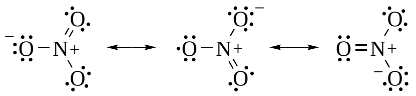
The dissociation to $NO_2^+NO_3^-$ in strong acids is a convenient pathway to nitronium salts like $(NO_2^+)_2S_2O_7^{2-}$ from the reaction with SO_3 or $NO_2^+FSO_3^-$.

Dinitrogen pentoxide forms an adduct $N_2O_5 \cdot BF_3$ (NO_2^+ $(BF_3 \cdot ONO_2^-)$) with boron trifluoride, which is a good nitrating reagent. The reaction of N_2O_5 with halogens X_2 (X = F, Cl) forms nitryl halides XNO_2.

N_2O_5 is slowly replacing nitrating acid ($HNO_3 + 2H_2SO_4$) in some applications, because nitration with pure nitrogen pentoxide is acid free and can take place in an anhydrous solvent. For nitration, a dilute solution of N_2O_5 in chlorinated organic solvents like CH_2Cl_2 is used.

6.8 Nitrogen Trioxide

NO_2 and excess dioxygen form nitrogen trioxide ($\Delta H_f = 74(1)\,\text{kJ mol}^{-1}$) in a glow discharge.



(200)

The nitrogen trioxide radical has a D_{3h} structure (d(N–O) = 120.4 pm). The spin density of nitrogen is zero for symmetrical reasons and the unpaired electron is located at the oxygen atoms.

The reaction of NO_2 and N_2O_5 with ozone as well as the decomposition of N_2O_5 yields NO_3. $NO_3{\bullet}$ decomposes according to two dissociation channels:

$$NO_3{\bullet} \longrightarrow NO_2{\bullet} + O{\bullet} \quad (201)$$

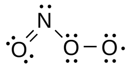
$$NO_3{\bullet} \longrightarrow NO{\bullet} + O_2 \quad (202)$$

The mechanism for the formation of nitric oxide (202) is still unclear.

The formation of an intermediate ONOO (**69**) species in Figure 8 has been claimed in a spectroscopic study but was later questioned due to multireference calculations.[98] NO_3 reacts with NO_2 to form dinitrogen pentoxide.[97]

$$NO_3{\bullet} + NO_2{\bullet} \rightleftharpoons N_2O_5 \quad (203)$$

N_2O_5 acts as a reservoir species in atmospheric chemistry making NO_3, formed by the dissociation of N_2O_5, the major nighttime oxidant in the stratosphere.



(**69**)

Figure 8 ONOO isomer of NO_3

A mass spectrometric investigation of $NO_2/O_3/O_2$ mixtures with chemical ionization has identified the NO_5^+ cation from the reaction of NO_2^+ with ozone.[99] The decomposition products NO_4^+ and NO_3^+ indicate an O_nNO_2 connectivity of NO_5^+ and its decomposition products.

Mixtures of $NO/O_3/O_2$ also produce NO_4^+ ions under the conditions described above, but their decomposition products indicate an O_3NO connectivity. Three isomeric NO_3^+ cations have been detected in the mixtures described above under different conditions: one has O_2NO connectivity and two share $O{-}NO_2$ connectivity, but with different structures. One NO_3^+ cation has a trigonal structure like the radical $NO_3{\bullet}$, the other corresponds to a weakly bound species that undergoes a near threshold decomposition and is assumed to have ONOO connectivity. Neutralisation-reionization mass spectrometry of this NO_3^+ isomer shows weak evidence for a neutral ONOO isomer (**69**) with a lifetime exceeding 1 µs.

7 OXOACIDS OF NITROGEN

The strength of the nitrogen oxoacids given in Table 26 increases with higher oxidation numbers of nitrogen. While hydroxylamine is only a very weak acid, nitrous acid is an acid of medium strength and nitric acid is a very strong acid. The anions of orthonitric acid HNO_4 and oxohyponitric acid $H_2N_2O_3$ are known, but the free acids have not yet been observed. HNO and HNOO are not stable at standard conditions and are metastable at lower temperatures. Salts with the formula M_3NO_3, formally salts of orthonitrous acid H_3NO_3, are obtained from the reaction of equimolar amounts of alkali metal nitrites with alkali metal oxides M_2O.[100]

$$MNO_2 + M_2O \longrightarrow M_3NO_3 \quad (204)$$

Yellow Na_3NO_3, red K_3NO_3, and red-brown Rb_3NO_3 do not contain the orthonitrite anion NO_3^{3-}, but are mixed crystals of the salts MNO_2 and M_2O with an anti-perovskite $(NO_2)OM_3$

Table 26 Oxoacids of nitrogen in different oxidation states

Oxidation state	Formula	Name	Salt
−1	H_2NOH	hydroxylamine	hydroxylamide
0	HNOO	imine peroxide	–
+1	HNO	nitrosyl hydride (nitroxyl)	nitroxyl anion
	HONNOH	hyponitrous acid	hyponitrite
+2	$H_2N_2O_3$	oxohyponitric acid, only salts	hyponitrate, trixodinitrate
+3	HNO_2	nitrous acid	nitrite
	HONOO	peroxonitrous acid	peroxonitrite
+5	HNO_3	nitric acid	nitrate
	H_3NO_4	orthonitric acid, only salts	orthonitrate
	HNO_4	peroxonitric acid	peroxonitrate
–	H_2NNO	nitrosamine	–
–	H_2NNO_2	nitramide	–
–	$HN(NO_2)_2$	dinitramic acid	dinitramide

structure.[101] The trialkoxyamines $(RO)_3N$, organic derivatives of orthonitric acid, are also unstable species.

Reduction of a solution of sodium nitrite in ammonia with sodium produces a deep yellow solid with the formula Na_2NO_2, sodium nitroxylate.

$$2NaNO_2 + 2Na \longrightarrow 2Na_2NO_2 \quad (205)$$

The compound has only a small paramagnetic susceptibility. The unexpected low paramagnetic susceptibility suggests that the compound dimerizes to $Na_4N_2O_4$, and is dissociated to about 20% to Na_2NO_2 at room temperature. The structure of this salt is unknown.[102]

The oxidation potentials of nitrogen compounds in different oxidation states are shown in Scheme 26 and Scheme 27. The oxidants are stronger in acidic solution and the reductants are stronger in basic solution. The strongest oxidants are hyponitrous acid $H_2N_2O_2$ and HNO_3, the strongest reductants NH_2OH and $N_2O_2{}^{2-}$. It follows that dinitrogen N_2 cannot disproportionate to compounds with any oxidation state. Nitrogen fixation is not possible this way. On the other hand, depending on the pH of the medium, hydroxylamine can disproportionate to form ammonia and dinitrogen, and hyponitrous acid can disproportionate to form nitrous acid and dinitrogen. Nitrous acid can disproportionate to form nitric acid and dinitrogen.

7.1 Hydroxylamine

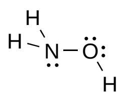
Hydroxylamine crystallizes as colorless needles ($\Delta H_f^\circ = -114\,\mathrm{kJ\,mol^{-1}}$), which melt at 305 K. The boiling point of liquid hydroxylamine is 329.5 K at 22 HPa and the density is $1.204\,\mathrm{g\,cm^{-1}}$ at 306 K. The N–O bond distance is 146 pm in the gas phase and 147 pm in the solid state. Other gas-phase bonding parameters include: d(O–H) = 96 pm, d(N–H) = 101 pm, <(H–O–N) = 103°, <(H–N–O) = 105°, <(H–N–H) = 107°. In the solid state (Figure 9), hydrogen bonds connect hydroxylamine molecules with a *trans* conformation (**70**). The NH···O distance is 274 pm.

Hydroxylamine can disproportionate to form ammonia and dinitrogen or dinitrogen oxide:

$$3NH_2OH \longrightarrow NH_3 + N_2 + 3H_2O \quad (206)$$

$$4NH_2OH \longrightarrow 2NH_3 + N_2O + 3H_2O \quad (207)$$

Pure hydroxylamine or its aqueous solutions can be stored for several weeks in the absence of oxygen at low temperatures.



(**70**)

Figure 9 Structure of hydroxylamine molecules in the solid state

The decomposition rate increases with increasing pH. In the presence of oxygen, for example, in air, pure hydroxylamine or its aqueous solution decompose rapidly, especially at slightly elevated temperatures. At temperatures above 373 K, hydroxylamine decomposes explosively. Autoxidation takes place in basic solutions in the presence of transition metals and dioxygen. Hydroxylamine is oxidized to nitrite via nitrosyl and peroxonitrite ions.

$$NH_2O^- + O_2 \longrightarrow H_2O_2 + NO^- \quad (208)$$

$$NO^- + O_2 \longrightarrow ONOO^- \quad (209)$$

$$ONOO^- + NH_2O^- \xrightarrow{[Cu^{2+}]} NO_2{}^- + NO^- + H_2O \quad (210)$$

7.1.1 *Production of Hydroxylamine*

Hydroxylamine is prepared by reducing nitrogen oxides in higher oxidation states, for example, nitric oxide, nitrous acid, or nitric acid.[5]

For reduction of nitric oxide, a mixture of nitric oxide and dihydrogen is passed through a suspension of a platinum (BASF process) or palladium in sulfuric acid. Ammonium sulfate and dinitrogen oxide are by-products.

$$2NO + 3H_2 + H_2SO_4 \longrightarrow (NH_3OH)_2SO_4 \quad (211)$$

Nitrous acid can be reduced to hydroxylamine with sulfurous acid:

$$HNO_2 + 2H_2SO_3 + H_2O \longrightarrow NH_2OH + 2H_2SO_4 \quad (212)$$

In the Raschig process, ammonium nitrite is converted to ammonium hydroxylamine disulfonate with sulfur dioxide in sulfuric acid at 273 K:

$$2SO_2 + NH_4NO_2 + NH_3 + H_2O \longrightarrow (NH_4)_2[HO\text{–}N(OSO_2)_2] \quad (213)$$

The sulfonate is then hydrolyzed at 373 K to form hydroxylammonium sulfate and ammonium sulfate.

A phosphoric acid/ammonium nitrate buffer solution with a suspended noble metal catalyst can be reduced with hydrogen to hydroxylammonium dihydrogenphosphate:

$$NH_4NO_3 + 2H_3PO_4 + 3H_2 \longrightarrow [NH_3OH]^+[H_2PO_4]^- + NH_4H_2PO_4 + 2H_2O \quad (214)$$

The hydroxylammonium solution is then directly used for oxime formation and the consumed nitrate ions are replaced by addition of nitric acid.

Nitric acid can also be reduced between lead electrodes in the presence of hydrochloric or sulfuric acid:

$$HNO_3 + 6H^+ + 6e^- \longrightarrow NH_2OH + 2H_2O \quad (215)$$

The acidic cleavage of nitroalkanes has only found limited use due to its cost and the limited availability of the raw materials.

$$2RCH_2NO_2 \xrightarrow[H_2SO_4]{H_2O} (NH_3OH)_2SO_4 + 2RCOOH \qquad (216)$$

7.1.2 *Anhydrous Hydroxylamine*

All hydroxylamine syntheses yield hydroxylammonium salts. Free hydroxylamine can be prepared by adding a strong base to the hydroxylammonium salts. Sodium methanolate $NaOCH_3$ can be used for this purpose:

$$NH_3OH^+X^- + NaOCH_3 \longrightarrow NH_2OH + NaX + CH_3OH \qquad (217)$$

After the reaction, the solid sodium salt is filtered off and methanol is distilled off under reduced pressure. Hydroxylamine can also be prepared by the ammonolysis of hydroxylammonium salts in liquid ammonia. The ammonium salt precipitates and is filtered off. Hydroxylamine is obtained after evaporating the excess ammonia.

7.1.3 *Chemical Properties of Hydroxylamine*

As a hydroxyderivative of ammonia, hydroxylamine is a weak base ($pK_b = 8.2$) and forms hydroxylammonium salts with acids:

$$NH_2OH + HX \longrightarrow NH_3OH^+X^- \qquad (218)$$

In contrast to free NH_2OH, the hydroxylammonium salts are relatively stable. Dry hydroxylammonium salts disproportionate upon heating to form the ammonium salts and dinitrogen.[4]

The hydroxylammonium salts ($pK_a = 5.8$) are more acidic in aqueous solution than the ammonium salts ($pK_a = 9.25$) because NH_2OH is less basic than NH_3. NH_2OH is a weak acid ($pK_a = 13.7$), only slightly more acidic than water. The hydroxylamides NH_2O^-, of which the sodium, calcium, and zinc salts are known, are very unstable and explosive.

Like ammonia, hydroxylamine can form complexes in basic solution (*see* ***Ammonia & N-donor Ligands***), coordinating via the nitrogen atom as in (**71**) in Scheme 28. Complexes of the deprotonated hydroxylamides show N,O coordination as in (**72**). Both coordination modes are found in $[UO_2(ONH_2)(HONH_2)]$.

(**71**) (**72**)

$[Ni(NH_2OH)_6]^{2+}$ $Mo(N_3)_4(NO)(NH_2O)$

Scheme 28 Coordination of hydroxylamine and the hydroxylamide ion in complexes

Hydroxylamine ($E° = 1.87$ V) is a strong reducing agent (see Scheme 26 and Scheme 27).

$$2NH_3OH^+ \longrightarrow N_2 + 2H_2O + 4H^+ + 2e^- \qquad (219)$$

N_2 and N_2O are the products of the oxidation of hydroxylamine. With an excess of oxidizing agent, NO, NO_2^-, NO_2, as well as NO_3^- are formed. Hydroxylamine reacts as an oxidant with reducing agents ($E° = 1.35$ V).

$$NH_3OH^+ + 2H^+ + 2e^- \longrightarrow NH_4^+ + H_2O \qquad (220)$$

One-electron oxidants like Ce^{4+}, Mn^{3+}, Fe^{3+}, Co^{3+}, Cu^{2+}, Ag^+, or Ag^{2+} generate the intermediate radical •NHOH that can react with Ce^{4+}, Mn^{3+}, or Cu^{2+} to form HNO:

$$NHOH\bullet \longrightarrow HNO + H^+ + e^- \qquad (221)$$

which in turn forms N_2O

$$2HNO \longrightarrow N_2O + H_2O \qquad (222)$$

or decomposes directly to form dinitrogen (with Co^{3+}, $Fe(CN)_6^{4-}$).

$$2NHOH\bullet \longrightarrow HONHNHOH \longrightarrow N_2 + 2H_2O \qquad (223)$$

Two-electron oxidants such as CrO_4^{2-}, MnO_4^-, or ClO^- produce N_2O via HNO.

Sn(II), V(II), or Cr(II) salts can reduce hydroxylamine to ammonia, here the amino radical $NH_2\bullet$ is an intermediate.

$$NH_2OH + e^- \longrightarrow NH_2\bullet + OH^- \qquad (224)$$

$$NH_2\bullet + H^+ + e^- \longrightarrow NH_3 \qquad (225)$$

Reaction of hydroxylamine with ketones or aldehydes yields oximes, aldoximes RHC=NOH, or ketoximes R_2C=NOH. Almost all the hydroxylamine production (95%) is used for the production of either cyclohexanone oxime or caprolactam, both of which are intermediates for polyamide synthetics. The remainder of the hydroxylamine production is used as an anticreaming agent in paints and coatings, as an auxiliary in refining fats for soap production, as a regulator or inhibitor for various polymerizations, as a stabilizer for developers, and as an additive for color emulsions. Oximes are also used as pharmaceuticals or in crop protection.

7.2 Nitrosyl Hydride (Nitroxyl)

The reaction of atomic hydrogen with NO at 77 K yields a pale yellow substance with the composition HNO that

condenses on the walls of the reaction vessel ($\Delta H_f = +107\,\text{kJ mol}^{-1}$). At 178 K, it decomposes to form hyponitrous acid $H_2N_2O_2$ (80%) and dinitrogen oxide (20%). HNO is also a reactive intermediate of the oxidation of hydroxylamine NH_2OH and the reduction of nitrous acid HNO_2. It dimerizes to hyponitrous acid $H_2N_2O_2$. HNO is also formed during the decomposition of Angeli's salt $Na_2N_2O_3$:

$$N_2O_3^{2-} + H^+ \longrightarrow HNO + NO_2^- \quad (226)$$

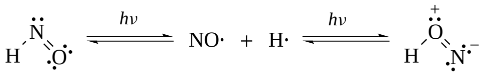
The weak acid HNO (p$K_a = 11.4$) has a singlet ground state (X $^1A'$).[103] The nitroxyl anion NO^- has a triplet ground state (X $^3\Sigma^-$), therefore the dissociation of HNO to NO^- and H^+ is spin forbidden and inherently slow. In physiological systems, HNO is the dominant form, but NO^-, once formed, has sufficient lifetime to react with other species. HNO is like NO a transient intermediate in physiological systems.

$$HNO \rightleftharpoons H^+ + NO^- \quad (227)$$

The nitroxyl anion dimerizes to form hyponitrite:

$$2NO^- \longrightarrow N_2O_2^{2-} \quad (228)$$

The isomer HON was detected in matrix isolation and is in a photoequilibrium with HNO.[104]



(229)

Reaction of the nitroxyl anion NO^- with dioxygen O_2 forms peroxonitrite, which isomerizes in acidic solution to nitrate.

$$NO^- + O_2 \longrightarrow OONO^- \quad (230)$$

The presence of HNO as an intermediate in this reaction can be verified with the violet complex $[Ni(CN)_3NO]^{2-}$:

$$Ni(CN)_4^{2-} + NO^- \longrightarrow [Ni(CN)_3NO]_2^- + CN^- \quad (231)$$

In HNO complexes, the HNO molecule (d(N=O) 120 pm, <(H–N–O) 99°) is bonded via nitrogen and has a bent conformation.

7.3 Imine Peroxide

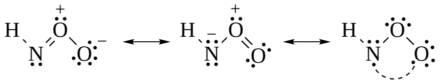
The reaction of ground-state nitrene NH(X $^3\Sigma^-$) with molecular oxygen in argon or xenon matrices at temperatures of 20 K yields imine peroxide:[105]

$$NH(X^3\Sigma^-) + O_2(X^3\Sigma_g^-) \longrightarrow HNOO(X^1A) \quad (232)$$

It is also formed in the photodissociation of matrix-isolated methyl nitrate that yields either HNO_2 (hydrogen nitryl) or imine peroxide HNOO.[106]

$$H_3CNO_2 \longrightarrow H_2CO + HNO_2$$
$$H_3CNO_2 \longrightarrow H_2CO + HNOO \quad (233)$$

Theoretical calculations suggest that HNOO has a singlet electronic ground state with considerable diradical character, similar to ozone. HNOO is, therefore, a member of the group of 1,3-dipole molecules whose electronic structure has been described as a resonance of the zwitterionic versus the radical structure.



(234)

A *cis* and a *trans* form are possible for HNOO. However, only one form, probably the *trans* form, was detected in the matrix-isolation experiments. Imine peroxide isomerizes to nitrous acid upon irradiation with UV or IR light.

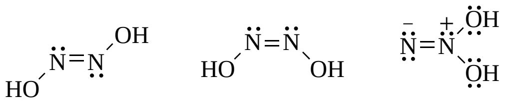
7.4 Hyponitrous Acid

The hydroxygroups of hyponitrous acid are found in a *trans* (**73**) and a *cis* (**74**) conformation (Scheme 29). The nitridonitrate isomer (**75**) is only known in form of its tautomer, nitramide.

While *trans*-hyponitrous acid has been known for a long time, only salts of *cis*-hyponitrous acid are stable. The isolated $N_2O_2^{2-}$ dianion, which was insulated from stabilizing cations in solid argon, has been observed with matrix-isolation techniques and is one of the smallest known dianions that is stable toward electron loss.[107]

7.4.1 *trans-Hyponitrous Acid*

trans-Hyponitrous acid forms colorless rods, which are very sensitive when dry and decompose violently.[108] A comparison of the bonding parameters of several $N_2O_2^{2-}$ compounds is given in Table 27.



(**73**) *trans* C_{2h} (**74**) *cis* C_{2v} (**75**) C_{2v}

Scheme 29 Isomers of hyponitrous acid

Table 27 Structural data of $N_2O_2^{2-}$ compounds

	trans-$H_2N_2O_2^{a}$	*trans*-$HN_2O_2^{-a}$	*trans*-$N_2O_2^{2b}$	*cis*-$N_2O_2^{2-c}$
d(N=N) [pm]	122.6(4)	123.2(3)	1.233(2)	120(3)
d(N–O) [pm]	136.3(3)	NOH 140.2(3) NO 137.1(3)	1.389(1)	140(1)
<(N–N–O) [°]	109.0(3)	NNOH 110.1(2) NNO 108.2(2)	107.6(1)	120.8(4)

[a][$HEt_2NCH_2CH_2NEt_2H$][HN_2O_2]$_2$·$H_2N_2O_2$; [b][2,2′-bipyridinium][N_2O_2]; [c]*cis*-$Na_2N_2O_2$.

trans-$H_2N_2O_2$ is obtained by reducing nitrous acid with sodium amalgam at 273 K:

$$2NaNO_2 + 4Na/Hg \longrightarrow trans\ Na_2N_2O_2 + 2Na_2O + 4Hg \quad (235)$$

After the reaction is finished, the insoluble silver hyponitrite $Ag_2N_2O_2$ is precipitated with $AgNO_3$. $H_2N_2O_2$ is accessible by treating the silver salt with a solution of HCl gas in diethyl ether, or by oxidation of hydroxylamine with copper, silver, or mercury oxide.

Aqueous solutions of *trans*-hyponitrous acid are acidic ($pK_1 = 7.21$, $pK_2 = 11.54$) and decompose slowly, faster at higher temperatures, via $HO–N=N–O^-$ to form water and dinitrogen oxide ($t_{1/2}$ (298 K) = 16 days at pH = 1–3, at higher pH values *trans*-$H_2N_2O_2$ is unstable).

$$H_2N_2O_2 \longrightarrow N_2O + H_2O \quad (236)$$

This reaction is not reversible, and dissolving of N_2O in water does not give hyponitrous acid. As a dibasic acid, *trans*-hyponitrous acid forms two types of salts: acidic hyponitrites $M^+\ HN_2O_2^-$ that decompose readily and are more stable, and neutral hyponitrites $M_2{}^+N_2O_2^{2-}$. Both types of salts react basic, are reductants, and are remarkably stable against reduction.

Reaction of iodine with *trans*-hyponitrous acid yields nitrous acid and nitric acid:

$$trans\ H_2N_2O_2 + 3I_2 + 3H_2O \longrightarrow HNO_3 + HNO_2 + 6HI \quad (237)$$

Nitrous acid reduces *trans*-hyponitrous acid to dinitrogen:

$$trans\ H_2N_2O_2 + HNO_2 \longrightarrow N_2 + HNO_3 + H_2O \quad (238)$$

Liquid N_2O_4 oxidizes *trans*-hyponitrous acid stepwise: $N_2O_2^{2-} \rightarrow N_2O_3^{2-} \rightarrow N_2O_4^{2-} \rightarrow N_2O_5^{2-} \rightarrow N_2O_6^{2-}$.

7.4.2 cis-Hyponitrites

Disodium *cis*-hyponitrite can be obtained by passing NO through a solution of sodium in liquid ammonia:

$$2NO + 2Na \xrightarrow{NH_3(l)} cis\text{-}Na_2N_2O_2 \quad (239)$$

Reaction of disodium oxide and dinitrogen oxide at 633 K also yields disodium *cis*-hyponitrite.[109]

$$N_2O + Na_2O \xrightarrow{633\,K} cis\text{-}Na_2N_2O_2 \quad (240)$$

Disodium *cis*-hyponitrite is very sensitive to moisture and CO_2.

$$cis\text{-}Na_2N_2O_2 + H_2O \longrightarrow N_2O + 2NaOH \quad (241)$$

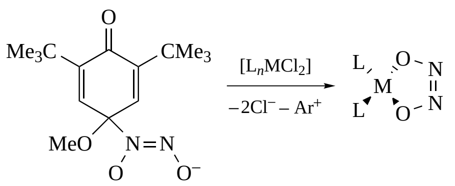
$$cis\text{-}Na_2N_2O_2 + CO_2 \longrightarrow N_2O + Na_2CO_3 \quad (242)$$

Thermal decomposition of *cis*-$Na_2N_2O_2$ leads to sodium orthonitrite.

$$3cis\text{-}Na_2N_2O_2 \longrightarrow 2NaNO_2 + 2N_2 + 2Na_2O \quad (243)$$

$$NaNO_2 + Na_2O \longrightarrow Na_3NO_3 \quad (244)$$

cis-Hyponitrite is found in transition metal complexes as a chelating ligand in the yellow $(PH_3)_2Pt(N_2O_2)$ with a PtO_2N_2 five-membered ring and as a bridging ligand that is coordinated via one nitrogen atom and one oxygen atom in red $[(H_3N)_5Co(N_2O_2)Co(NH_3)_5]^{4+}$. The reaction of diazenium diolates with metal chlorides can be used for the synthesis of chelating *cis*-hyponitrite complexes.[110]



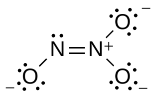
(245)

7.5 Oxohyponitrous Acid

Oxohyponitrous acid is not known. The trioxodinitrate anion (**76**) in Figure 10 is planar (d(N1–O1) 131.0(4) pm, d(N2–O2/3) 132.2(4) pm, d(N–N) 126.4(5) pm, <(O2–N2–O3) 119.1(5)°, <(O1–N–N) 118.4(3)°).

It is relatively stable in very basic solutions and forms insoluble precipitates with alkaline earth, lead, and cadmium dications. Dioxygen oxidizes the trioxodinitrate anion.

The monoanion $HN_2O_3^-$ is found in mildly basic to mildly acidic solution and is very sensitive toward oxidation by



(**76**)

Figure 10 Structure of the trioxodinitrate dianion

dioxygen. It is unstable and decomposes via HNO to form N_2O and nitrite:[111]

$$HN_2O_3^- \rightleftharpoons HNO + NO_2^- \quad (246)$$

$$2HNO \longrightarrow N_2O + H_2O \quad (247)$$

The proton of $HN_2O_3^-$ is bound to a nitrogen atom according to O_2N–NH–O^-. Addition of nitrite to an aqueous solution of $HN_2O_3^-$ shifts the dissociation equilibrium (246) to the left side and stabilizes the protonated anion.

Oxohyponitrous acid, an acid of medium strength ($pK_1 = 2.4$, $pK_2 = 9.4$), is unstable like the $HN_2O_3^-$ anion. The same is true for very acidic solutions of $N_2O_3^{2-}$. The decomposition of the free acid is catalyzed by nitrite ions, traces of which are initially formed during decomposition of $HN_2O_3^-$.

$$H_2N_2O_3 \xrightarrow{[NO_2^-]} 2NO + H_2O \quad (248)$$

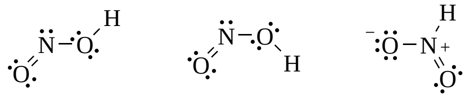
This reaction is not reversible, therefore, NO is not the anhydride of oxohyponitrous acid.

The disodium salt of oxohyponitrous acid, Angeli's salt, is formed by the nitration of hydroxylamine $HONH_2$ with alkylnitrates RNO_3 in methanol with sodium methanolate at 273 K.

$$O_2N\text{–}OR + H_2N\text{–}OH \xrightarrow[-HOR]{} (O_2N\text{–}NH\text{–}OH) \xrightarrow[-2CH_3OH]{+2CH_3ONa} (Na^+)_2N_2O_3^{2-} \quad (249)$$

7.6 Nitrous Acid

Planar nitrous acid forms two isomers (Scheme 30). The *trans* form (**77**) ($\Delta H_f = -80.18\,kJ\,mol^{-1}$, d(N=O) 117.7 pm,

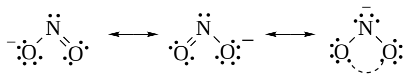


(**77**) *trans*, C_s (**78**) *cis*, C_s (**79**) C_{2v}

Scheme 30 Isomers of nitrous acid

d(N–O) 143.3 pm, d(O–H) 95.4 pm), <(O–N–O) 110.7°, d(N–O–H) 102.1° is more stable than the *cis* isomer (**78**) ($\Delta H_f = -78.04\,kJ\,mol^{-1}$) in the gas phase and is the only one observed in the gas phase.[4] Another tautomeric form, the C_{2v} structure (**79**), was detected as an intermediate in the photodissociation of nitric acid in noble gas matrices. Organic derivatives of both forms play important roles in industrial chemistry. Organic derivatives R–NO_2 of the C_{2v} structure (**79**) are called nitro compounds; derivatives ONOR of the C_s structures (**77**) and (**78**) are called nitrite esters. Nitro complexes (**80**) that contain the –NO_2 ligand (e.g. $K_3[Co(NO_2)_6]$) are more stable than nitrito complexes (**81**) with the –ONO ligand. Because nitrito complexes are usually less dense, nitro and nitrito complexes can be transformed into each other. The red nitro complex $[Ni(en)_2(NO_2)_2]$ is converted to the violet nitrito complex $[Ni(en)_2(ONO)_2]$ on raising the temperature from room temperature to 400 K. Application of 2 MPa pressure at 400 K reverses the change. An in plane rotation of the nitro group is responsible for theses changes. The nitrite ion also shows chelating (**82**) ($[Cu(ONO)(2,2'\text{-bipy})_2]NO_3$), unsymmetrical bridging (**83**) ($[Ni(en)_2NO_2]^+$), and η^1 bridging (**84**) coordination ($\{Cu(2,2'\text{-dipyridylamine})NO_2\}_2(\mu^1NO_2)_2$) (see Scheme 31).

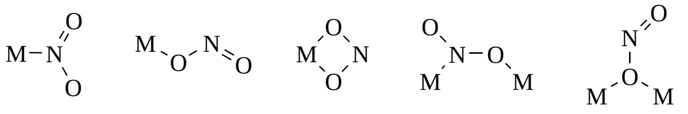
The nitrite ion is isoelectronic to ozone and NOF, and has an angular structure (d(N–O) = 123.6 pm, <(O–N–O) 115.4°).



(250)

Nitrous acid is only stable in dilute, cold aqueous solution and in the form of its salts, the nitrites. Upon heating or increasing the concentration, the following equilibria are in effect:

$$2HNO_2 \rightleftharpoons N_2O_3 + H_2O \quad (251)$$



(**80**) nitro (**81**) nitrito (**82**) chelating (**83**) unsymmetrical bridging (**84**) η^1 bridging

Scheme 31 Coordination modes of nitrite ligands

$$N_2O_3 \rightleftharpoons {\bullet}NO + {\bullet}NO_2 \quad (252)$$

$$2{\bullet}NO_2 \rightleftharpoons N_2O_4 \quad (253)$$

$$N_2O_4 + H_2O \rightleftharpoons HNO_3 + HNO_2 \quad (254)$$

The equilibrium constant K of (251) at room temperature is around 0.2, therefore a 0.1 mol L^{-1} solution of nitrous acid contains 0.002 mol L^{-1} N_2O_3. In total, nitrous acid disproportionates to nitric acid and NO.

$$3HNO_2 \rightleftharpoons HNO_3 + 2NO + H_2O \quad (255)$$

Aqueous solutions of nitrous acid are synthesized by the reaction of nitrite salts with strong acids. The reactions of silver nitrite with HCl and barium nitrite with sulfuric acid both produce insoluble precipitates that can easily be separated from the nitrous acid solution.

$$Ba(NO_2)_2 + H_2SO_4 \longrightarrow 2HNO_2 + BaSO_4 \quad (256)$$

$$AgNO_2 + HCl \longrightarrow HNO_2 + AgCl \quad (257)$$

Anhydrous nitrous acid can be prepared in the gas phase; liquid HNO_2 has not been isolated.

$$N_2O_3 + H_2O \rightleftharpoons 2HNO_2 \quad (258)$$

The disproportion reaction (255) shows that nitrous acid can react both as an oxidizing or reducing agent. In combination with strong oxidizing agents like MnO_4^-, BrO_3^-, O_2, H_2O_2, or PbO_2, nitrous acid acts as a reducing agent ($E° = 0.949$ V).

$$HNO_2 + H_2O \rightleftharpoons NO_3^- + 3H^+ + 2e^- \quad (259)$$

Nitrous acid acts as an oxidizing agent toward iodides, iron(II) salts, and oxalates. ($E° = 0.996$ V).

$$HNO_2 + H^+ + e^- \longrightarrow NO + H_2O \quad (260)$$

Other compounds reduce nitrous acid to $H_2N_2O_2$ (sodium amalgam, H_2NOH), N_2O (Sn(II) salts), N_2 (NH_3), HN_3 (N_2H_4), H_2NOH (H_2SO_3), or NH_3 (H_2S).

Nitrous acid is a moderately weak acid ($pK_a = -3.35$ at 291 K). Aqueous solutions of nitrite salts contain nitrous acid and are therefore not very stable. Nitrous acid is an extremely weak base:

$$HNO_2 \underset{-H^+}{\overset{+H^+}{\rightleftharpoons}} H_2NO_2^+ \underset{+H_2O}{\overset{-H_2O}{\rightleftharpoons}} NO^+ \quad (261)$$

Only very strong, concentrated acids produce the nitrosyl cation in small concentrations (e.g. 9 mol L^{-1} sulfuric acid). NO^+ reacts with nitrous acid to form N_2O_3.

$$NO^+ + HNO_2 \longrightarrow N_2O_3 + H^+ \quad (262)$$

Therefore, pouring sulfuric acid over nitrites results in the formation of both NO and NO_2. Nitrates do not form brown gases on reaction with sulfuric acid, a reaction that is used for the analytic distinction between nitrates and nitrites.

With the exception of silver nitrite, which is only slightly soluble, nitrite salts readily dissolve in water. The alkali metal nitrites and ammonium nitrite are hygroscopic. While sodium nitrite melts without decomposition, most other nitrites decompose before reaching the melting point ($Ba(NO_2)_2 > 593$ K, $AgNO_2 > 413$ K, $Hg(NO_2)_2 > 348$ K). Ammonium nitrite decomposes above 333 K, sometimes explosively, to dinitrogen and water:

$$NH_4NO_2 \longrightarrow N_2 + 2H_2O \quad (263)$$

Ammonium nitrite is only stable as a dry solid; it can be used to prepare very pure nitrite salts on reaction with hydroxides.

The reaction of alkali metal nitrites with alkali metal oxides M_2O yields salts M_3NO_3 that do not contain the orthonitrite anion NO_3^{3-} but are mixed crystals of the salts MNO_2 and M_2O with anti- perovskite structure $(NO_2)ONa_3$.[100,101] Some properties of important nitrite salts are given in Table 28.

$$MNO_2 + M_2O \longrightarrow M_3NO_3 \quad (264)$$

Sodium nitrite, the most important nitrite salt, is produced by the reaction of nitrogen oxides with sodium carbonate or sodium hydroxide solution.[5] Formation of nitrates can be inhibited by using an excess of NO and working with a pH higher than 8.

Sodium nitrite is still the most reliable agent for preventing botulism, a dangerous bacterial contaminant of meats and in curing salts is used in the food industry. High nitrite concentrations can, however, lead to the formation of carcinogenic nitrosamines. Nitrous acid and its salts are used in nitrosation reactions. The nitrosation of aromatic amines leads to diazonium compounds (for dyes). Primary aliphatic amines form the corresponding alcohol and dinitrogen upon nitrosation with nitrous acid. Secondary aliphatic amines form *N*-nitrosamines and R_2NNO and tertiary aliphatic alcohols form trialkylammonium nitrites R_3NH^+ NO_2^-, which react further to an alcohol and the dialkylnitrosamines R_2NNO upon warming.

7.7 Peroxohyponitrous Acid

The peroxonitrite ion has a partial double bond between nitrogen and the first peroxide oxygen. As shown in

Table 28 Properties of important nitrite salts

	NH_4NO_2	$NaNO_2$	KNO_2
m.p. [K]	–	557	714 (decomp.)
ΔH_f [kJ mol^{-1}]	−260(5)	−358(2)	−375(5)
ρ [g cm^{-3}]	1.69	2.168	1.915

Scheme 32, the molecule exists in a *cis* (**85**) and a *trans* form (**86**).[112]

The *cis* form (**85**) is predicted to be more stable than the *trans* form (**86**) by 12–17 kJ mol^{-1} by quantum chemical calculations. Tetramethylammonium peroxonitrite crystallizes in the *cis* form (**85**) (d(O=N) 116 pm, d(N–O) 135 pm, d(N–O) 141 pm)[113] and is nearly flat with a torsion angle of 22°. In a solid argon matrix, both conformers show a reversible photoisomerism.

$$\textit{cis}\ \mathrm{ONOO^-} \underset{\text{vis, near IR}}{\overset{\text{near UV, vis}}{\rightleftharpoons}} \textit{trans}\ \mathrm{ONOO^-} \qquad (265)$$

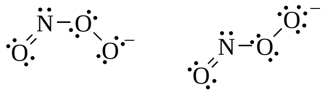
Peroxonitrous acid is an acid of medium strength (pK_a = 6.8), which rapidly decomposes in neutral conditions ($t_{1/2}$ = 1s at pH = 7.4). Peroxonitrite can isomerize to nitrate or decompose to nitrite and dioxygen. Isomerization to nitrate is a major pathway in acidic media. The mechanism for the decomposition is still in doubt, but it is believed that HOONO homolyzes to give the NO_2/OH radical pair.[114] Peroxonitrites are stable in basic solution. Peroxonitrous acid is formed as a yellow intermediate in the reaction of nitrite solutions with hydrogen peroxide that leads to nitrates.

$$\mathrm{HNO_2 + H_2O_2 \longrightarrow ONOOH + H_2O} \qquad (266)$$

It is a powerful oxidizing agent, stronger than nitric acid or hydrogen peroxide. The two-electron reduction potential of peroxonitrous acid is 1.68 V.

Tetramethylammonium *cis*-peroxonitrite, which decomposes at 383 K, is prepared by reacting tetramethylammonium superoxide with nitric oxide in liquid ammonia at 195 K.[115]

$$\mathrm{NMe_4{}^+O_2{}^- + NO \xrightarrow{NH_3(l)} NMe_4{}^+ONOO^-} \qquad (267)$$



(**85**) *cis* (**86**) *trans*

Scheme 32 Isomers of peroxonitrite

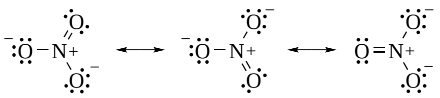
Peroxonitrous acid reacts with azide to form dinitrogen oxide, nitrous acid, and N_2.

$$\mathrm{ONOOH + N_3{}^- \longrightarrow N_2O + 0.5N_2 + HNO_2} \qquad (268)$$

It is believed that in biological systems NO reacts with superoxide $O_2{}^-$ to form the cytotoxic $ONOO^-$. In biological media, low concentration levels of $HCO_3{}^-$ prevent the toxic effects of $ONOO^-$, due to the formation of an unstable adduct with the composition $ONO_2CO_2{}^-$, which homolyzes to give the $NO_2/CO_3{}^-$ radical pair.[116]

7.8 Nitric Acid

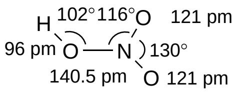
Pure, anhydrous nitric acid is a colorless liquid that fumes when exposed to air. Some of its physical properties are summarized in Table 29.[4,5]



(269)

The nitrate ion has a symmetrical, trigonal planar structure (D_{3h}, d(N–O) 121.8 pm, <(O–N–O) 120°). In nitric acid (**86**) (C_s) (Figure 11), the N–O bond of the N–OH group with 140.5 pm is longer than the N–O bond lengths with 120.6 pm.

Nitric acid can be mixed with water in all proportions. It forms two hydrates, a monohydrate $HNO_3{\cdot}H_2O$ (m.p. 236 K), and a trihydrate $HNO_3{\cdot}3H_2O$ (m.p. 255 K). A third hydrate, the dihydrate $HNO_3{\cdot}2H_2O$ (m.p. 233 K) can be obtained by careful thermal treatment. In all three crystal structures, hydrogen bonds connect the oxygen atoms of planar $NO_3{}^-$ ions with pyramidal H_3O^+ ions. In the monohydrate layers of hydrogen, bonded H_3O^+ and $NO_3{}^-$ ions are formed, the other two hydrates have three-dimensional hydrogen-bonded networks. At a concentration of 69.2 wt%, nitric acid forms a maximum-boiling azeotrope with water with a boiling point



(**86**)

Figure 11 Structure of the nitric acid

Table 29 Physical properties of nitric acid

m.p. [K]	231.56	$\Delta H_{vap.}$ [kJ mol^{-1}]	39.465 kJ mol^{-1}
b.p. [K]	355.8	$S°$ (l) [J mol^{-1} K^{-1}]	155.6 J mol^{-1}K^{-1}
ρ [g cm^{-3}]	1.504	Dielectric constant	50(10)
Thermal conductivity [W m^{-1} K^{-1}]	0.343	μ[D]	1.84 D
C_p [J g^{-1} K^{-1}]	1.7481	Index of refraction n_D	1.3970
ΔH_f [kJ mol^{-1}]	−174.1[1]		

of 395 K.[117] The azeotropic mixture is known as concentrated nitric acid ($\rho = 1.410\,\mathrm{g\,cm^{-3}}$). Some physical properties of aqueous nitric acid in different concentrations are given in Table 30.

Nitric acid decomposes thermally in the reverse reaction of its formation:

$$2HNO_3 \rightleftharpoons 2NO_2 + H_2O + 0.5O_2 \quad (270)$$

In ambient light, this decomposition already takes place at room temperature so that pure nitric acid has to be stored at temperatures below 273 K. At 303 K, the equilibrium contains 98% HNO_3, at 323 K 89% HNO_3. The photodissociation of the nitrate anion in aqueous solution may proceed according to one of the following three paths:[118]

$$NO_3^- \xrightarrow{h\nu} \bullet NO_2 + \bullet O^- \quad (271)$$

$$NO_3^- \xrightarrow{h\nu} ONOO^- \quad (272)$$

$$NO_3^- \xrightarrow{h\nu} NO_2^- + O \quad (273)$$

Decomposition occurs to the same extent for pathways (272) and (273), whereas path (273) is of very minor importance. No peroxonitrite is formed in a cage-recombination reaction of the products of (271). The oxygen anion of (271) reacts further with water to form hydroxyl radicals that can oxidize nitrite anions back to NO_2.

$$O^-\bullet + H_2O \longrightarrow OH\bullet + OH^- \quad (274)$$

$$OH\bullet + NO_2^- \longrightarrow NO_2\bullet + OH^- \quad (275)$$

Reaction of the peroxonitrite $ONOO^-$ anion with OH• radicals from (274) forms the peroxonitrite radical ONOO•, that decomposes to dioxygen and NO, the major source for the formation of nitrite ions NO_2^- in the system.

Dissolved nitrogen dioxide gives nitric acid a yellow color (fuming nitric acid). Higher concentrations of nitrogen dioxide give the nitric acid a red color (red fuming nitric acid). If the oxygen produced is allowed to dissipate, even aqueous nitric acid solutions can decompose in this manner.

Table 30 Physical properties of aqueous nitric acid as a function of composition

Concentration [wt%]	ρ[g cm^{-3}]	m.p. [K]	b.p. [K]

The chemistry of nitric acid is characterized by its acidity and oxidation strength. In dilute solutions of nitric acid, the acidity is more important for its chemical behavior, in concentrated nitric acid the oxidizing character dominates its chemical behavior.

Nitric acid is a strong acid ($\mathrm{p}K_\mathrm{a} = -1.44$).

$$HNO_3 \rightleftharpoons NO_3^- + H^+ \quad (276)$$

Dilute solutions of nitric acid are almost completely dissociated. In concentrated nitric acid, which dissociates according to (277), the nitracidium ion $H_2NO_3^+$ is formed:

$$2HNO_3 \rightleftharpoons H_2NO_3^+ + NO_3^- \quad (277)$$

In the gas phase, two isomeric structures of the neutral radical H_2NO_3 are found,[119] $(HO)_2NO$ and the more stable $H_2O{\cdot}NO_2$. $H_2NO_3^+$, which decomposes under elimination of water in analogy to the isoelectronic H_2CO_3:

$$H_2NO_3^+ \rightleftharpoons NO_2^+ + H_2O \quad (278)$$

$H_2NO_3^+$ is formed by adding a strong acid to nitric acid (279).

$$HClO_4 + HNO_3 \rightleftharpoons H_2NO_3^+ + ClO_4^- \quad (279)$$

The decomposition of the nitracidium ion (278) shifts the dissociation equilibrium (276) to the right side.

$$2HNO_3 \rightleftharpoons NO_2^+ + NO_3^- + H_2O \quad (280)$$

The formation of nitronium ions NO_2^+ and of water, that further reacts to

$$H_2O + HNO_3 \rightleftharpoons H_3O^+ + NO_3^- \quad (281)$$

with a net equation of

$$3HNO_3 \rightleftharpoons NO_2^+ + 2NO_3^- + H_3O^+ \quad (282)$$

explains the high electric conductivity ($3.7210^{-2}\Omega\ \mathrm{cm}^{-1}$) of anhydrous nitric acid. These equilibria are also responsible for a rapid exchange of nitrogen atoms in nitric acid.

$$NO_3^- + 4H^+ + 3e^- \longrightarrow NO + 2H_2O \quad (283)$$

Nitrate has an oxidation potential of +0.96 V. Copper (+0.342 V) and silver (+0.799 V) are dissolved by nitric acid under formation of NO (which is instantly oxidized to NO_2 in air), gold (+1.498 V) and platinum (+1.118 V) are not attacked. The oxidation of metals yields different products depending on the concentration of nitric acid. In

dilute solutions of nitric acid, NO is formed, whereas in concentrated solutions, NO is oxidized by nitric acid to NO_2. Moderately concentrated nitric acid oxidizes metals under formation of a mixture of NO and NO_2. A 50% solution of HNO_3 (aqua fortis) is used to separate silver from gold. The oxidation power of nitric acid increases with increasing concentration. Dilute solutions of nitric acid do not attack copper and more noble metals.

Some metals (Al, Cr, and Fe) are not oxidized by concentrated nitric acid even though they would be expected to be oxidized based on their oxidation potentials. These metals form thin oxide layers that protect the metal core (passivation). As a result, alloyed steel equipment can be used in nitric acid technology.

In concentrated nitric acid, the NO_2^+ ion has the highest oxidation potential. Increasing its concentration increases the oxidizing power of nitric acid. This is commonly achieved by adding a strong acid, normally sulfuric acid:

$$HNO_3 + 2H_2SO_4 \rightleftharpoons H_3O^+ + NO_2^+ + 2HSO_4^- \qquad (284)$$

The mixture of nitric acid and two parts of sulfuric acid is known as nitrating acid and is mainly used in organic chemistry for nitration reactions. In the mixture of one part nitric acid and three parts hydrochloric acid, NOCl and active chlorine (chlorine radicals) are formed:

$$HNO_3 + 3HCl \longrightarrow NOCl + 2Cl\bullet + 2H_2O \qquad (285)$$

This mixture dissolves almost all metals, even gold (aqua regia) but not niobium, tantalum, and tungsten.

In pure nitric acid, dissolved N_2O_4 dissociates completely to NO^+ and NO_3^-, and N_2O_5 dissociates to NO_2^+ and NO_3^-.

7.8.1 *Production of Nitric Acid*

Historically, nitric acid was synthesized by adding sulfuric acid to Chile saltpeter:[5]

$$NaNO_3 + H_2SO_4 \longrightarrow HNO_3 + NaHSO_4 \qquad (286)$$

The process of Birkeland and Eyde involved the direct combination of dinitrogen, dioxygen, and water ($\Delta H = -30.3$ kJ):

$$N_2 + 2.5O_2 + H_2O \longrightarrow 2HNO_3 \qquad (287)$$

This reaction requires an electric arc to provide the high activation energy and is therefore quite expensive. The availability of cheap ammonia synthesized by the Haber–Bosch process signaled the demise of this process.

Today, nitric acid is produced by the Ostwald process, which involves three chemical steps:

First, ammonia is catalytically oxidized to nitric oxide with atmospheric oxygen ($\Delta H = -904\,\text{kJ mol}^{-1}$):

$$4NH_3 + 5O_2 \longrightarrow 4NO + 6H_2O \qquad (288)$$

This is one of the most efficient catalytic processes known. With a suitable catalyst, 93–98% of ammonia is oxidized to NO. Side reactions include the formation of dinitrogen oxide ($\Delta H = -1105\,\text{kJ mol}^{-1}$) (289) and the formation of dinitrogen (290) ($\Delta H = -1268\,\text{kJ mol}^{-1}$).

$$4NH_3 + 4O_2 \longrightarrow 2N_2O + 6H_2O \qquad (289)$$

$$4NH_3 + 3O_2 \longrightarrow 2N_2 + 6H_2O \qquad (290)$$

Decomposition of the formed NO (291) ($\Delta H = -90\,\text{kJ mol}^{-1}$) and its reaction with ammonia (292) ($\Delta H = -1808\,\text{kJ mol}^{-1}$) also occur:

$$2NO \longrightarrow N_2 + O_2 \qquad (291)$$

$$4NH_3 + 6NO \longrightarrow 5N_2 + 6H_2O \qquad (292)$$

A short reaction time (in the order of 10^{-3} s) is necessary to avoid the decomposition of the metastable NO according to (291). Closely stacked, fine mesh gauzes of platinum, usually alloyed with 5–10% of rhodium to improve its mechanical strength, are used as catalysts. The loss of precious metal catalysts has a significant effect on the operating costs, therefore great efforts are made to recover the catalyst loss by filters and recovery gauzes. In the technical process, a 1:10 mixture of ammonia and oxygen is pressed at high velocity at temperatures between 973 K and 1223 K and pressures between 0.1 and 1.2 MPa through the catalyst gauzes.

The nitrogen oxide gas is then cooled down and, if necessary, compressed. Here the nitrogen oxide is partly oxidized by the dioxygen in air to NO_2 (293) ($\Delta H = -113.6\,\text{kJ mol}^{-1}$), which dimerizes to N_2O_4 (294) ($\Delta H = -58.08\,\text{kJ mol}^{-1}$):

$$2NO + O_2 \longrightarrow 2NO_2 \qquad (293)$$

$$2\,\bullet NO_2 \rightleftharpoons N_2O_4 \qquad (294)$$

Dinitrogen trioxide is also formed ($\Delta H = -40\,\text{kJ mol}^{-1}$):

$$NO + NO_2 \longrightarrow N_2O_3 \qquad (295)$$

The absorption of this complex mixture of gases and the formation of nitric acid follows a complicated mechanism. The main route involves two steps in the liquid phase. First, dinitrogen tetroxide reacts with water to form nitric acid and nitrous acid ($\Delta H = -87\,\text{kJ mol}^{-1}$):

$$N_2O_4 + H_2O \longrightarrow HNO_3 + HNO_2 \qquad (296)$$

Nitrous acid then disproportionates to nitric acid and NO ($\Delta H = -15.3\,\text{kJ mol}^{-1}$), which again enters the oxidation process.

$$3HNO_2 \longrightarrow HNO_3 + H_2O + 2NO \quad (297)$$

Absorption is normally performed in plate columns. Nitrogen monoxide is constantly reformed in this step and prevents the complete absorption of the inlet gases. Oxidation of nitrogen monoxide mainly occurs in the gas phase between the plates, but also in the bubble layer on the plates. The absorption efficiency increases at lower temperatures (higher N_2O_4 concentration) and higher pressures. Temperatures of 293 to 303 K and pressures of 5–10 MPa are used. The emission of nitrous gases is an environmental problem, which led to the design of advanced absorption towers and the development of different scrubbing processes for the stack gas. Nitric acid produced in technical processes has concentrations of 50–70%, depending on the absorption process. This is enough for most uses, including the production of fertilizers. Some processes require 100% nitric acid, which cannot be obtained by distillation because of the formation of an azeotropic mixture with water containing 68.4% HNO_3. Greater concentrations are obtained in a direct process by reacting liquid dinitrogen under pressure with pure oxygen and a certain quantity of dilute nitric acid. In an indirect process, either sulfuric acid or magnesium nitrate is added to commercial nitric acid. Distillation of these mixtures yields 99% nitric acid.

The principal use of nitric acid is the production of fertilizers, which uses between 75 and 85% of the total nitric acid production. Further uses include the production of organic nitro compounds that are used as explosives and rocket fuels. In 1987, 26.5 megatons of nitric acid were produced worldwide.

7.8.2 Nitrates

The reaction of nitric acid with metal oxides, hydroxides, or carbonates yields metal nitrates.[5] Hydrogendinitrates $H(NO_3)_2^-$ and dihydrogentrinitrates $H_2(NO_3)_3^-$ that contain nitrogen ions bound by hydrogen bonds are also known. $H(NO_3)_2^-$ has a symmetrical hydrogen bond between the nitrate ions with an O–O distance of 245 pm, the hydrogen bonds in $H_2(NO_3)_3^-$ are asymmetrical with O–O distances of 260 pm. Nitrates of the alkali and alkaline-earth metals as well as ammonium nitrate contain discrete NO_3^- ions; transition metal nitrates show a coordinative bond to the nitrate group. All nitrates dissolve readily in water. Heating results in decomposition under elimination of dioxygen. Alkali and alkaline-earth nitrates form nitrites, heavy metal nitrites form oxides and NO_2.

$$KNO_3 \xrightarrow{\Delta} KNO_2 + 0.5O_2 \quad (298)$$

$$Cu(NO_3)_2 \xrightarrow{\Delta} CuO + 2NO_2 + 0.5O_2 \quad (299)$$

For the complex decomposition processes of ammonium nitrate, see section 'Ammonium Nitrate'.

Alkali metal nitrates have comparatively low-melting points and the solid nitrates are excellent oxidizers at higher temperatures. Potassium nitrate is used as an oxidizer in black powder (75 wt% KNO_3, 15% charcoal, 10% sulfur). Fertilizer mixtures commonly contain ammonium nitrate or potassium nitrate, sometimes sodium or calcium nitrate as nitrogen compounds. Ammonium nitrate is also used as an explosive or as an oxidizer in an explosive mixture. Some properties of important nitrate fertilizers are summarized in Table 31.

In nitrate complexes, the nitrate ligand is found in the different coordination modes shown in Scheme 33:

7.9 Orthonitrates

Free orthonitric acid H_3NO_4, which would be analogous to H_3PO_4, has not been observed yet. The salts of orthonitric acid, the orthonitrates, contain tetrahedral T_d NO_4^{3-} (d(N–O) 139 pm) with somewhat smaller N–O distances than expected for N–O single bonds.[120]

Sodium orthonitrate is prepared by the reaction of sodium nitrate and sodium oxide at 573 K for one week:[100]

$$NaNO_3 + Na_2O \longrightarrow Na_3NO_4 \quad (300)$$

Water decomposes the orthonitrate ion to nitrate:

$$Na_3NO_4 + 2H_2O \longrightarrow 2NaOH + NaH_2NO_4 \quad (301)$$

$$NaH_2NO_4 \longrightarrow NaNO_3 + H_2O \quad (302)$$

The orthonitrates, for example, sodium orthonitrate, readily react with atmospheric water vapor and carbon dioxide:

$$Na_3NO_4 + H_2O + CO_2 \longrightarrow NaNO_3 + NaOH + NaHCO_3 \quad (303)$$

7.10 Peroxonitric Acid

In the reaction of pure hydrogen peroxide with dinitrogen pentoxide at 195 K, peroxonitric acid is formed:

$$N_2O_5 + H_2O_2 \longrightarrow O_2NOOH + HNO_3 \quad (304)$$

Peroxonitric acid is very unstable[121] and decomposes explosively at temperatures above 243 K. It has a pK_a of

Table 31 Properties of important nitrate fertilizers

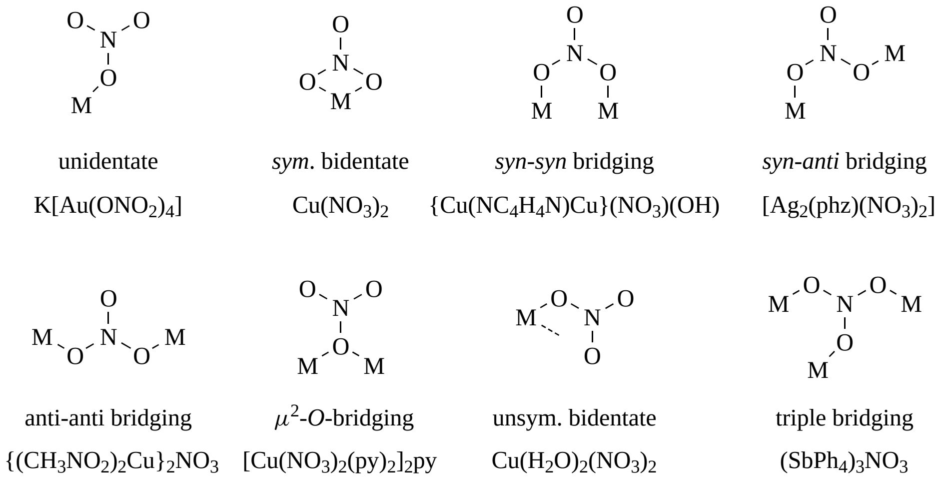
ρ [g cm^{-3}]	1.725	2.261	2.109	2.504



Scheme 33 Coordination modes of nitrate ligands

5.9, which is similar to the pK_a of peroxonitrous acid of 6.8. In dilute solutions, peroxonitric acid can be stored for a short time at 293 K. In contrast to peroxonitrous acid, which is stable in basic solution and decomposes in acidic solution, peroxonitric acid is relatively stable at moderate to low pH. Under these conditions, a slow N–O bond cleavage reaction gives the OOH/NO_2 radical pair. If peroxonitric acid is diluted too much, it hydrolyzes to form hydrogen peroxide and nitric acid. At a pH higher than 5, peroxonitrates decompose rapidly as follows:

$$O_2NOO^- \longrightarrow NO_2^- + O_2 \qquad (305)$$

The decomposition either follows homolysis, initially to NO_2/O_2^-, or heterolysis, initially to $^1O_2/NO_2^-$. In contrast to peroxonitrous acid, peroxonitric acid is insensitive to the presence of CO_2. Peroxonitric acid is a strong oxidizer with a two-electron reduction potential of 1.83 V.

7.11 Nitrosamine

NH_2NO is a transient intermediate in the reaction,

$$NH_2 + NO \longrightarrow H_2NNO \qquad (306)$$

which is part of the deNOx process. In the deNOx process, nitrogen oxides are reduced to dinitrogen with either ammonia or urea. The process works both catalytically (SCR, selective catalytic reduction) or noncatalytically (SNCR, selective non-catalytic reduction). In the noncatalytic process, temperatures have to be between 1025 and 1300 K, at lower temperatures the reduction does not work. The noncatalytic process follows a radical mechanism. In the catalytic process, lower temperatures between 473 and 573 K are sufficient. Titanium oxide catalysts are used with promoter oxides like V_2O_5. The process is used in large industrial plants and for diesel engines. Depending on the composition of the exhaust, different reactions occur:

$$6NO + 4NH_3 \longrightarrow 5N_2 + 6H_2O \qquad (307)$$

$$6NO_2 + 8NH_3 \longrightarrow 7N_2 + 12H_2O \qquad (308)$$

$$4NO + 4NH_3 + O_2 \longrightarrow 4N_2 + 6H_2O \qquad (309)$$

$$2NO + 4NH_3 + 2O_2 \longrightarrow 3N_2 + 6H_2O \qquad (310)$$

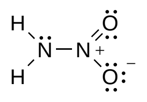
Under the reaction conditions in the NO_x removal process, H_2NNO is very short-lived because it is formed in a vibrationally excited state. The highly carcinogenic organic derivatives of nitrosamine R_2NNO are more stable and can be isolated in bulk.

7.12 Nitramide

Nitramide[122] (**87**) is a structural isomer of hyponitrous acid HON=NOH ($H_2N_2O_2$) (Figure 12).

It is a colorless solid, which melts in the range of 354–359 K. In a dry environment, it is stable up to 393 K, in the presence of moisture the decomposition may begins at 343 K.

The N–N bond in nitramide is shorter than a typical N–N single bond (145 pm in hydrazine) (see Table 32). The N–O bonds are also shorter than typical N–O single bonds. Both bonds have a greater bond order than one. In the solid state, hydrogen bonds connect the NH hydrogen atoms to



(**87**)

Figure 12 Lewis structure of nitramide

Table 32 Bonding parameters of nitramide in the gas phase and the solid state

	X-ray	GED	Microwave
d(N–N) [pm]	131.9(2)	138.1	142.7(2)

d(N–H) [pm]	0.86(2)	–	1.01(1)
<(H–N–H) [°]	–	120.9	115(2)
<(O–N–O) [°]	123.2(1)	132.7	130.1(3)
<(O–N–N) [°]	118.4(6)	–	–
<(H–N–N) [°]	117(1)	109.7	109

the oxygen atoms of the nitro group of another molecule, building a structure of hydrogen-bonded nitramide molecules. This hydrogen bonding results in a planar structure and a shorter N–N bond length in the solid phase. In the gas phase, the amino and nitro groups are twisted.

Aqueous solutions of nitramide are slightly acidic ($pK_a = 6.6$). The nitramide anion is not stable in salts, and the sodium, potassium, and ammonium salts decompose in solution. Nitramide, like hyponitrous acid, decomposes slowly forming N_2O and water. The decomposition is base-catalyzed and proceeds faster with stronger bases OR^-,

$$O_2NNH_2 + OR^- \xrightleftharpoons{\text{slow}} O_2NNH^- + HOR \quad (311)$$

$$O_2NNH^- \xrightarrow{\text{fast}} N_2O + OH^- \quad (312)$$

$$OH^- + OHR \xrightarrow{\text{very fast}} H_2O + OR^- \quad (313)$$

thus giving the overall reaction:

$$O_2NNH_2 \longrightarrow N_2O + H_2O \quad (314)$$

The nitramide anion O_2NNH^- can rearrange to imidonitric acid $HNN(OH)O^-$, which in turn decomposes to N_2O. In mildly acidic solution, the decomposition is nonetheless base-catalyzed with water acting as a base.

Nitramide can be prepared by the decomposition of potassium nitrocarbamate in an acidic medium:

$$K_2[O_2N\text{–}NCO_2] + 2H_2SO_4 \longrightarrow O_2NNH_2 + CO_2 + 2KHSO_4 \quad (315)$$

Other preparations include the hydrolysis of nitrocarbamic acid (316), the reaction of $NaSO_3NH_2$ with concentrated nitric acid, (317) and the reaction of N_2O_5 with two equivalents of ammonia (318) (see Scheme 34).

$$O_2N\text{–}NHCOOH \longrightarrow O_2NNH_2 + CO_2 \quad (316)$$

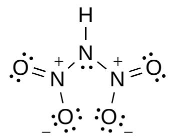
$$NaSO_3NH_2 + HNO_3 \longrightarrow O_2NNH_2 + NaHSO_4 \quad (317)$$

$$N_2O_5 + 2NH_3 \longrightarrow O_2NNH_2 + NH_4NO_3 \quad (318)$$

7.13 Dinitramic Acid

Dinitramic acid[123] (**88**) and the dinitramide anion were discovered in 1971 (Figure 13). However, it was then only known in the former Soviet Union and was independently discovered in the United States in 1989.

In the gas phase, the dinitramide ion $N(NO_2)_2^-$ has C_s symmetry. In the solid state, the symmetry is often distorted by interactions with the counterion, for example, hydrogen bonding with the ammonium ion in ammonium dinitramide (see Table 33). The N–NO_2 rotation barrier is very low. In fact, though the bond lengths of the nitramide ion remain fairly constant, no two-dinitramide crystal structures show the same geometry of the dinitramide anion.[124] The crystal structure of lithium dinitramide shows the symmetric anion.



(**88**)

			<(O3–N3–O4) [°]	122.18(9)	121.5(2)

The N–N bonds of dinitramide are shorter than N–N single bonds (145 pm in N_2H_4).

Dinitramic acid (**88**) is a strong acid ($pK_a = -5.62$). Aqueous solutions of dinitramic acid with a concentration of 7–10% can be safely and easily prepared by passing a solution of $KN(NO_2)_2$ through a protonated ion-exchange resin. A nonaqueous solution is obtained by passing HCl through a suspension of $KN(NO_2)_2$ in ether at 273–278 K. Removal of ether yields a viscous yellow liquid that still contains some ether and is very shock and heat sensitive. After removal of the solvent at 273 K, dinitramic acid decomposes, often explosively, to a mixture of nitrogen oxides. Slow decomposition in air results in nitric acid as the major product. Solutions of dinitramic acid, either in water or in organic solvents, can be stored without noticeable decomposition if their concentration is less than 20%. The dinitramide anion is stable in the pH range 0–15. In concentrated acids, the dinitramide anion decomposes slowly at room temperature.

Solutions of dinitramic acid can be used to synthesize dinitramide salts with metal hydroxides, carbonates or oxides, and the salts of amine bases:

$$HN(NO_2)_2 + MOH \longrightarrow M^+N(NO_2)_2^- + H_2O \quad (319)$$

$$HN(NO_2)_2 + RNH_2 \longrightarrow RNH_3^+N(NO_2)_2^- \quad (320)$$

The metal dinitramides are crystalline substances that are generally stable at 298 K and have low-melting points. They are usually nicely soluble in water, alcohols, acetonitrile, and other polar solvents. Heavy metal dinitramides like silver dinitramide are sensitive to friction. Silver dinitramide is used in metathesis reactions with halides to produce dinitramide salts.

$$n AgN(NO_2)_2 + MX_n \longrightarrow M^{n+}(N(NO_2)_2^-)_n + n AgX \quad (321)$$

7.13.1 Ammonium Dinitramide

Ammonium dinitramide ($\rho = 1.82\ g\ cm^{-3}$, $\Delta H_f = 148(10)\ kJ\ mol^{-1}$) is a colorless solid with a melting point of 365 K. The four hydrogen atoms of the ammonium ion form hydrogen bonds to oxygen atoms of surrounding dinitramide ions (d(N–O) 215.3 to 223.0 pm). These tetrahedrally arranged hydrogen bonds set up a three-dimensional network of hydrogen bonds. Slow decomposition of ammonium dinitramide begins above the melting point. The salt decomposes, often explosively, at 408 K. Like many other ammonium salts, the first step in the volatization (ΔH_{sub} between 125 and 185 $kJ\ mol^{-1}$, $\Delta H_{fusion} = 130\ kJ\ kg^{-1}$) of ammonium dinitramide is proton transfer from the ammonium NH_4^+ cation to the dinitramide anion $N(NO_2)^-$, to form a hydrogen-bonded acid base pair ($NH_3{\cdot}HN(NO_2)_2$).

Depending on the temperature, ammonium dinitramide can then decompose in two different ways. At temperatures between 328 K and 373 K, N_2O is eliminated from the molecule:[125]

$$NH_3{\cdot}HN(NO_2)_2 \longrightarrow NH_3{\cdot}HNNO_2 + NO_2 \quad (322)$$

Above 383 K, the favored decomposition pathway produces NO_2 in a homolytic bond fission reaction:

$$NH_3{\cdot}HN(NO_2)_2 \longrightarrow NH_4NO_3 + N_2O \quad (323)$$

$HNNO_2$ further decomposes to N_2O and OH or NH and NO_2. The decomposition to N_2O is slow, whereas the decomposition forming NO_2 is rapid.

Ammonium dinitramide can be obtained in low yields of 13–30% by the nitration of ammonia with N_2O_5, and extraction of the solid products with ethyl acetate. The main product of this reaction is ammonium nitrate. Nitramide or ammonium dinitramide can be obtained by careful control of the reaction conditions (see Scheme 34).

Organic dinitramines of the type $RCH_2CH_2N(NO_2)_2$ with an electron accepting group (R = CN, CHO, COR, COOR, or NO_2) eliminate ammonium dinitramide and acrylic compounds $H_2C{=}CHR$ during decomposition in aqueous solutions of ammonia.

The nitration of deactivated amines H_2NR (R = NO_2, $OOCC_2H_5$, $H_4NO(O)C$, $H_4NOS(O)_2$, H_2NCO) with strong nitrating agents (N_2O_5, NO_2BF_4, $O_2NS_2O_7H$, $HNO_3/SO_3/H_2SO_4$) and neutralization of the reaction mixture with ammonia or aqueous solutions of ammonia also yields ammonium dinitramide.

All nitration reactions are highly exothermic and require temperatures below 273 K to achieve good yields and to avoid decomposition of ammonium dinitramide to gaseous products and ammonium nitrate.

Current research aims to establish ammonium dinitramide as a replacement for ammonium perchlorate as an oxidizer

in rocket propellants and other explosive formulations to avoid the environmental problem of chlorine emission. Unfortunately, ammonium dinitramide is thermally and mechanically more sensitive than ammonium perchlorate.

Hydroxylammonium dinitramide is not stable at ambient conditions. However, a salt with the formula $(H_3NOH)_2[N(NO_2)_2]\cdot 2H_2NOH$ is known. All hydroxylamine species in this salt are involved in hydrogen bonding, and one of the coordinated hydroxylamine molecules shows zwitterionic behavior. The salt resembles the formula $(H_3NOH)_2[N(NO_2)_2]\cdot H_2NOH\cdot H_3N^+O^-$. Hydrazinium dinitramide $(N_2H_5)_2[N(NO_2)_2]$ also has a three-dimensional hydrogen bond network, but is less stable than ammonium dinitramide.

8 NITROGEN HALIDES

The properties of nitrogen halides are summarized in Table 34.

8.1 Nitrogen Fluoride compounds

All NCl, NBr, and NI compounds are thermodynamically unstable ($\Delta H_f > 0$). Some, but not all binary NF compounds are exothermic species, with NF_3 as the most stable species. During the 1960s, NF compounds were investigated as rocket propellants. Today, NF compounds are used in chemical lasers and as high-energy density materials, but no compound has achieved widespread use.[126,127] The bonding situation in nitrogen fluorides is explained in the literature.[128] The N–F bond lengths are given in Table 35, the other bonding parameters in Table 36.

8.1.1 *Fluoramine*

Fluoramine is synthesized by vaporizing the adduct $NH_2F\cdot 2HF$ ($NH_3F^+\ HF_2^-$) in a dynamic vacuum. The reaction gas is passed through activated, powdered KF to absorb HF and is collected at 76 K.[126]

$$\text{RO–CO–NH}_2 \xrightarrow[-\text{HF}]{\text{F}_2/\text{N}_2} \text{RO–CO–NHF} \xrightarrow[-\text{RCO}_2^-]{\text{HF/H}_2\text{O}} \text{FNH}_3^+\text{HF}_2^- \xrightarrow[-2\text{KHF}_2]{+2\text{KF},\ \Delta} \text{NH}_2\text{F} \qquad (324)$$

Table 35 N–F bond lengths in binary N–F compounds

	Symmetry	d(N–F) [pm]
NF_3	C_{3v}	137

NCl_3	–	gas: 176 solid: 171 to 177	–	gas: 107 solid: 105.1 to 109.6	–

Above 173 K fluoramine decomposes:

$$3NH_2F \longrightarrow NH_4F + 2HF + N_2 \quad (325)$$

As a weak base, fluoramine reacts with strong acids HX (X e.g. HF_2^-, SO_3F^-,ClO_4^-, and HSO_4^-) forming fluorammonium salts $NH_3F^+X^-$. The stability of the NH_3F^+ salts is influenced by the acidity of the anion and increases in the order $SO_3Cl^- < ClO_4^- < H_3CSO_3^- < SO_3F^- < F_3CSO_3^-$.

8.1.2 *Difluoramine*

Difluoramine has a melting point of 156.6 K and a boiling point of 249.4 K. The boiling point is considerably higher than the boiling point of NF_3 (144.2 K) due to hydrogen bonding in the liquid.[130] It is an unstable compound that requires very careful handling since it often explodes spontaneously, especially on freezing or melting.[126]

Difluoramine can be obtained by the hydrolysis of *N*,*N*-difluorourea with concentrated sulfuric acid.

$$H_2NCO–NH_2 \xrightarrow[-2HF]{F_2/N_2} H_2NCO–NF_2$$

$$\xrightarrow{\text{conc. } H_2SO_4} NHF_2 + NH_4^+ + CO_2 \quad (326)$$

Other preparations include the hydrolysis of *N*,*N*-difluorosulfamide ($F_2NSO_2NH_2$) or trityldifluoramine ($(C_6H_5)_3CNF_2$).

Anhydrous difluoramine decomposes thermally (in the presence of KF as HF absorber) to dinitrogen difluoride.

$$2NHF_2 \xrightarrow{(KF)} N_2F_2 + 2HF \quad (327)$$

Difluoramine is a versatile reagent in organic synthesis and is used, among others, to synthesize organic difluoramino and geminal bis(difluoramino) derivatives of organic compounds. Reaction of NHF_2 with ClF at low temperatures leads to chlorodifluoramine.

$$HNF_2 + ClF \longrightarrow ClNF_2 + HF \quad (328)$$

Reaction of difluoramine with ClO^- also yields chlorodifluoramine NF_2Cl, and reaction with bromine yields bromodifluoramine NF_2Br.

Difluoramine is a weak base that can form adducts with Lewis acids (BF_3, BCl_3, PF_5, SO_2) that are formed at 195 K and decompose well below ambient temperature. NHF_2 reacts with AsF_5 in anhydrous HF below 195 K to $NH_2F_2^+$ AsF_6^-. Otherwise difluoramine reacts as an acid:

$$NHF_2 \rightleftharpoons NH_2^- + H^+ \quad (329)$$

In the absence of other reaction partners the diflouroamide anion reacts to form *cis*/*trans*-N_2F_2.

$$2NF_2^- \longrightarrow N_2F_2 + 2F^- \quad (330)$$

Fe^{3+} oxidizes NF_2^- to tetrafluorohydrazine.

$$NF_2^- + Fe^{3+} \longrightarrow NF_2\bullet + Fe^{2+} \quad (331)$$

$$2\,NF_2\bullet \rightleftharpoons N_2F_4 \quad (332)$$

8.1.3 *Nitrogen Trifluoride*

Nitrogen trifluoride is a colorless, odorless gas with a boiling point of 144.2 K and a melting point of 66.4 K. It has a trigonal pyramidal structure with a F–N–F angle of 102.1°. The dipole moment of NF_3 (0.2340 D) is lower than the dipole moment of ammonia (1.47 D), which can be explained by the reversed polarity of nitrogen. NF_3 has a positively polarized nitrogen atom and the dipole moment of the lone pair is in opposite direction to the dipole moment along the same axis associated with the three N–F bonds. In ammonia, the polarities are reversed and the dipole moments, of the NH bonds and the lone pair operate in the same direction. Compared to other fluoramines, the N–F bond in NF_3 is relatively short (see Table 35). This can be explained by an electrostatic model. The partial charges in NF_3 ($N^{\delta+}$ $F^{\delta-}$) indicate a strong attractive interaction, a weak attraction in HNF_2, and a repulsive electrostatic interaction ($N^{\delta-}$ $F^{\delta-}$) in H_2NF.[126,127]

NF_3 is synthesized by the melt electrolysis of NH_4F/HF mixtures, or by the fluorination of ammonia catalyzed by copper.

$$4NH_3 + 3F_2 \xrightarrow{[Cu]} NF_3 + 3NH_4F \quad (333)$$

At low temperatures, NF_3 reacts only sluggishly, giving no reaction with H_2, CO, CH_4, H_2S and many other compounds. Although these reactions are in fact thermodynamically favored, they are prevented at ambient temperatures by the kinetic stability of NF_3. When the activation energy is provided by heating or an electric spark, NF_3 reacts readily and sometimes explosively.

At higher temperatures, NF_3 reacts with metals (e.g. Li, Na, K, Cu, Ag, Mg, Ca, Ba, Zn, Cd, Hg, Sn, Pb) and nonmetals (e.g. H_2, B, Si, As, Sb) to form fluorides. In the reaction with the metals Bi, Sb, Cu, or As in a flow reactor, the metals are converted to the respective fluorides and NF_3 is reduced to tetrafluorohydrazine.

$$2NF_3 + Cu \longrightarrow N_2F_4 + CuF_2 \quad (334)$$

After ignition with a spark, the reaction with dihydrogen proceeds with a sharp bang and a red–violet glow (*see* ***Hydrogen: Inorganic Chemistry***). Ignition of a mixture of NF_3 and water vapor gives a slow reaction that is accompanied by a blue glow, and leads to hydrogen fluoride and nitrous acid. At room temperature, NF_3 does not react with water.

$$2NF_3 + 3H_2 \longrightarrow N_2 + 6HF \quad (335)$$

$$NF_3 + 2H_2O \longrightarrow HNO_2 + 3HF \quad (336)$$

NF_3 shows low inclination toward coordination and is a poor ligand.

The reaction of NF_3 with AsF_5, SbF_5 or BF_3, and fluorine leads to salts of the tetrahedral NF_4^+ ion (d(N–F) 130 pm).

$$NF_3 + F_2 + BF_3 \xrightarrow{80\,K,\,UV} NF_4^+BF_4^- \quad (337)$$

NF_4^+ is one of the strongest fluorinating agents known.

Metathesis reactions that form $CsSbF_6$, which is almost insoluble in HF, can be used to obtain different NF_4^+ salts.

$$NF_4^+SbF_6^- + CsHF_2 \xrightarrow[195\,K]{HF} NF_4^+HF_2^- + CsSbF_6 \quad (338)$$

$NF_4^+\ HF_2^-$ cannot be obtained in a pure form, as it always contains some HF. It decomposes at room temperature to form NF_3, F_2, and HF. The HF solution of this salt is stable at room temperature. Theoretical calculations indicate that a hypothetical NF_5 has a decomposition barrier of 69 kJ mol^{-1} but so far no experimental evidence has been found for this species.[131] For more information on hypervalent compounds, *see* ***Hypervalent Compounds***.

In the thermal decomposition of $NF_4^+H^{18}F_2^-$, the fluorine atom of HF_2^- only attacks fluorine atoms and not the central nitrogen atom.

$$NF_4^+H^{18}F_2^- \xrightarrow{\Delta} NF_3 + H^{18}F + {}^{18}F\text{–}F \quad (339)$$

8.1.4 *Tetrafluorohydrazine*

Tetrafluorohydrazine is a colorless gas with a melting point of 108.7 K and a boiling point of 200 K. The structure of tetrafluorohydrazine (microwave: d(N–N) 140(2) pm, d(N–F) 135 pm, <(F–N–F) 107(2)°, electron diffraction: d(N–N) 148(2) pm, d(N–F) 139(1) pm, <(F–N–F) 103.0(1)°) resembles hydrazine. In the temperature range of 123–193 K, the staggered (C_{2h}) and gauche (C_2) isomers of tetrafluorohydrazine are in equilibrium both in the condensed phase and the vapor phase. The staggered conformation is favored by about 2 kJ mol^{-1} and a barrier of 12.5 kJ mol^{-1} hinders the free rotation of the NF_2 groups. N_2F_4 is synthesized by fluorine abstraction from NF_3 with metals, or by the oxidation of difluoramine with an alkaline solution of hypochlorite.[126]

$$2NF_3 + M \longrightarrow N_2F_4 + MF_2 \quad (340)$$

$$(NH_2)_2CO \xrightarrow{F_2/N_2} NH_2CONF_2 \xrightarrow{H_2SO_4} HNF_2 \xrightarrow[pH12]{NaOCl} 0.5N_2F_4 \quad (341)$$

Tetrafluorohydrazine is a strong fluorinating agent.

$$N_2F_4 + 10Li \longrightarrow 4LiF + 2Li_3N \quad (342)$$

$$S_8 \xrightarrow[N_2F_4]{383-413\,K} \begin{cases} SF_4 \\ SF_5NF_2 \end{cases} \quad (343)$$

Tetrafluorohydrazine has a long and weak nitrogen–nitrogen bond and dissociates easily into deep blue $\cdot NF_2$ radicals (d(N–F) 136.3 pm, <(F–N–F) 102.5°).

$$2NF_2\cdot \rightleftharpoons N_2F_4 \quad (344)$$

The easy dissociation (K = 0.03 at 43K, $\Delta H° = 83.2$ kJ mol^{-1}) into radicals explains the higher reactivity of N_2F_4 compared to NF_3. Reaction of N_2F_4 with chlorine yields chlorodifluoramine. In the reaction with NO, the purple, easily dissociating nitrosodifluoramine NF_2NO is formed and reaction with S_2F_{10} yields the colorless NF_2SF_5.

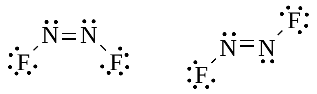
$$N_2F_4 + Cl_2 \longrightarrow 2NF_2Cl \quad (345)$$

$$N_2F_4 + 2NO \longrightarrow F_2NNO \quad (346)$$

$$N_2F_4 + S_2F_{10} \longrightarrow 2NF_2SF_5 \quad (347)$$

The highly unstable F_2NNO_2 is formed in the reaction with NO_2 at 583 K and rapid quenching at 77 K.

$$N_2F_4 + NO_2 \longrightarrow F_2NNO_2 \quad (348)$$



(**89**) (**90**)

Scheme 35 N_2F_2 isomers

Tetrafluorohydrazine is used for the synthesis of organic compounds containing the -NF_2 or =NF group, for example, it adds to olefines.

$$R_2C{=}CR_2 + N_2F_4 \longrightarrow R_2C(NF_2){-}C(NF_2)R_2 \quad (349)$$

The reaction of tetrafluorohydrazine with strong fluorine acceptors (AsF_5, SbF_5) forms salts of the planar C_s cation $N_2F_3^+$.[132]

$$N_2F_4 + 2SbF_5 \xrightarrow{HF} N_2F_3^+Sb_2F_{11}^- \quad (350)$$

8.1.5 *Difluorodiazene*

Two planar isomers of N_2F_2 are known (Scheme 35), the *cis* (**89**) (C_{2v}, m.p. <78 K, b.p. 167.3 K, μ 0.18D) and *trans* isomers (**90**) (C_{2h}, m.p. 101 K, b.p. 161.8 K, μ 0 D).[126] Their bonding parameters are given in Table 37.

The shortening of the N–N bond in the *cis* isomer (**89**), which is accompanied by a lengthening of the N–F bond, can be explained by negative hyperconjugation. This corresponds to the partial delocalization of the nitrogen lone pair into the antibonding $\sigma*$ orbital of the neighboring N–F group. This donor–acceptor interaction is only present in the *cis* isomer. The *cis* isomer (**89**) is thermodynamically favored by 13 kJ mol^{-1}. At 298 K, the equilibrium has about 90% *cis* and 10% *trans*, and at about 342 K the *trans* isomer (**90**) rearranges to the *cis* form (**89**). At 570 K, N_2F_2 dissociates to the elements. The equilibrium is only slowly attained at lower temperatures without catalysts. Therefore, the pure isomers of N_2F_2 can be obtained.

The two isomers react very differently. The *cis* form is more stable as well as more reactive. The *trans* form can be stored in glass vessels, whereas the *cis* form reacts slowly with glass to form SiF_4 and N_2O.

Dinitrogen difluoride is best synthesized by passing difluoramine over KF.

$$HNF_2 + KF \xrightarrow{193\,K} HNF_2{\cdot}KF \xrightarrow{293\,K} 0.5N_2F_2 + KHF_2 \quad (351)$$

Table 37 Bonding parameters of N_2F_2 compounds

	cis	*trans*
d(N–F) [pm]	140.9	139.8
D(N–N) [pm]	120.9	122.4
<(F–N–N) [°]	114	106

(**91**)

Figure 14 Lewis structure of the N_2F^+ cation

The thermal decomposition of fluorine azide also yields N_2F_2.

$$2FN_3 \longrightarrow 2N_2 + N_2F_2 \quad (352)$$

These preparations, as well as the reaction of nitrogen trifluoride with mercury vapor in an electric discharge, and the fluorination of sodium azide yield mixtures of both isomers. The pure *trans* isomer is produced in 45% yield by the reaction of tetrafluorohydrazine with aluminum trichloride, or by the reaction of a mixture of the N_2F_2 isomers with aluminum trichloride.

$$2N_2F_4 + 2AlCl_3 \longrightarrow trans\text{-}N_2F_2 + 3Cl_2 + 2AlF_3 + N_2 \quad (353)$$

$$3\ cis\text{-}N_2F_2 + 2AlCl_3 \longrightarrow 3Cl_2 + 2AlF_3 + N_2 \quad (354)$$

$$3\ trans\text{-}N_2F_2 + 2AlCl_3 \longrightarrow \text{no reaction} \quad (355)$$

Only the *cis* isomer reacts with AsF_5 to form the linear fluorodiazenium ion N_2F^+ (**90**) in Figure 14 that has the shortest known N–F bond (d(N–F) 122 pm, d(N–N) 109.9 pm). N_2F^+ is isoelectronic to NO_2^+.[133]

$$cis\text{-}N_2F_4 + AsF_5 \longrightarrow N_2F^+AsF_6^- \quad (356)$$

In the reaction of N_2F^+ (**91**) with NaF and HF, only *cis*-N_2F_2 is formed.

Heating a mixture of FN_3 and ClN_3 to 393K results in a yellow, highly explosive substance that has not been isolated so far. It is assumed to be ClNNF.[134]

$$FN_3 \longrightarrow N_2 + NF \quad (357)$$

$$ClN_3 \longrightarrow N_2 + NCl \quad (358)$$

$$NF + NCl \longrightarrow FNNCl \quad (359)$$

8.2 Nitrogen Chlorides

8.2.1 *Chloramine*

Chloramine has a melting point of 203 K. Decomposition begins at 163 K, and above 233 K the decomposition is explosive. Gaseous NH_2Cl at low pressures and dissolved NH_2Cl at low concentrations are thermally slightly more stable. NH_2Cl is readily soluble in water and ether, but less soluble in $CHCl_3$ and CCl_4. In aqueous solution, it decomposes according to (360):

$$3NH_2Cl \longrightarrow N_2 + NH_4Cl + 2HCl \quad (360)$$

This decomposition occurs in a neutral, or mildly alkaline (up to pH = 11) medium. The reaction is slow, only a few percent of a 0.1 M solution of NH_2Cl in water decompose according to (360) in several weeks. At pH values above 11, the equilibrium for the synthesis (365) is shifted to the hypochlorite side and the following reaction slowly occurs:

$$3NH_2Cl + 3OH^- \longrightarrow NH_3 + N_2 + 3Cl^- + 3H_2O \qquad (361)$$

In an acidic medium at pH values of around 4, chloramine disproportionates to form dichloramine (362), which in turn disproportionates at pH values below 3 (363), so that at low pH values, NCl_3 dominates and between pH 3–5 $NHCl_2$ dominates.

$$2NH_2Cl + H^+ \rightleftharpoons NHCl_2 + NH_4^+ \qquad (362)$$

$$3NHCl_2 + H^+ \rightleftharpoons 2NCl_3 + NH_4^+ \qquad (363)$$

These equilibria are disturbed by the irreversible decomposition of $NHCl_2$ and NCl_3:

$$NHCl_2 + NCl_3 + 2H_2O \longrightarrow N_2 + 3HCl + 2HOCl \qquad (364)$$

In dilute aqueous solution, chloramine is prepared by the reaction of ammonia with sodium hypochlorite:

$$NH_3 + OCl^- \rightleftharpoons NH_2Cl + HO^- \qquad (365)$$

As a result of the decomposition reactions shown above, the reaction has to be carried out in a slightly alkaline medium (pH = 8.5 to 11). This is also the first step of the Raschig hydrazine synthesis. The acting chlorinating agent in this reaction is hypochloric acid HOCl, which has to be generated by protonation of hypochlorite, and then reacts in a nucleophilic substitution of the hydroxo against the amino group. The reaction occurs quickest at around pH = 8, at higher pH values the concentration of hypochloric acid is lower, at lower pH values ammonia NH_3 is protonated to form ammonium ions NH_4^+, which do not react further. The NH_2Cl solutions can be concentrated by vacuum distillation, and passing the vapor through potassium carbonate which absorbs the water. NH_2Cl can be extracted with ether. Gaseous chloramine can be obtained from the reaction of gaseous ammonia with chlorine gas that is diluted with nitrogen gas in molar ratios of 20:1 to 6:1.[135]

$$2NH_3(g) + Cl_2(g) \rightleftharpoons NH_2Cl(g) + NH_4Cl(s) \qquad (366)$$

By passing the effluent from the gas-phase reaction into a solvent at 253 K and then removing the ammonia by warming up the solution or passing it through a column with anhydrous copper(II) sulfate, solutions of chloramine in various solvents can be obtained. Almost pure (97%) NH_2Cl is obtained by the fractional low-temperature condensation of the effluent. Pure NH_2Cl is synthesized by passing pure fluoramine through a layer of $CaCl_2$:

$$2NH_2F + CaCl_2 \longrightarrow NH_2Cl + 2CaF_2 \qquad (367)$$

Chloramine is both a very weak base and a very weak acid ($pK_a = 14$, $pK_b = 15$). In water NH_2Cl acts neutral. It is an oxidizing agent (acidic solution: $E° = -1.48$ V, in basic solution $E° = -0.81$ V)

$$NH_2Cl + 2H^+ + 2e^- \longrightarrow NH_4^+ + Cl^- \qquad (368)$$

Reactions of chloramine include radical, nucleophilic, and electrophilic substitution of chlorine, electrophilic substitution of hydrogen, and oxidative additions, for example:

$$Ph_2C{=}C{=}O + NH_2Cl \longrightarrow Ph_2CCl–CONH_2 \qquad (369)$$

Chloramine can, like HOCl, donate positively charged chlorine Cl^+ in reactions with nucleophiles Nu^-.

$$Nu^- + NH_3Cl^+ \longrightarrow Nu–Cl + NH_3 \qquad (370)$$

These reactions follow the S_N2 mechanism at the chlorine atom of NH_2Cl or NH_3Cl^+. An example is the chlorination of the hydroxide ion OH^- in highly alkaline solution (reverse of (365)).

$$NH_2Cl + HO^- \rightleftharpoons NH_3 + OCl^- \qquad (371)$$

Another chlorination is the reaction of chloramine to form dichloramine, which starts the decomposition in an acidic medium.

$$2NH_2Cl \rightleftharpoons NHCl_2 + NH_3 \qquad (372)$$

This equilibrium lies to the left side under normal conditions, but can be shifted to the right side by removing ammonia, for example, by protonation. Hydrazine is chlorinated in acidic solution:

$$NH_2Cl + N_2H_4 \rightleftharpoons NH_3 + N_2H_3Cl \qquad (373)$$

Chlorohydrazine, like all chloro-, bromo- or iodohydrazines, is not stable and immediately decomposes to diimine,

$$N_2H_3Cl \longrightarrow N_2H_2 + HCl \qquad (374)$$

which in turn disproportionates to dinitrogen and hydrazine.

$$2N_2H_2 \longrightarrow N_2 + N_2H_4 \qquad (375)$$

The overall equation of the reaction of chloramine with hydrazine is as follows (Raschig process, see Section 5.2.1):

$$2NH_2Cl + N_2H_4 \longrightarrow N_2 + 2NH_4Cl \qquad (376)$$

Nucleophiles can also react according to an S_N2 mechanism at the nitrogen atom. This is an amination reaction, where the NH_2^+ group is transferred to the nucleophile.

$$Nu^- + NH_2Cl \longrightarrow Nu\text{–}NH_2 + Cl^- \quad (377)$$

The reaction is also called electrophilic amination and amino donors like NH_2Cl or NH_2OSO_3H are called electrophilic amination agents.

The amination of ammonia with chloramine to form hydrazine is an example of this mechanism (Raschig process):

$$NH_2Cl + NH_3 \longrightarrow N_2H_5{}^+Cl^- \quad (378)$$

This reaction can also be carried out with substituted amines RNH_2, R_2NH, and R_3N to form the corresponding substituted hydrazines $RNH\text{–}NH_2$, $R_2NH\text{–}NH_2$, or $R_3N^+\text{–}NH_2$ salts.

Chloramine electrophilically aminates itself in neutral and alkaline media to start its decomposition.

$$2NH_2Cl \longrightarrow N_2H_3Cl + HCl \quad (379)$$

Chlorohydrazine decomposes as described above (374), the net reaction of this decomposition is given by equation (360).

Hydrazine can also be aminated by chloramine, but only in alkaline solution:

$$NH_2Cl + H_2N\text{–}NH_2 \longrightarrow [H_2N\text{–}NH_2{}^+\text{–}NH_2]Cl^- \quad (380)$$

In acidic solution, the chlorination to form chlorohydrazine (373) is much faster. Triazanium chloride is only stable at temperatures below 223 K, otherwise it decomposes under cleavage of NH_4Cl to diimine.

$$H_2N\text{–}NH_2\text{–}NH_2{}^+Cl^- \longrightarrow N_2H_2 + NH_4Cl \quad (381)$$

In turn, diimine disproportionates according to (375), thus giving an overall equation that is identical to the reaction in the acidic medium (376):

The reaction of chloramine with *N*,*N*-disubstituted hydrazines R_2NNH_2 yields stable triazanium salts:

$$NH_2Cl + R_2N\text{–}NH_2 \longrightarrow [H_2N\text{–}NR_2{}^+\text{–}NH_2]Cl^- \quad (382)$$

In the reaction of $(CH_3)_2NNH_2$ with chloramine, $(CH_3)_2NN{=}CH_2$ and $(CH_3)_2NN{=}NN(CH_3)_2$ were found as side products, indicating the intermediate formation of dimethyldiazine.

$$NH_2Cl + (CH_3)_2N\text{–}NH_2 \longrightarrow (CH_3)_2NN + NH_4Cl \quad (383)$$

Amination of the hydroxide ion to form hydroxylamine is only fast enough in very basic solutions (here chloramine has already partly decomposed to hypochlorite and ammonia according to (372)):

$$NH_2Cl + OH^- \longrightarrow NH_2OH + Cl^- \quad (384)$$

Hydroxylamine cannot be isolated because it is rapidly aminated by chloramine to form the unstable hydroxylhydrazine H_2NNHOH, which eliminates water and forms diimine, whose decomposition has been described above (375). The net equation of the amination of hydroxide ions is therefore (361).

Analogous to the amination of NH_3, NH_2Cl, N_2H_4, sulfanes R_2S are aminated to $[R_2S\text{–}NH_2]^+Cl^-$, phosphanes R_3P are aminated to $[R_3P\text{–}NH_2]^+Cl^-$, arsanes R_3As are aminated to $[R_3As\text{–}NH_2]^+Cl^-$, and the cyanide ion CN^- is aminated to form cyanamide $NC\text{–}NH_2$.

Nucleophiles Nu^- attack the N–Cl bond ((371) and (378)), formally an electrophilic or nucleophilic substitution of chlorine. In the reaction of electrophiles E^+ with chloramine NH_2Cl, a nitrogen bound proton is substituted. This results in the transfer of the $NHCl^-$ to E^+.

$$E^+ + NH_2Cl \longrightarrow E\text{–}NHCl + H^+ \quad (385)$$

Examples for this reaction are the chloramidation of chlorine in hypochloric acid

$$NH_2Cl + HOCl \rightleftharpoons NHCl_2 + H_2O \quad (386)$$

or of chloramine (372).

In radicalic reactions, NH_2Cl can react as a chlorinating agent:

$$H_2C{=}C(CH_3)_2 \xrightarrow[NH_2Cl]{UV} H_2C{=}C(CH_3)CH_2Cl + CH_2Cl\text{–}CCl(CH_3)_2 \quad (387)$$

Saturated hydrocarbons react similarly:

$$HC(CH_3)_3 \xrightarrow[NH_2Cl]{UV} (CH_3)_3CCl + (CH_3)_2CHCH_2Cl \quad (388)$$

These reactions are believed to have a free radical mechanism where the neutral amino radical abstracts a hydrogen atom from the hydrocarbon.

$$NH_2Cl \longrightarrow H_2N\bullet + Cl\bullet \quad (389)$$

$$RH + H_2N\bullet \longrightarrow R\bullet + NH_3 \quad (390)$$

$$R\bullet + H_2NCl \longrightarrow RCl + H_2N\bullet \quad (391)$$

$$R\bullet + Cl\bullet \longrightarrow R\text{–}Cl \quad (392)$$

The oxidative power of chloramine has been used for the oxidative coupling of X–H bonds (X = nonmetal).

$$2Ph_2PH + NH_2Cl \longrightarrow Ph_2P\text{–}PPh_2 + NH_4Cl \quad (393)$$

$$5PhPH_2 + 5NH_2Cl \longrightarrow [PhP]_5 + 5NH_4Cl \quad (394)$$

Chloramine is used as a disinfectant for water because it is less aggressive than Cl_2 and more stable against light than ClO^-.

8.2.2 *Dichloramine*

Dichloramine is highly unstable and has not been isolated as a pure substance yet. Its yellow aqueous solutions are almost undissociated ($pK_a = 7$) and unprotonated.[135]

$$HNCl_2 \rightleftharpoons NCl_2^- + H^+ \quad (395)$$

$$HNCl_2 + H^+ \longrightarrow H_2NCl_2^+ \quad (396)$$

It is less polar than chloramine and has a higher solubility in unpolar solvents. Solutions containing NH_4^+ are relatively stable at pH = 3.5–4 with about 10% decomposition per day, whereas solutions without NH_4^+ ions decompose totally within hours. The ammonium ions inhibit the decomposition by reacting with hypochloric acid HOCl, which is formed in small amounts by the hydrolysis of $NHCl_2$ and accelerates the decomposition of dichloramine.

$$NH_4^+ + HOCl \longrightarrow NH_2Cl + H_3O^+ \quad (397)$$

The decomposition of dichloramine without NH_4^+ ions is dependant on the pH of the solution. In very acidic solution (pH $<$ 4), dichloramine disproportionates to trichloramine:

$$3HNCl_2 + H^+ \rightleftharpoons 2NCl_3 + NH_4^+ \quad (398)$$

In mildly acidic solution (pH = 4), dinitrogen and trichloramine are formed.

$$3HNCL_2 \longrightarrow NCl_3 + N_2 + 3HCl \quad (399)$$

At pH 12, hypochlorite is formed:

$$2HNCl_2 + 4OH^- \longrightarrow N_2 + 3Cl^- + ClO^- + 3H_2O \quad (400)$$

In the pH range of 4 to 12, both reactions (400) and (401) take place, for example, at pH = 7 the ratio of (400) and (401) is 1:10.

Dichloramine is an intermediate in the chlorination of NH_3 in acidic solution that leads to NCl_3 (see Section 8.2.3), but the best synthesis is the chlorination of ammonium ions with hypochloric acid (ratio NH_4^+:HOCl = 1:2) in dilute aqueous solution at pH values around 4. NH_2Cl is an intermediate in this reaction since the chlorination of NH_2Cl is slower than the chlorination of NH_3.

$$NH_4^+ + 2HOCl \rightleftharpoons NHCl_2 + H_3O^+ + H_2O \quad (401)$$

Dichloramine can be extracted with organic solvents. Comproportionation of NH_2Cl and NCl_3 in organic solvents at 195 K also gives dichloramine:

$$NCl_3 + NH_2Cl \rightleftharpoons 2NHCl_2 \quad (402)$$

As explained above, dichloramine is formed during the disproportionation of chloramine at pH 3.5–4, thus it can be obtained by adding perchloric acid to a solution of chloramine:

$$2NH_2Cl + H^+ \rightleftharpoons NHCl_2 + NH_4^+ \quad (403)$$

Pure, ammonia-free solutions of dichloramine can be obtained by passing chloramine through an acidic ion-exchange column (which exchanges NH_4^+ ions from the disproportionation reaction (403) against H^+).

In analogy to chloramines, dichloramine can react as a chlorinating agent and can transfer positive chlorine to ammonia or water.

$$HNCl_2 + NH_3 \longrightarrow 2NH_2Cl \quad (404)$$

$$HNCl_2 + H_2O \rightleftharpoons NH_2Cl + HOCl \quad (405)$$

The equilibrium of hydrolysis is on the side of $HNCl_2$. Hypochloric acid, which is formed during the hydrolysis of $HNCl_2$, chlorinates $HNCl_2$ to NCl_3.

$$HNCl_2 + HOCl \rightleftharpoons NCl_3 + H_2O \quad (406)$$

This reaction is much faster than the hydrolysis and lowers the HOCl concentration so that the hydrolysis equilibrium is shifted to the HOCl side. Excess $HNCl_2$ then reacts with the formed trichloramine to form decomposition products.

$$HNCl_2 + NCl_3 + 2H_2O \longrightarrow N_2 + 3HCl + 2HOCl \quad (407)$$

The formed hypochloric acid further accelerates the decomposition. The reaction rate of (407) increases rapidly with increasing pH so that the decomposition of NCl_3 according to (407) is faster than the formation of NCl_3, thus producing only a small static concentration and a small yield of NCl_3. In acidic solution, the decomposition of NCl_3 is slower, NCl_3 is formed in good yield.

8.2.3 *Nitrogen Trichloride*

Nitrogen trichloride is a dark yellow liquid ($\rho = 1.65\,g\,cm^{-3}$) that is only poorly soluble in water but dissolves well in nonpolar solvents like CCl_4 or CS_2. For the same reasons as for NF_3, NCl_3 has a low polarity ($\mu = 0.6(2)$ D). NCl_3 is a highly endothermic compound ($\Delta H_f = 229\,kJ\,mol^{-1}$) that explodes when heated to 363 K, after slight mechanical stress or by contact with oxidizable organic matter. The low solubility in water can cause the formation of droplets of NCl_3 in the aqueous solution that readily explode. The explosive decomposition produces dinitrogen and Cl_2 via a radical decomposition mechanism.

$$2NCl_3 \longrightarrow N_2 + 3Cl_2 \quad (408)$$

Nitrogen trichloride is more stable than chloramine and dichloramine. Decomposition occurs only slowly at room temperature. The decomposition is accelerated by light, arsenic trifluoride, or silver halides.

Nitrogen trichloride is formed in the reaction of chlorine with solutions of ammonium chloride in water at pH 3–4.[135]

$$NH_3 + 3Cl_2 \rightleftharpoons NCl_3 + 3HCl \quad (409)$$

Nitrogen trichloride is also produced by electrolysis of NH_4Cl solutions. The reaction is carried out in a buffer system because of the formed HCl. NCl_3 can be extracted with organic solvents like carbon tetrachloride. Ammonium ions can be chlorinated with hypochloric acid at pH 3–4:

$$NH_4^+ + 3HOCl \rightleftharpoons NCl_3 + H_3O^+ + 2H_2O \quad (410)$$

In this reaction, NH_2Cl and $NHCl_2$ are intermediates, the chlorination speed decreases from NH_4^+ over NH_2Cl to $NHCl_2$. Quantitative yields are not achieved because the NCl_3 formed can be attacked by $NHCl_2$ according to (407).

NCl_3 has a low basicity and decomposes on reaction with very strong acids HX, forming NH_4X and Cl_2. HCl reacts with NCl_3 to form ammonium chloride and chlorine:

$$NCl_3 + 4HCl \longrightarrow NH_4Cl + 3Cl_2 \quad (411)$$

Salts of $HNCl_3^+$ have not been isolated, but $HNCl_3^+$ has been observed mass spectrometrically. Addition of the Lewis acid Cl^+ to NCl_3 in SO_2 yields colorless NCl_4^+ ions (T_d symmetry):

$$2NCl_3 + Cl_2 + 3AsF_5 \longrightarrow 2NCl_4^+AsF_6^- + AsF_3 \quad (412)$$

Oxygen can also react with NCl_3, but $ONCl_3$ is only known in the form of the light yellow, planar cation $NOCl_2^+$ (d(N–Cl) 161 and 172 pm, d(N–O) 130 pm, <(ONCl) 118.5/117.9°, <(ClNCl) 118.5°):[136]

$$NCl_3 + SOCl_2 + SbCl_5 \longrightarrow NOCl_2^+SbCl_6^- + SCl_2 \quad (413)$$

A quaternary $ONCl(F)^+$ cation was formed in the reaction of NOCl with NF_2^+.

$$ONCl + N_2F^+AsF_6^- \xrightarrow{195\,K} ONCl(F)^+AsF_6^- + N_2 \quad (414)$$

$ONClF^+$ decomposes in SO_2 solution at 195 K in the course of several days to form NO^+ and ClF. The stability of the NOX_2^+ salts decreases in the order $NOF_2^+ > NOCl_2^+ \sim NOCl(F)^+$.

The reactions of NCl_3 with water and ammonia proceed as follows:

$$2NCl_3 + 3H_2O \longrightarrow N_2 + 3HOCl + 3HCl \quad (415)$$

$$2NCl_3 + 3NH_3 \longrightarrow N_2 + 3NH_2Cl + 3HCl \quad (416)$$

In these reactions, NCl_3 acts as a chlorinating agent by transferring positively charged chlorine Cl^+. During the slow hydrolysis of NCl_3, $NHCl_2$ and hypochloric acid are initially formed:

$$NCl_3 + H_2O \rightleftharpoons HNCl_2 + HOCl \quad (417)$$

The equilibrium is on the left side, but the $NHCl_2$ formed decomposes by the reaction with NCl_3 according to (407) to yield the overall equation (415).

The first step in the reaction of $HNCl_2$ and NCl_3 is the formation of tetrachlorohydrazine from the reaction of NCl_3 with the nucleophile NCl_2^-, which is formed from $HNCl_2$. Here NCl_3 is an electrophilic amination agent that transfers NCl_2^+.

$$NCl_3 + NCl_2^- \longrightarrow Cl_2NNCl_2 + Cl^- \quad (418)$$

The tetrachlorohydrazine formed is not stable, and instantly decomposes via the unstable dichlorodiazene N_2Cl_2 to dinitrogen.

$$Cl_2NNCl_2 + OH^- \longrightarrow ClNNCl + Cl^- + HOCl \quad (419)$$

$$ClNNCl + OH^- \longrightarrow N_2 + Cl^- + HOCl \quad (420)$$

The reaction of NCl_3 with bromide anions in aqueous solution proceeds via an $NBrCl_2$ intermediate to form dinitrogen and Br_2.[137]

8.3 Nitrogen Bromides

Aqueous solutions of bromamine NH_2Br are formed during the bromination of NH_3 with hypobromite:[4]

$$NH_3 + BrO^- \rightleftharpoons NH_2Br + OH^- \quad (421)$$

Ethereal solutions can be obtained by passing ammonia through an ethereal solution of Br_2.

$$2NH_3 + Br_2 \longrightarrow NH_2Br + NH_4Br \quad (422)$$

After the removal of insoluble NH_4Br, the ethereal solution is poured into pentane at 153 K, and black–violet NH_2Br precipitates.

NH_2Br is a weak base ($pK_b = 7.7$). In absence of ammonia, NH_2Br reacts in an equilibrium in aqueous and ethereal solutions to form dibromamine $NHBr_2$.

$$2NH_2Br \rightleftharpoons NHBr_2 + NH_3 \quad (423)$$

The equilibrium can be shifted to the right side by removing ammonia with $CaCl_2$ or acid. Solutions of $NHBr_2$ in ether are short-lived.

NH_2Br decomposes in the presence of ammonia more or less rapidly like chloramine ($t_{1/2} = 580$ min at 203 K, $t_{1/2} = 124$ min at 273 K, $t_{1/2} = 6.9$ min at 297 K).

$$3NH_2Br + 2NH_3 \longrightarrow N_2 + 3NH_4Br \qquad (424)$$

In this reaction hydrazine is an intermediate, but contrary to chloramine, hydrazine reacts rapidly with NH_2Br, so that hydrazine can not be isolated as in the NH_2Cl/NH_3 system.

The equilibria between the various bromination products of ammonia are strongly influenced by the pH value. At pH values above 9, the equilibria are displaced almost totally toward $BrNH_2$. With high NH_3:Br_2 ratios and pH values between 6.3 and 5.8, the very unstable $NHBr_2$ is the main species. At low NH_3:Br_2 ratios and pH values lower than 6, NBr_3 is the dominant product. NBr_3 can be extracted with various solvents such as chloroform, carbon tetrachloride, or ether. Pure NBr_3 is available by treating $(Me_3Si)_2NBr$ with BrCl in pentane at 286 K. NBr_3 is a deep red, insoluble substance in pentane that explodes easily even at 173 K.[138]

$$(Me_3Si)_2NBr + 2BrCl \longrightarrow NBr_3 + 2Me_3SiCl \qquad (425)$$

8.4 Nitrogen Iodides

Addition of I_2 to liquid ammonia at temperatures below 240 K results in the precipitation of green $NI_3{\cdot}3NH_3$. The reaction proceeds via ammonia-iodine charge transfer complexes ($I_2{\cdot}NH_3$ and $I_2{\cdot}2NH_3$ are known), to iodamine, diiodamine, and to triiodamine. At temperatures below 200 K, red $NI_3{\cdot}5NH_3$ is obtained.[4]

$$2I_2 + 2NH_3 \underset{}{\overset{\pm 2NH_3}{\rightleftharpoons}} 2H_3N{\cdot}I_2 \underset{\pm 2NH_4I}{\overset{\pm 2NH_3}{\rightleftharpoons}} 2NH_2I \overset{\pm NH_3}{\rightleftharpoons} NHI_2$$
$$\overset{\pm NH_2I}{\rightleftharpoons} NI_3{\cdot}NH_3 \overset{\pm 2NH_3}{\rightleftharpoons} NI_3{\cdot}3NH_3 \qquad (426)$$

At temperatures above 40 K, $NI_3{\cdot}3NH_3$ loses ammonia to form the red–brown to black $NI_3{\cdot}NH_3$. The ammonia adduct $NI_3{\cdot}NH_3$ precipitates when ammonia is passed through an aqueous solution of potassium triiodide. In an atmosphere with a high partial pressure of ammonia, it can be stored in the dark for a long time. The dry compound is extremely sensitive and explodes after the slightest mechanical stress, slight heating, or irradiation.

$$8NI_3{\cdot}NH_3 \longrightarrow 5N_2 + 6NH_4I + 9I_2 \qquad (427)$$

The equilibria (426) are reversible, and on the side of the ammonia-iodine charge transfer complex. Solvation of $NI_3{\cdot}NH_3$ in diethylether in the presence of ammonium iodide yields the ether-soluble charge transfer complex $NH_3{\cdot}I_2$.

$$NI_3{\cdot}NH_3 + 3NH_4I \rightleftharpoons 3NH_3{\cdot}I_2 + 2NH_3 \qquad (428)$$

Removal of ammonia from $NI_3{\cdot}NH_3$ in vacuo results in the decomposition to dinitrogen and iodine.

$$2NI_3{\cdot}NH_3 \longrightarrow 2NH_3 + N_2 + 3I_2 \qquad (429)$$

In $NI_3{\cdot}NH_3$, slightly distorted NI_4 tetrahedra are linked by shared corners into indefinite I–N–I–N–I chains ($d(N{-}I_{bridge})$ 230 pm, $d(N{-}I_{term})$ 214 pm). Ammonia forms a charge transfer complex with the terminal iodine atoms ($d(N{-}I{\cdots}NH_3)$253 pm).

When a saturated solution of $NI_3{\cdot}3NH_3$ in liquid ammonia in the presence of NH_4I is cooled to below 198 K, a red adduct $NH_2I{\cdot}NH_3$ (see (426)) precipitates. Storing this adduct at 183 K in vacuo results in the removal of ammonia to form the black iodamine NH_2I. Warming up NH_2I to 213 K in vacuo removes another ammonia molecule and yields the very unstable diiodamine NHI_2.

Pure nitrogen triiodide ($\Delta H_f = +290\ \text{kJ mol}^{-1}$)[139] can be obtained by the reaction of iodine fluoride with boron nitride at 263 K in CF_3Cl.

$$BN + 3IF \longrightarrow NI_3 + BF_3 \qquad (430)$$

The deep red substance can be purified by sublimation at 253 K under partial decomposition. It decomposes fast and often explosively. This makes NI_3 thermally more stable than NBr_3 but less stable than NCl_3.

8.5 Mixed Nitrogen Halides

8.5.1 *Dichlorofluoramine*

Dichlorofluoramine has a boiling point of 270 K and is explosive in the liquid as well as in the solid state. $FNCl_2$ can be prepared by passing a ClF/N_2 mixture over sodium azide:

$$2ClF + NaN_3 \xrightarrow{-N_2} Cl_2NF + NaF \qquad (431)$$

The low-temperature chlorination of $FC(O)NF_2$ is also a convenient method for the synthesis of Cl_2NF.[140] Alternatively, $FNCl_2$ can be obtained from ClF and ClN_3 in perfluorinated ether. Irradiation of $FNCl_2$ with a high-pressure Hg lamp leads to the formation of *cis*-N_2F_2.

8.5.2 *Chlorodifluoramine*

Chlorodifluoramine ($\Delta H_f >= -104\ \text{kJ mol}^{-1}$) boils at 207.1 K, and has a melting point below 78 K. In Pyrex glass, it is thermally stable up to 393 K, where it decomposes to NF_3, N_2, and Cl_2. Irradiation at wavelengths < 300 nm results in the reversible photochemical decomposition to N_2F_4 and Cl_2.[141]

$$2ClNF_2 \rightleftharpoons 2{\bullet}NF_2 + 2Cl{\bullet} \rightleftharpoons N_2F_4 + Cl_2 \qquad (432)$$

As a Lewis base, chlorodifluoramine is intermediate in strength between HNF_2 and NF_3. It reacts vigorously with NO even at low temperatures:

$$ClNF_2 + NO \longrightarrow NOCl + 0.5N_2F_4 \quad (433)$$

Chlorodifluoramine is accessible by chlorinating HNF_2 with gaseous Cl_2 in CCl_4 solutions or with aqueous NaOCl at 273 K and pH 6–6.5. At pH 12, the major product is N_2F_4, whereas between pH 6–12 both $ClNF_2$ and N_2F_4 result. Difluoramine also reacts with HOCl, *t*BuOCl, $SOCl_2$, $COCl_2$, HCl, ClF_3, and ClF to form $ClNF_2$.

Tetrafluorohydrazine is converted to $ClNF_2$ by chlorine under UV irradiation. Reaction of fluorine with chlorine azide also yields chlorodifluoramine.

8.5.3 Bromodifluoramine

Bromodifluoramine ($\Delta H_f >= -39\,kJ\,mol^{-1}$) is a colorless liquid with a boiling point of 237 K and decomposes rapidly on warming.[142] Bromodifluoramine is prepared by the reaction of aqueous bromine with HNF_2 in the presence of HgO.

$$HNF_2 + Br_2 \xrightarrow{HgO} BrNF_2 + HBr \quad (434)$$

It was also prepared from NF_2• and bromine radicals, which were generated by microwave discharge in an atmosphere of N_2F_4 and Br_2:

$$\bullet NF_2 + Br\bullet \longrightarrow BrNF_2 \quad (435)$$

8.5.4 Dibromoiodamine

The reaction of tribromamine with iodine in dichloromethane yields red–brown NBr_2I, which is stable up to 253 K.[138]

$$2NBr_3 + I_2 \longrightarrow 2NBr_2I + Br_2 \quad (436)$$

8.6 Halogen Azides

In the gas phase, the halogen azides have a *trans Cs*-configuration like HN_3 with an N–N–N bond angle around 171°.[127,143] The N–N bond lengths are significantly different.

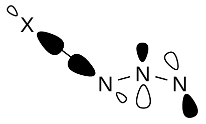


Figure 15 Negative hyperconjugation ion halogen azides XN_3

The N_α–N_β bond length is around 124 pm and N_β–N_γ is around 113 pm. The N_α–N_β bond can be considered as a long double bond, and the N_β–N_γ bond is a weak triple bond. The azides show a strong delocalization of the π-electron density over the complete molecule. A donor–accepter interaction leads to electron donation from a filled bonding σ(X–N_α) orbital to an empty antibonding $\pi*$(N_β–N_γ) orbital (see Figure 15).[144] The consequences of this negative hyperconjugation are the long and weak X–N_α bond, the short and strong N_α–N_β bond, the weak N_β–N_γ triple bond and the angle at the central N2 nitrogen atom.[145]

(437)

The crystal structure of iodine azide is polymeric with longer N–I distances than in the gas phase, because the IN_3 units are connected by linear coordinated iodine atoms.[146] Structural data of the halogen azides are summarized in Table 38.

The halogen azides are prepared by the reaction of metal azides with halogens or the hypohalogenic acids.

$$NaN_3 + HOCl \underset{}{\overset{H_2O}{\rightleftharpoons}} ClN_3 + NaOH \quad (438)$$

$$NaN_3 + Cl_2 \longrightarrow ClN_3 + NaCl \quad (439)$$

$$AgN_3 + I_2 \longrightarrow IN_3 + AgI \quad (440)$$

All halogen azides are sensitive and explode easily. The sensitivity decreases in the order $FN_3 > ClN_3 > BrN_3 > IN_3$. Fluorine azide decomposes to form dinitrogen difluoride and dinitrogen.

$$FN_3 \longrightarrow N_2F_2 + N_2 \quad (441)$$

The thermal decomposition of the other halogen azides is not initiated by the breaking of the X–N_3 bond, but, at least in

Table 38 Structural data of halogen azides compared to HN_3

	HN_3 (g)	FN_3 (g)	ClN_3 (g)	BrN_3 (g)	IN_3 (g)	IN_3 (s)

the gas phase, by dissociation into XN(X $^3\Sigma^-$) and N_2(X $^1\Sigma_g^+$).[147]

$$XN_3(XA') \longrightarrow XN(X^3\Sigma^-) + N_2(X^1\Sigma_g{}^+) \qquad (442)$$

Even though this decomposition is spin forbidden, pyrolysis experiments have clearly shown the fragmentation into XN(X $^3\Sigma^-$) fragments and N_2. The end products of the decomposition of chlorine, bromine, and iodine azide are dinitrogen and the dihalides. Iodine also forms other azide species, the orange $I(N_3)_2{}^-$, the deep violet $I_2N_3{}^-$,[148] the deep carmine–red $I_2N_3{}^+$,[149] and the yellow $I(N_3)_2{}^+$.[150]

$$NMe_4{}^+N_3{}^- + IN_3 \longrightarrow NMe_4{}^+[I(N_3)_2]^- \qquad (443)$$

$$NMe_4{}^+I^- + IN_3 \longrightarrow NMe_4{}^+[I_2N_3]^- \qquad (444)$$

$$AgN_3 + I_3SbF_6{}^- \xrightarrow[SO_2]{223\,K} AgI + [I_2N_3]^+SbF_6{}^- \qquad (445)$$

$$ICl_2AsF_6{}^- + 2AgN_3 \longrightarrow 2AgCl + [I(N_3)_2]^+AsF_6{}^- \qquad (446)$$

Chlorine, bromine, and iodine azide can act as donors of positive halides. The reaction of chlorine azide with water yields hydrazoic acid and hypochloric acid:

$$ClN_3 + H_2O \rightleftharpoons HN_3 + HOCl \qquad (447)$$

The halogen azides XN_3 (X = Cl, Br, I) react with element chlorides (e.g. BX_3, AlI_3, $SnCl_4$, $SbCl_5$, $TiCl_4$, $NbCl_5$, $TaCl_5$, $CrCl_3$, WCl_6, $ReCl_5$, UCl_6) under halogen elimination to form the element halogenide azides.[151]

$$X_{n-1}EX + XN_3 \longrightarrow X_{n-1}EN_3 + X_2 \qquad (448)$$

With other element halides ($SnCl_2$, PCl_3, and $SbBr_3$) oxidative addition occurs:

$$X_nE + XN_3 \longrightarrow X_{n+1}EN_3 \qquad (449)$$

9 OXOHALIDES OF NITROGEN

9.1 Nitrosyl Halides

The nitrosyl halides all assume an angular structure. In the gas phase, the nitrogen–halogen bond distances are quite long (see Table 39) compared to NF_3 (136.5(2) pm) and NCl_3 (175.9(2) pm) and the nitrogen–oxygen bond distances are so short that they are in the range of triple bonds.

(450)

μ [D]	1.81	0.42	–

The bond polarity has a strong influence on the N–X bond length, for less basic groups X^- a complete shift to NO^+X^- is observed (e.g. NO^+ $PF_6{}^-$, NO^+ $ClO_4{}^-$). In the solid state, both NOF and NOCl show longer N–X bonds and shorter N–O bonds. The effect is more pronounced for chlorine and is explained in terms of a stronger ionic character in the solid state.[152] IR data indicate a similar behavior of NOBr.[153] For a detailed analysis of the bonding situation, see Ref. 154.

Nitrosyl halides can be obtained by the direct reaction of the respective halides with nitrogen monoxide at slightly elevated temperatures (310–320 K).

$$2NO + X_2 \longrightarrow 2NOX \qquad (451)$$

In the case of fluorine, NOF_3 is also produced during this reaction. The stability of the nitrosyl halides decreases in the order F > Cl > Br. NOCl is 0.5% decomposed at 298 K, NOBr is 7% decomposed, and nitrosyl iodide is unstable and decomposes rapidly to nitrogen monoxide and iodine, and has so far only been observed in matrix isolation at 9K.

$$2NOI \longrightarrow 2NO + I_2 \qquad (452)$$

NOCl decomposes at 373 K to form NO and chlorine. NOCl is present in aqua regia and is responsible for its red–yellow color. In the presence of traces of water, NOCl is very aggressive and can only be stored in Tantalum or glass vessels. Dry NOCl does not attack nickel, lead, platinum, and some polymers.

NOCl is the mixed anhydride of nitrous acid and hydrochloric acid and is easily hydrolyzed by water.

$$NOCl + H_2O \rightleftharpoons HNO_2 + HCl \qquad (453)$$

Therefore, water has to be excluded during the synthesis, for example, by passing HCl gas into liquid N_2O_3 in the presence of P_2O_5 as a dehydrating agent.

$$N_2O_3 + 2HCl \longrightarrow 2NOCl + H_2O \qquad (454)$$

In another synthesis, sodium chloride reacts with nitrosyl hydrogensulfate to form NOCl:

$$NO^+HSO_4^- + NaCl \longrightarrow NOCl + NaHSO_4 \qquad (455)$$

A laboratory synthesis uses sodium nitrite and hydrochloric acid:

$$NaNO_2 + 2HCl \longrightarrow NOCl + NaCl + H_2O \qquad (456)$$

Other preparations include the treatment of KNO_2–$AlCl_3$ melts with ammonium chloride, reaction of nitric acid with HCl in aqua regia, or the reactions of metal chlorides with nitric acid.

NOF, NOCl, and NOBr form NO^+ salts in reactions with halogen acceptors:

$$NOF + BF_3 \longrightarrow NO^+BF_4^- \qquad (457)$$

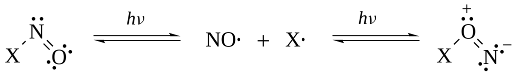
$$NOCl + SbCl_5 \longrightarrow NO^+SbCl_6^- \qquad (458)$$

NOBr has been obtained from nitrogen dioxide and potassium bromide:

$$2NO_2 + KBr \longrightarrow NOBr + KNO_3 \qquad (459)$$

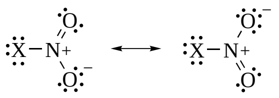
In the system, NO/Br_2 $NOBr_3$ is the main compound found below 293 K, above 313 K NOBr is the main compound.[155]

The photosensitive isonitrosylhalides NOX (X = Cl, Br) can be obtained using matrix-isolation technique by irradiation of the nitrosyl halides.[156]



(460)

9.2 Nitryl Halides



(461)

The nitryl halides (C_{2v} symmetry) are planar in analogy to the isoelectronic CO_3^{2-}. The gas phase and solid-state structures for $ClNO_2$ both show covalently bound molecules (see Table 40).[154] In contrast to the nitrosyl halides, the halogen–nitrogen bond distances in the gas phase and in the solid state are similar.[152] The nitryl halides NO_2F and NO_2Cl are the mixed anhydrides of nitric acid and hydrofluoric or hydrochloric acid, respectively.

$$XNO_2 + H_2O \rightleftharpoons HNO_3 + HX \qquad (462)$$

Table 40 Properties and bonding parameters of nitryl halides

<(O–N–O) [°]	125	gas: 130.6(2) solid: 130.4(1), 131.1(1)
μ [D]	0.47	0.42

Similar to the nitrosyl halides, the nitryl halides are easily hydrolyzed. During the synthesis, water has to be excluded, either by removing it:

$$HNO_3 + HCl + H_2SO_4 \longrightarrow ClNO_2 + H_3O^+SO_4H^- \qquad (463)$$

$$HNO_3 + HSO_3Cl \longrightarrow ClNO_2 + H_2SO_4 \qquad (464)$$

or by using a synthetic route that does not produce water:

$$N_2O_5 + NaF \longrightarrow FNO_2 + NaNO_3 \qquad (465)$$

The oxidation of nitrosyl chloride with ozone, N_2O_5, Cl_2O, and ClO_2 also yields nitryl chloride.

$$NOCl + N_2O_5 \longrightarrow ClNO_2 + 2NO_2 \qquad (466)$$

Nitrosyl fluoride was also made from NO_2 and CoF_3 and by the reaction of nitryl chloride with hydrogen fluoride:

$$NO_2 + CoF_3 \longrightarrow FNO_2 + CoF_2 \qquad (467)$$

$$ClNO_2 + HF \longrightarrow FNO_2 + HCl \qquad (468)$$

The stability of the nitryl halides follows the stability of the nitrosyl halides, F > Cl > Br > I. Nitryl bromide $BrNO_2$ exists in equilibrium with NO_2/N_2O_4 at room temperature and can be studied spectroscopically.[157] INO_2 has a lifetime of only a few seconds at room temperature.

$$2NO_2Br \rightleftharpoons 2NO_2 + Br_2 \qquad (469)$$

Reaction of the nitryl halides with strong Lewis acids yields nitryl salts with the linear NO_2^+ cation (**92**) (d(N=O) 115.4 pm) (see Figure 16).

$$NO_2F + BF_3 \longrightarrow NO_2^+BF_4^- \qquad (470)$$

(**92**)

Figure 16 Lewis structure of the NO_2^+ cation

At low temperatures, the structural isomers, the halogen nitrites (nitrosyl hypohalides) XONO can be observed in the photolysis reaction of X_2/NO_2 mixtures.

$$2NO_2 + X_2 \xrightarrow{h\nu} 2ONOX \qquad (471)$$

Nitryl chloride reacts with zinc, mercury, and bismuth to form mixtures of the metal chlorides and nitrates, but does not react with copper, magnesium, iron, aluminum, or tin at 243 K. In the reaction with ammonia, nitryl chloride acts as a source of positive chlorine:

$$ClNO_2 + 2NH_3 \longrightarrow ClNH_2 + NH_4NO_2 \qquad (472)$$

9.3 Trifluoramine Oxide

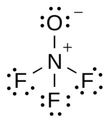
Trifluoramine oxide (**93**) (Figure 17) is a colorless and highly toxic gas ($\Delta H_f = -71\,\text{kJ mol}^{-1}$) with a melting point of 113 K and a boiling point of 185.6 K. It has a tetrahedral structure (C_{3v} symmetry) and is isoelectronic to NF_4^+.[154] The NF bond length (143 pm) is significantly longer than in NF_4^+ (130 pm), the NO bond length (116 pm) is shorter than the NO bond length in HNO (121 pm), thus indicating a bond order of around 2.

The bonding situation can be explained by negative hyperconjugation. Electron density is transferred from the oxygen p lone pairs to one of the antibonding $\sigma*$ (N–F) orbitals, thus strengthening the NO bond and weakening the NF bonds. The reaction of NF_3 and O_2 in electric discharge results in formation of NOF_3.

$$2NF_3 + O_2 \xrightarrow{77\,K} 2ONF_3 \qquad (473)$$

ONF_3 is also accessible from the reaction of nitrosyl fluoride with iridium hexafluoride:

$$3NOF + 2IrF_6 \longrightarrow ONF_3 + 2(NO)IrF_6 \qquad (474)$$



(**93**)

Figure 17 Lewis structure of F_3NO

Other methods for the preparation of ONF_3 include the fluorination of NO and the reaction of NF_3 with N_2O.[158]

$$2NO + 3F_2 \longrightarrow 2ONF_3 \qquad (475)$$

$$NF_3 + N_2O + 2SbF_5 \xrightarrow{423\,K} 2ONF_2^+Sb_2F_{11}^- + N_2 \qquad (476)$$

$$ONF_2^+Sb_2F_{11}^- \xrightarrow{>450\,K} ONF_3 + 2SbF_5 \qquad (477)$$

Irradiation with ultraviolet light forms the NOF_2• radical. NOF_3 decomposes at temperatures above 600 K to yield NOF, NO, NO_2, and NO_2F. It is a strong oxidizing agent toward organic and inorganic compounds.

As for NF_3, reactions with NOF_3 require an activation energy and do not occur spontaneously at room temperature, even though they are thermodynamically favored. In many instances, reactions result in fluorination rather than oxygenation, in keeping with the greater strength of the N–O bond.

$$NF_3O + SF_4 \xrightarrow{h\nu} NOF + SF_6 \qquad (478)$$

On reaction with strong fluorine acceptors (BF_3, AsF_5, SbF_5), NOF_3 can loose fluoride and form the planar ONF_2^+ cation (d(N–F) 128.4 pm, d(N–O) 111.4 pm, <(F–N–F) 107.9°, <(F–N–O) 126.0°).[159]

$$ONF_3 + AsF_5 \longrightarrow ONF_2^+AsF_6^- \qquad (479)$$

The NOF_2^+ cation reacts with HN_3 to form the N_3NOF^+ cation:

$$NOF_2^+SbF_6^- + HN_3 \longrightarrow N_3NOF^+SbF_6^- + HF \qquad (480)$$

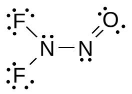
9.4 Nitrosodifluoramine

The reaction of the normally relatively unreactive N_2O with difluorine gas at 77 K under UV irradiation yields a dark blue liquid, nitrosodifluoramine F_2NNO (**94**) (Figure 18).[160]

$$F_2 + N_2O \xrightarrow{77\,K,\ UV} F_2NNO \qquad (481)$$

Nitrosodifluoramine (**94**) can also be obtained by reacting tetrafluorohydrazine with a tenfold excess of NO at 583 K followed by quenching at 77 K.

$$N_2F_4 + 2NO \xrightarrow{77\,K,\ UV} 2F_2NNO \qquad (482)$$



(**94**)

Figure 18 Lewis structure of F_2NNO

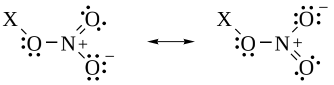
Nitrosodifluoramine (**94**) decomposes at 133 K to form tetrafluorohydrazine and NO, the reverse of the formation reaction (481).

$$F_2NNO \xrightarrow{133\,K} F_2 + N_2O \quad (483)$$

9.5 Halogen Nitrates

The halogen nitrates have planar C_s structures (see Table 41). The dissociation to XO and NO_2 gets easier from fluorine to iodine.



(484)

In the gas phase, the N–O bonds of chlorine and bromine nitrate are shorter and the O–X bonds longer than in the crystal structure.[154,161] In the solid state of the halogen nitrates, as for the nitrosyl halides, the contribution of the ionic X^+ NO_3^- structure is higher.[152] This makes the N–O bond shorter and the O–X bond longer. The crystal structures can be considered as adducts of the halogen oxide XO• and the NO_2• radicals.

Fluorine nitrate is best prepared by the fluorination of nitric acid:

$$F_2 + HNO_3 \longrightarrow FONO_2 + HF \quad (485)$$

The chlorine compound can by synthesized from nitric acid and ClF:

$$ClF + HNO_3 \longrightarrow ClONO_2 + HF \quad (486)$$

or by reacting N_2O_5 with Cl_2O at 253 K:

$$Cl_2O + N_2O_5 \longrightarrow 2ClONO_2 \quad (487)$$

The chlorine, bromine, and iodine nitrates (X = Cl, Br, I) can also be prepared by the reaction of silver nitrate with the halides.

$$X_2 + AgNO_3 \longrightarrow XONO_2 + AgX \quad (488)$$

Bromine nitrate reacts with N_2O_5 to form an adduct.

$$BrONO_2 + N_2O_5 \longrightarrow NO_2^+[Br(ONO_2)_2^-] \quad (489)$$

Bromine nitrate disproportionates to bromine, oxygen, and N_2O_5 at 273 K:[162]

$$2BrONO_2 \longrightarrow Br_2 + 0.5O_2 + N_2O_5 \quad (490)$$

The unstable chloryl nitrate was detected in the reaction of ClO_2 with NO_3:[163]

$$ClO_2 + NO_3 \xrightarrow{(M)} O_2ClONO_2 \quad (491)$$

and bromyl nitrate from the ozonization of bromine nitrate at 196 K:

$$BrONO_2 + 2O_3 \longrightarrow O_2BrONO_2 + 2O_2 \quad (492)$$

Bromyl nitrate thermally decomposes to dibromine, dioxygen, and nitrogen dioxide.

$$2O_2BrONO_2 \longrightarrow Br_2 + 2NO_2 + 3O_2 \quad (493)$$

The high levels of chlorine radicals ClO_x observed in the polar stratosphere couple with nitrogen oxides NO_x, resulting in the removal of reactive chlorine species by conversion into

temporary reservoir species. The association reaction between ClO and NO_2 forming chlorine nitrate has been considered the most significant:

$$ClO\bullet + NO_2\bullet \xrightarrow{(M)} ClONO_2 \quad (494)$$

Chlorine nitrate and HCl are considered to be the most important chlorine reservoir species in the stratosphere.[164] Iodine nitrate has also been considered as a reservoir species for iodine radicals that could destroy tropospheric ozone, but photodissociation of $IONO_2$ to form iodine radicals is only effective at temperatures below 290 K, at higher temperatures thermal decomposition takes place which does not yield iodine radicals.[165]

Several iodine nitrates in the oxidation state +III are known: $I(ONO_2)_3$ and $CF_3I(ONO_2)_2$.[166] The other halogens do not form binary nitrates in the oxidation state +III. Iodine (III) nitrates are available by substitution of iodine(III)compounds

$$ICl_3 + 3ClONO_2 \longrightarrow I(ONO_2)_3 + 3Cl_2 \quad (495)$$

or by the oxidation of iodine(I) compounds:

$$CF_3I + 2ClONO_2 \longrightarrow CF_3I(ONO_2)_2 + Cl_2 \quad (496)$$

$I(ONO_2)_3$ has also been prepared by the oxidation of iodine with $ClONO_2$ at 238 K:

$$I_2 + 6ClONO_2 \longrightarrow 2I(ONO_2)_3 + 3Cl_2 \quad (497)$$

Vibrational spectra indicate a polymeric structure with bridging nitrate ligands for $I(ONO_2)_3$. The fluffy light yellow solid decomposes at 273 K to form N_2O_5 and $IONO_2$, which is only marginally stable and decomposes under formation of N_2O_5.

$$I(ONO_2)_3 \longrightarrow OINO_3 + N_2O_5 \quad (498)$$

The $XeNO_3^+$ cation, which is isoelectronic to the halogen nitrates has been detected in a mass spectrometer and seems to have the same connectivity as the halogen nitrates, but can isomerize to an $OXeNO_2$ structure. $XeNO_2^+$ was also detected, here xenon acts as a ligand of the nitronium ion. In the solid state, $NO_2^+Xe_2F_{13}^-$ consists of $X_2F_{13}^-$ and nitronium ions. In solution, the reaction of xenon difluoride with a HNO_3/NO_2 mixture produces the neutral species $Xe(ONO_2)_2$.[167]

1 INTRODUCTION

Reduced nitrogen is essential to all forms of life for it is present in many important and universal biological molecules such as nucleotides and amino acids, the building blocks of DNA and proteins. Although abundant in its molecular state in today's earth atmosphere (78%), dinitrogen is very difficult to reduce. Indeed, the N≡N triple bond dissociation energy, as high as $940\,kJ\,mol^{-1}$, and the unstability of some reduced intermediates make N_2 kinetically very stable. Thermodynamically, however, its reduction is generally favorable: for instance ΔG^0 for $N_2 + 3H_2 \rightarrow 2NH_3$ is $-32\,kJ\,mol^{-1}$ in the gas phase.[1] Hence, dinitrogen is often referred to as an inert medium, as inferred by the Greek root of its name in French: *azote* (without life). Nevertheless, a restricted class of microorganisms called diazotrophs, comprising different archaea and bacteria, are able to overcome this relative inertness thanks to the nitrogenase enzyme, which catalyzes the biological reduction of dinitrogen to ammonia (*see* ***Nitrogenase Catalysis & Assembly***). Ammonia, in the protonated form of ammonium, is indeed the primary entry point of fixed nitrogen into the living world, mainly via the glutamate/glutamine biosynthesis pathway of plants. Before the advent of an efficient artificial ammonia synthesis (the Haber–Bosch process) at the beginning of the twentieth century,[2] dinitrogen reduction by nitrogenases was even the major (and almost the sole) provider of primary assimilable nitrogen for living organisms.[3]

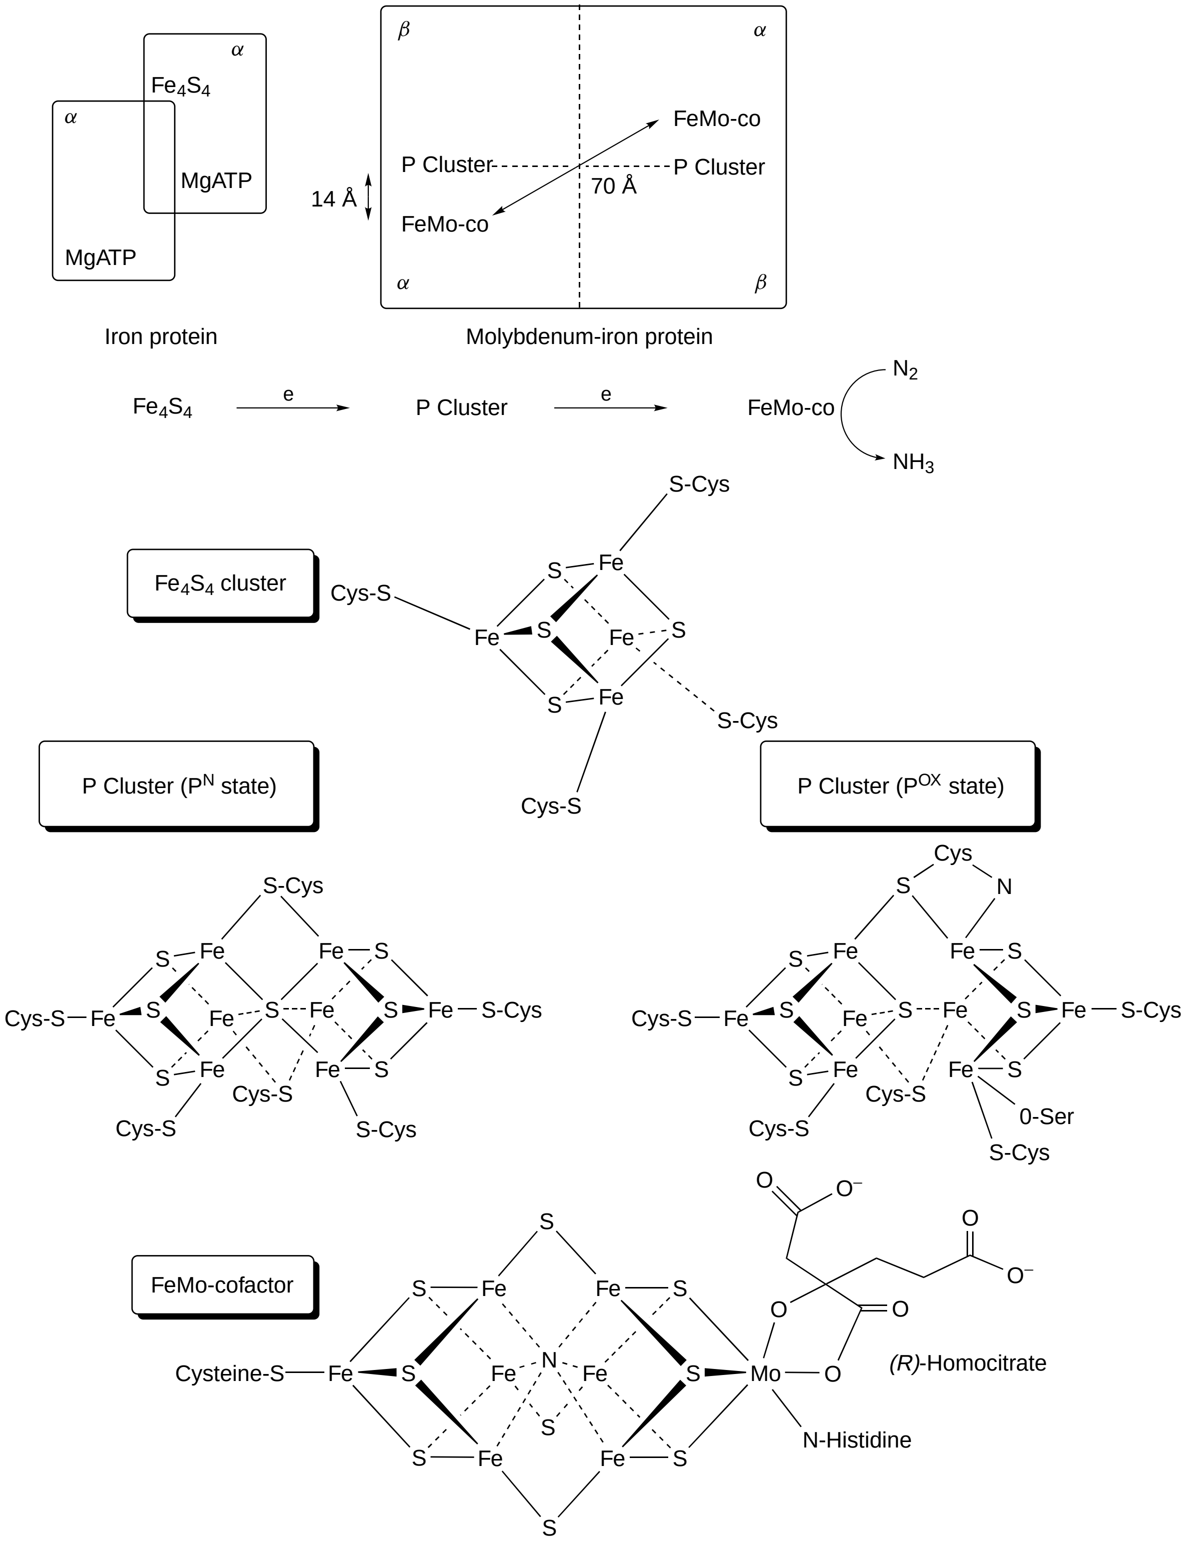
The most extensively studied nitrogenase enzyme contains two kinds of transition metals, that is, iron and molybdenum, and is called molybdenum nitrogenase.[4–7] In growth conditions where molybdenum concentration is low, a nitrogenase depending on iron and vanadium is expressed.[8–11] When both molybdenum and vanadium are unavailable, a third type of nitrogenase is expressed that contains iron as the only transition metal.[8,12,13] The vanadium–nitrogenase and iron-only nitrogenases, also known as alternative nitrogenases, are related to the molybdenum nitrogenase but are all genetically distinct. A fourth and completely different 'nonconventional' type of nitrogenase is known; it also contains iron and molybdenum, but couples dinitrogen reduction to the oxidation of superoxide and carbon monoxide.[14]

Mo-nitrogenase is the only one for which both detailed structural and mechanistic data are available.[4–7,15–17] The enzymatic complex comprises two proteins: the iron-protein and the molybdenum iron-protein. The Fe-protein is an α_2 homodimer with a Fe_4S_4 cluster (*see* ***Iron–Sulfur Models of Protein Active Sites***; ***Iron–Sulfur Proteins***) bridging the two α-subunits via four iron-cysteinate ligations. Each α-monomer of the iron-protein possesses a nucleotide-binding site (ATP or ADP). The Fe-protein is a specific reductant of the MoFe-protein, an event that depends on, and is coupled to, the hydrolysis of MgATP. The MoFe-protein is an $\alpha_2\beta_2$ tetramer and contains two types of metal–sulfur centers: the so-called P-cluster of Fe_8S_7 stoichiometry that is located at the interface of each homologous $\alpha-\beta$ subunit, and the FeMo-cofactor ($MoFe_7S_9$) found in each α-subunit.

Two different structures are known for the P-cluster and are assigned to different cluster core oxidation states. In the reduced or P^N (native) state, the Fe_8S_7 cluster can be described as two Fe_4S_4 cubes sharing one common hexacoordinate sulfur atom, the iron atoms being linked to the protein by cysteinate ligands, two of them bridging the subcubes. In the P^{OX} state, oxidized by two electrons relative to P^N, the central sulfur atom loses two bonds with two iron atoms in one of the subcubes, thus becoming more open. The tetrahedral coordination of these two iron atoms is then completed by extra ligations from neighboring cysteine or serine residues.

The FeMo-cofactor structure can be viewed as the assembly of two incomplete $Fe_4(\mu_3\text{-}S)_3$ and $MoFe_3(\mu_3\text{-}S)_3$ subcubes, linked together by three central μ_2-S bridging sulfide ligands. The six central iron atoms form an approximate trigonal prism centered on a light atom 'Y' that has only been structurally recognized recently.[17] The identity of the light atom has been proposed to be nitrogen although carbon or oxygen have not been ruled out, while sulfur seems to be less likely. Theoretical investigations from different authors also concluded that 'Y' is most likely a nitrogen atom.[18–20] The pseudooctahedral coordination of molybdenum is completed by the exogenous bidentate (R)-homocitrate ligand and by imidazole from a neighboring histidine residue. A cysteine residue, covalently bound to the tetrahedral apical iron atom, provides the cofactor with its other protein ligation. The structure and location of the Mo-nitrogenase metal clusters are depicted in Figure 1.

The electrons transferred from the Fe_4S_4 cluster of the iron-protein to the molybdenum–iron protein are believed to shuttle through the P-cluster before eventually reaching



$$N_2 + 8H^+ + 16MgATP + 8e^- \longrightarrow 2NH_3 + H_2 + 16MgADP + 16P_i$$

Figure 1 Schematic representation of the Fe-protein (60 kD, α_2 dimer) and the MoFe-protein (250 kD, $\alpha_2\beta_2$ tetramer) of the Mo-nitrogenase. Outline of the electron transfer path through the metal clusters. Structure of the Fe_4S_4 cluster of the Fe-protein. Structure of the P-cluster (in two oxidation states) and of the FeMo-cofactor in the MoFe-Protein. Limiting stoichiometry for the function of Mo-nitrogenase

the FeMo-co where N_2 binding, reduction, and protonation occurs.

The limiting stoichiometry for the reduction of one equivalent of dinitrogen by Mo-nitrogenase to two equivalents of ammonia involves the hydrolysis of 16MgATP and the production of one molecule of dihydrogen, as outlined in Figure 1. The three metal clusters found in Mo-nitrogenase belong to the diverse class of iron–sulfur prosthetic centers largely distributed in all living organisms.[21–24] However, while the Fe_4S_4 center is a common cluster found in many other iron–sulfur proteins, the P-cluster and the FeMo-cofactor represent to date unique structures in biology.

The complexity of the enzyme system, together with the extraordinary ambient conditions of transition metal-assisted dinitrogen reduction, have long fascinated inorganic chemists, still left with the high-temperature and high-pressure Haber–Bosch process for the artificial synthesis of ammonia from molecular nitrogen and hydrogen.

The current status of nitrogenase metal-cluster modeling by synthetic inorganic clusters and complexes is reported here. Modeling is to be understood not only in terms of structure and associated spectroscopic properties, but also in terms of function, that is, how well the models reproduce, or help to understand, the biological role of the metal–sulfur assemblies in nitrogenase, that is, electron transfer and the reduction of substrates.

The sequential electron transfer path in nitrogenase is followed: first models of the Fe_4S_4 cluster of the iron-protein are discussed, then mimics of the P-cluster in the molybdenum–iron protein, and finally structural and functional models of the FeMo-cofactor are summarized.

2 MODELS FOR THE Fe_4S_4 CLUSTER OF NITROGENASE

Fe_4S_4 clusters with cysteinate ligation at iron, in their $[Fe_4S_4]^{1+/2+/3+}$ redox states, are of pervasive occurrence in iron–sulfur proteins, functioning mostly as electron transfer relays as in ferredoxins (1+/2+) and high-potential iron proteins (2+/3+) (*see* ***Iron–Sulfur Proteins***). Examples are also known where they are implied in catalysis.[21,22] In Mo-nitrogenase,[4] the Fe-protein specifically reduces the MoFe-protein with its Fe_4S_4 cluster cycling between the $[Fe_4S_4]^{1+}$ and $[Fe_4S_4]^{2+}$ redox states at a potential of −0.31 V versus the normal hydrogen electrode (NHE), that is lowered by about 0.1 V upon nucleotide binding. The Fe_4S_4 cluster is symmetrically bridged between the α-subunits of the iron-protein and is accessible to solvent molecules (H_2O). Vicinal amino acid residues provide NH-S hydrogen bonds from amide groups to the iron–sulfur center. The $[Fe_4S_4]^0$ state can be artificially generated as a stable center within the protein (−0.79 V vs. NHE), however it is not known if this state is biologically relevant.[25,26]

The iron–sulfur cluster of the iron-protein in its $[Fe_4S_4]^{1+}$ redox state exists in a mixture of spin states of similar energy in frozen solution (S = 3/2) and (S = 1/2). However, proton NMR analysis suggests that in standard conditions only one spin state is populated (S = 1/2). Proton NMR spectroscopy is useful for the analysis of paramagnetic iron–sulfur clusters (those with the $[Fe_4S_4]^{1+}$ and $[Fe_4S_4]^{3+}$ core). Indeed, significant low- or high-field hyperfine isotropic shifts for the resonance of the protons bound at the carbon β to an iron center greatly simplify the analysis of the chemical environment of each iron center of the protein even if the signal is usually broad. ^{57}Fe Mössbauer spectroscopy is a method of choice to assign the overall core oxidation state of a native or synthetic iron–sulfur cluster. There exists an empirical linear relationship between the ^{57}Fe Mössbauer spectroscopy isomer shift (i.s.) and the oxidation state (or mean oxidation state) of an iron center (or a cluster of iron centers) in a pseudo-tetrahedral sulfur environment.[27]

Synthetic structural models for the Fe_4S_4 clusters have been known for three decades now.[27] They are readily prepared by self-assembly from ferric or ferrous chloride, a source of reduced sulfur and thiolates, acting as ligands to the iron sites (Figure 2). Ligand-substitution reactions at the iron centers allow the tuning over a large window of their redox potential that is linearly linked to the electron donor/acceptor properties of the ligands, usually an alkyl or phenyl thiolate, or a halide (Figure 2). Crystal structures of model Fe_4S_4 clusters with thiolate ligands are available for all $[Fe_4S_4]^{1+/2+/3+}$ redox states, the $[Fe_4S_4]^0$ state being only transiently generated in solution.

It has been shown that the Fe_4S_4 cluster of the Fe-protein can be further reduced with nonbiological reductants from the $[Fe_4S_4]^{1+}$ to the $[Fe_4S_4]^0$ (all ferrous) redox state, which suggests that the Fe-protein could transfer two electrons per reduction cycle to the MoFe-protein.[25] Although there is no precedence for a functional $[Fe_4S_4]^0$ state in biology, this is an attractive proposal considering that (1) substrates of nitrogenase can be reduced by multiple of two electrons, (2) the dicubane structure of both the P-cluster and the FeMo-cofactor is perhaps tailored to accept two electrons at once and (3) the homodimeric structure of the Fe-protein that may bind two donor molecules at a time.[26,28] Moreover, the redox potential originally reported for the $[Fe_4S_4]^{1+/0}$ redox couple (−0.46 V vs. NHE) was well within physiological range and only 150 mV negative of that of the $[Fe_4S_4]^{2+/1+}$ redox couple. The biological relevance of the $[Fe_4S_4]^0$ oxidation state however is contentious. In synthetic models with thiolate ligands, the all-ferrous redox state ($[Fe_4S_4]^0$) is only detected transiently in some instances at the cyclic voltammetry timescale, and has only been generated, but not isolated, as a persistent species in solution in the case of $Fe_4S_4(PR_3)_4$ bearing less relevant phosphine ligands, known to stabilize reduced oxidation states of metal complexes. Such a narrow potential separation ($\Delta E = 0.15$ V) between the 2+/1+ and

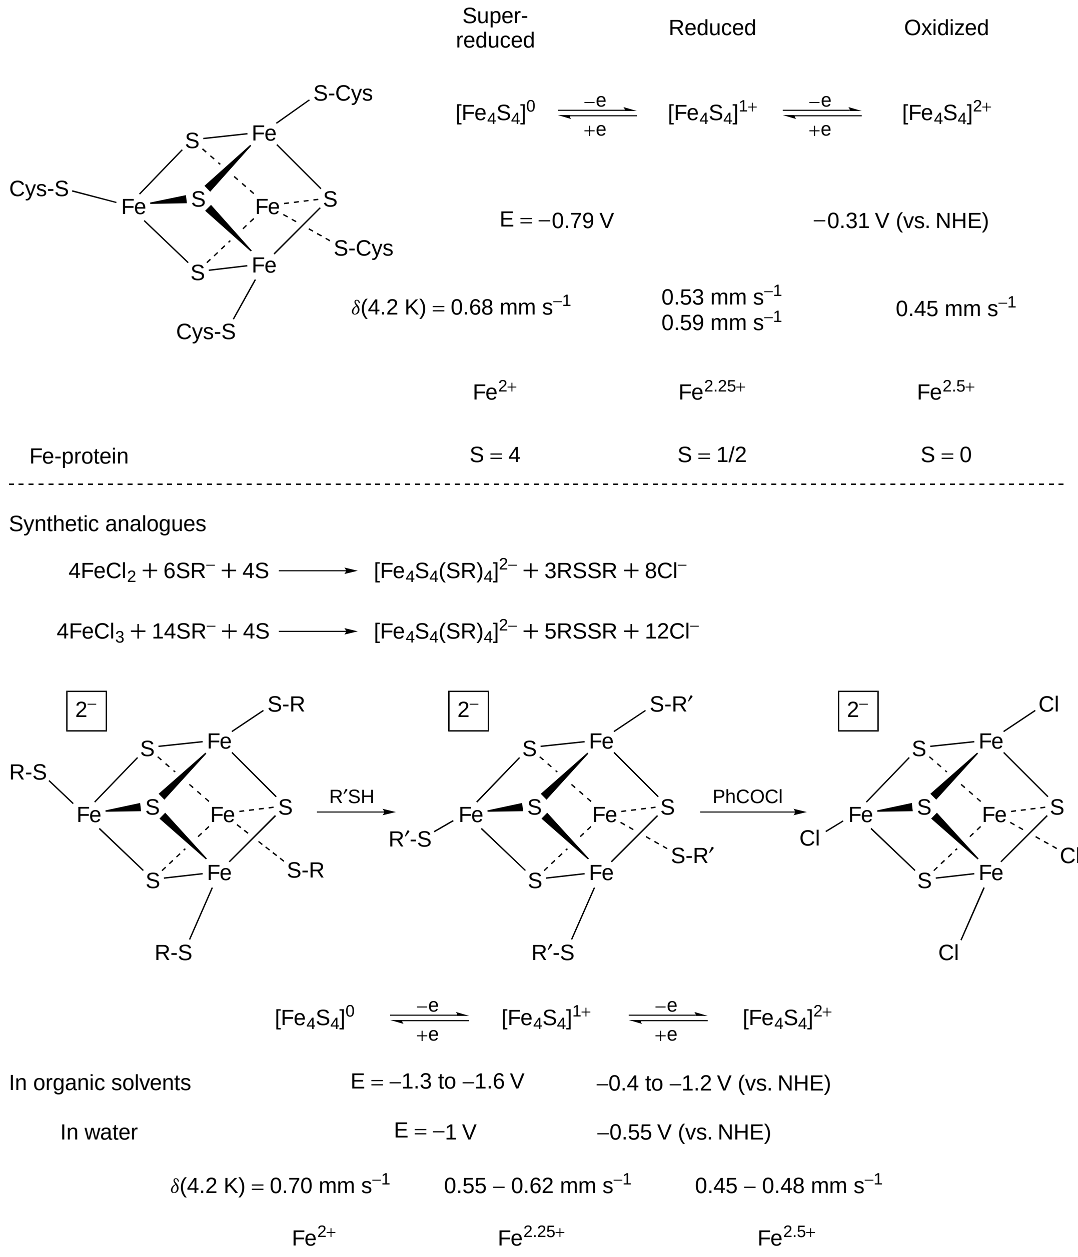


Figure 2 Electron transfer series in native and synthetic model clusters of the Fe_4S_4 center in the Fe-protein. Syntheses and ligand-substitution reactions are indicated for synthetic clusters

1+/0 redox couples of the iron-protein Fe_4S_4 cluster, was hard to reconcile with redox potentials of synthetic models. Indeed, a range of models with ligands differing by their charge, structure, and electron-withdrawing properties, has been studied electrochemically in dipolar aprotic organic solvent electrolytes (MeCN, DMF, DMSO) in order to assess the effect of the direct environment of the cluster core on its redox potentials.[29] The measured Δ E between the 2+/1+ and 1+/0 redox potentials of model clusters remains consistently in the range ca. 0.70 ± 0.05 V in organic solvent electrolytes, and ca. 0.40 ± 0.02 V in water. The reported absolute potential for the one-electron reduction of $[Fe_4S_4]^{1+}$ in nitrogenase was also too high compared to model system values generally reported to be in the range −1.50 to −1.85 V (saturated calomel electrode (SCE)) in organic solvent electrolytes and ca. −1.2 V (SCE) in water. Recently, the redox potential for the $[Fe_4S_4]^{1+/0}$ couple of the iron-protein has been measured at −0.79 V (NHE; i.e. ca. −1.03 V SCE), corresponding to a ΔE of 0.48 V between the two redox couples, more in line with experimental

and theoretical redox potential and associated ΔE in model clusters.[29,30]

The polypeptide environment of the iron-protein Fe_4S_4 cluster appreciably stabilizes the $[Fe_4S_4]^0$ state compared to corresponding model clusters. This can be assigned to the network of hydrogen bonds between the protein residues and the cluster sulfide groups, and, to some extent, to the accessibility of water molecules to the cluster. However, the iron-protein iron–sulfur cluster in its $[Fe_4S_4]^{1+}$ state does not appear to be reducible in vivo by known physiological electron donors, unless a currently unknown mechanism, such as a protein conformation change, stabilizes the $[Fe_4S_4]^0$ state even more. Accurate synthetic models have helped to understand the structural, spectroscopic, and electronic properties of the Fe_4S_4 cluster, particularly that of the iron-protein of nitrogenase. Whether or not the $[Fe_4S_4]^0$ state is implied in the physiological electron transfer chain in nitrogenase remains to be proven. However, the sole fact that this latter state can be generated as a stable center within the protein encourages the quest for stable synthetic models in the all-ferrous state. These future models might bear a ligand scaffold mimicking the immediate stabilizing protein environment of the native cluster. In particular, it would be interesting to study the effect in terms of structure and associated electronic properties (electron transfer) of specific hydrogen bonds to the bridging sulfides as a function of the oxidation state of the cluster core. The modeling of a dielectric medium similar to the polarity and Lewis acidity experienced by iron–sulfur centers within proteins might be imposed by ligands sharing both covalent and noncovalent bonds to the cluster core. For recent progress towards the stabilization of the $[Fe_4S_4]^0$ state and the measurement of the hydrogen bonding effect on the redox potential of Fe_4S_4 clusters see references 73 and 74 respectively.

3 MODELS FOR THE Fe_8S_7 P-CLUSTER

Simple synthetic models for the active site of iron–sulfur proteins bearing centers of low nuclearity (one to four iron centers) have been relatively promptly synthesized and studied (*see* ***Iron–Sulfur Models of Protein Active Sites***).[27] Centers of higher nuclearity however, such as the P-cluster or the FeMo-cofactor of the nitrogenase MoFe-protein, present a greater synthetic challenge not only because of their higher metal–sulfur content and structural complexity but also because faithful structural models were obtained only recently by protein crystallography. Recent progress in the artificial synthesis of the P-cluster core of nitrogenase is now discussed.[31]

The Fe_8S_7 inorganic core of the P-cluster has been synthesized from tetramethylthiourea, 2,4,6-triisopropylbenzenethiol, elemental sulfur, and iron(II)bis(ditrimethylsilylamide) in toluene, in the respective 3/12/7/8 ratio (Figure 3a).[32] The differences between the model and the native P-cluster lie within the nature of the ligands to the iron–sulfur sites, the iron atoms' oxidation states, and the shorter bond distances in the model around the central hexacoordinated sulfur. While the iron atoms are terminated or bridged by cysteinate ligands in the P-cluster, different ligations are involved in the model. Indeed, the two opposite apical iron sites of the synthetic cluster have a terminal bis-amide ligation, thiourea completes the tetrahedral coordination of two opposite central iron atoms, and the two remaining pairs of opposite iron centers are linked by a bis-amide bridge, as shown in Figure 3. The tighter amide bridge of the model compared to the cysteinate bridge found in the MoFe-protein explains the shorter μ_6S-Fe bonds and shorter distance between opposite central iron atoms in the model. ^{57}Fe Mössbauer spectroscopy of the model compound distinguishes two iron sites in a 3/1 ratio: each quadrupole doublet's isomer shift and quadrupole splitting are consistent respectively with 6 Fe(II) and 2 Fe(III), the former assigned to the six central iron atoms and the latter assigned to the two opposite apical iron centers. The oxidation state of the model (6 ferrous/2 ferric) is therefore directly related to that of the P-cluster in the P^{OX} state. Nevertheless, the structure of the Fe_8S_7 core of the model resembles closely that of the P^N state, probably because the bridging amide prevents a more open structure similar to that of P^{OX}.

The model cluster has been reported to be very sensitive to oxygen and heat. This is consistent with the known instability of the P-cluster toward extraction from the MoFe-protein. Perhaps, for this reason no redox potentials were reported for the model. However, the current synthetic model (despite its different terminal and bridging ligands) provides the missing link for understanding the basic energetics of the electron transfer chain between the Fe_4S_4 cluster, the P-cluster, and FeMo-co. Indeed, the redox potentials of Fe_4S_4 clusters are well known both in vivo for the iron-protein Fe_4S_4 cluster and in accurate synthetic or theoretical models.[27,29,30] The electrochemistry of the extracted FeMo-cofactor has also been studied in depth.[33,34] The knowledge of the detailed electrochemical properties of each metallo-cluster would also help to assess the extent of redox potential control by the surrounding supramolecular protein interactions and possible associated structural changes.

While the former model has been obtained by self-assembly from its basic components, the detailed step-by-step synthesis of topological analogues of the P-cluster has been reported (Figure 3c).[31,35–38] Cubane-like clusters with the $[MoFe_3S_4]^{3+}$ or $[VFe_3S_4]^{2+}$ core oxidation state and chloro ligands at Fe (see Section 4 for their synthesis) react respectively with phosphine and $NaBPh_4$, or phosphine only, to yield the phosphine-substituted $[MoFe_3S_4]^{2+}$ and $[VFe_3S_4]^{2+}$ clusters. Reduction of these phosphine-substituted cubane-like clusters yield edge-bridged double cubanes with the $[M_2Fe_6S_8]^{2+}$ core (M = Mo or V). Upon exposure to 3 or 4 equivalents of $[Et_4N][HS]$, the edge-bridged double cubanes rearrange into topological analogues of the Fe_8S_7 P-cluster with the $[Mo_2Fe_6S_7]^{5+}$ or

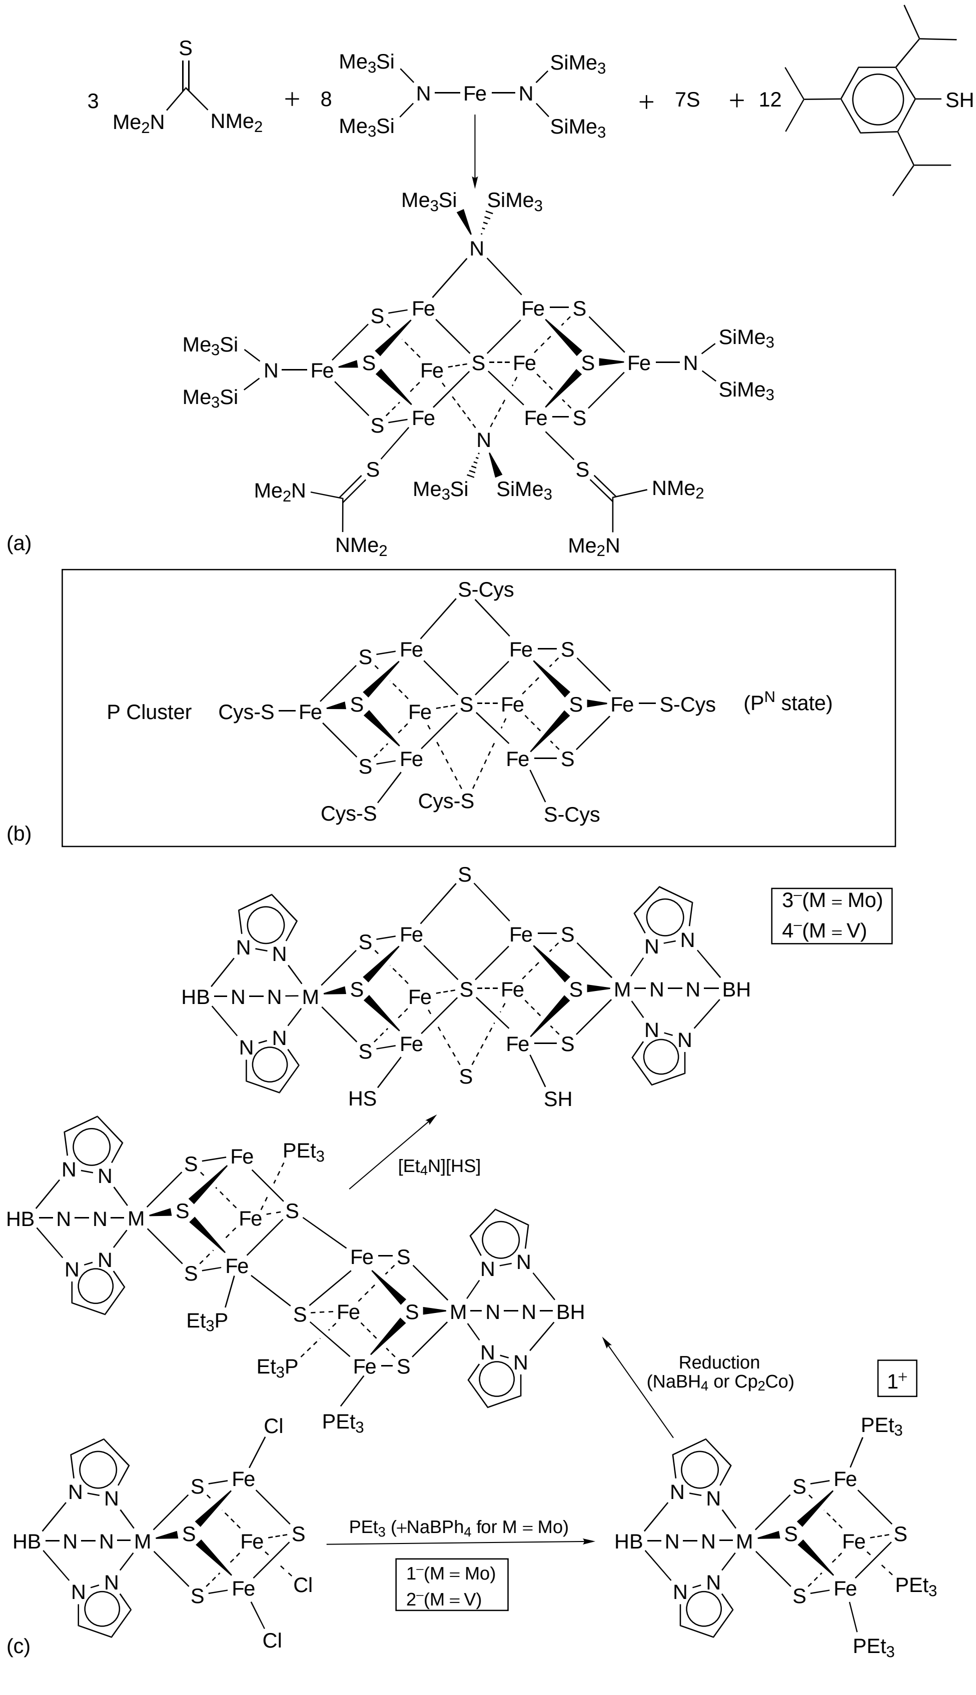

Figure 3 (a) Synthesis of a P-Cluster analogue by self-assembly. (b) The structure of the P-Cluster in its native oxidation state (P^N state). (c) Stepwise synthesis of topological analogues of the P-cluster

$[V_2Fe_6S_7]^{4+}$ core respectively. Despite the heterogeneity of the metal content in the models, their inorganic cores are almost isostructural with the Fe_8S_7 P-cluster in the P^N state. In addition, the bridging sulfides or terminal hydrosulfide ligands are closer analogues to the natural cysteinate ligations found in the MoFe-protein. It is proposed that such a rearrangement (of an all-iron edge-bridged double cubane) could be of relevance to the biosynthesis of the P-cluster of nitrogenase. A similar biosynthesis might be envisaged as well for the FeMo-cofactor provided two different cubes are condensed ($MoFe_3S_4$ and Fe_4S_4). However, according to the recent crystallographic analysis of the MoFe-protein, the central light atom is unlikely to be a sulfur atom.

4 STRUCTURAL MODELS FOR THE $MoFe_7S_9$ FeMo-COFACTOR

As mentioned in the introduction, the crystallographic model of FeMo-co has been recently revised to include a light atom 'Y' at the center of the Fe_6 trigonal prism.[17] Among the possible candidates for the light atom, nitrogen fits most closely to the experimental X-ray diffraction data,[17] and is also the choice of theoreticians.[18–20] If 'Y' is a nitrogen atom, a question remains as to whether it is a permanent structural component of FeMo-co or originates from dinitrogen itself and is included into the cluster framework at some stage of catalysis. It has been argued that if the interstitial nitrogen had to be released as ammonia before a new N_2 molecule could bind to FeMo-co, then stoichiometric ammonia release should be detected after the transfer of three electrons. This is not consistent with available presteady state kinetic data.[39] In addition, spectroscopic investigations (by electron-nuclear double resonance and electron spin-echo envelope modulation) of both a wild type and a site-specifically altered nitrogenase MoFe-protein turning over $^{14}N_2$ and $^{15}N_2$, led to the conclusion that, if the central atom in FeMo-co is N, then it is not an exchangeable nitrogen.[40]

These observations point toward a permanent structural role of an interstitial nitrogen atom at the center of FeMo-co, although this is not yet proven.

The revised version of the crystallographic FeMo-co model implies an obvious reappraisal of the synthetic structural modeling toward iron–sulfur nitride chemistry, a field that does not currently exist as such.[41]

It would be far from fair however, to say that structural modeling has to start from scratch again. Of course, the quest for tricoordinate iron–sulfur metal centers is no longer relevant to the biological catalysis,[42] although some of the low-coordinate complexes may be promising as abiological catalysts for dinitrogen reduction.[43] Many of the impressive array of MoFeS clusters, first developed long before the publication of the first crystallographic FeMo-co model remain highly pertinent to structural modeling.[31,44–46] Lessons from the biosynthesis of FeMo-co should also in principle help to define a synthetic strategy toward a cofactor model cluster. This process is however very complicated and not fully understood.[47] It is known that the cluster is assembled outside the MoFe-protein before being inserted. The maturation of FeMo-co goes through the mobilization of iron and sulfur (encoded by the NifU and NifS genes) and rearrangement to a Fe–S cluster called NifB-co (encoded by the NifB genes) of unknown structure. Mo (or V) and a homocitrate are inserted (or substituted) in this cluster at a later stage of maturation. A speculative proposal on the structure of NifB-co and its biosynthesis by cluster rearrangement has been put forward and is shown in Figure 4 (*see also* ***Nitrogenase Catalysis & Assembly***).

The fragment of FeMo-co that has been most accurately modeled by synthetic clusters is its molybdenum cap. Indeed, cubane-like $MoFe_3S_4$ clusters reproduce very well the first and second coordination sphere of molybdenum in nitrogenase. $MoFe_3S_4$ clusters are usually synthesized from the double cubane $[Mo_2Fe_7S_8(SEt)_{12}]^{3-}$ (Figure 5) whose central iron bridge can be cleaved to yield independent $MoFe_3S_4$ monocubes.[31,44–46,48,49] As shown in Figure 6, the use of encumbered chelators (e.g. tetrachlorocatecholate or dimethylphosphino ethane) is required to isolate independent cubes.[48] If less bulky chelators like catecholate or π-acceptor ligands like carbon monoxide or isocyanides are used, the

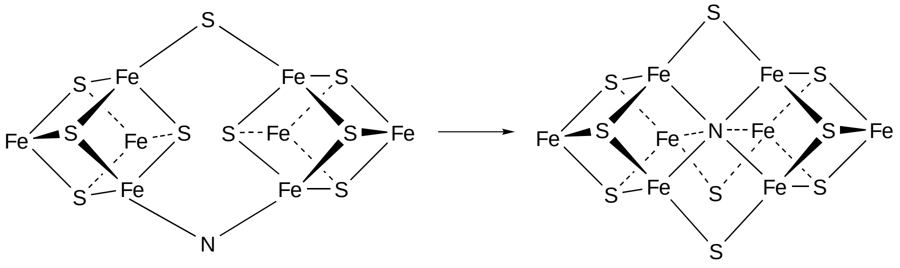

Figure 4 Proposed core rearrangement of the NifB-cofactor (within a protein) intermediate in the biosynthesis of the FeMo and FeV-cofactor. The heterometal and homocitrate ligands are inserted at a later stage of biosynthesis, in a different protein

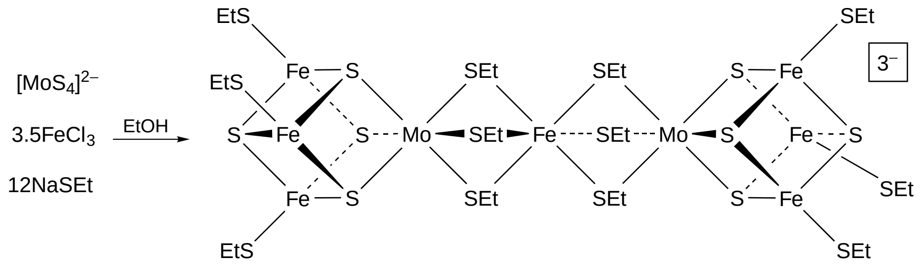

Figure 5 Self-assembly synthesis of the iron-bridged double cubane $[Mo_2Fe_7S_8(SEt)_{12}]^{3-}$

iron-bridged double cubane is heterolytically cleaved to yield a $MoFe_3S_4$ cube linked via Mo and thiolate bridges to an *exo*-Fe center.[49] When $[Mo_2Fe_7S_8(SEt)_{12}]^{3-}$ is left in solution (acetonitrile), it thermally evolves to the $[Mo_2Fe_6S_8(SEt)_9]^{3-}$ double cubane, demonstrating the inherent lability of the central iron bridge in $[Mo_2Fe_7S_8(SEt)_{12}]^{3-}$ and its great value as a synthon.

Alternatively, direct synthesis of $MoFe_3S_4$ clusters is also possible from $TpMoS(S_4)$, $FeCl_2$, and $NaSEt/PPh_3$ (Tp is hydro(trispyrazolyl)borate(1-)) (Figure 7).[50] In addition to being a simpler synthetic procedure, the trigonal symmetry imposed at Mo by the Tp ligand also avoids isomeric mixtures when bridged $MoFe_3S_4$ cubes are synthesized by the reaction of two single $MoFe_3S_4$ cubes (see Section 2 on P-cluster modeling and references 31, 35–38 and 50).

Similarly, VFe_3S_4 clusters are obtained by direct self-assembly from simple chemicals (ferrous chloride and tetrathiovanadate (Figure 7)).

Although the $MoFe_3S_4$ cubes have not been found to interact with dinitrogen, some partial functional chemistry relevant to nitrogenase has been developed. First, in some examples where the Mo site is coordinated by a labile solvent molecule, it has been shown that the solvent ligand could be displaced by different unsaturated nitrogenase substrates. Examples with cyanide, azide, hydrazine, phenylhydrazine, or piperidine bound at Mo have been characterized by X-ray crystallography and/or by NMR spectroscopy.[48] Furthermore, these $MoFe_3S_4$ with a labile solvent molecule at Mo catalyze the reduction of hydrazine to ammonia, of acetylene to ethylene and ethane, of *cis*-dimethyldiazene to methylamine, methane, and ammonia, or the disproportionation of hydrazine.[44,51–54] The involvement of the heterometal as the site of hydrazine reduction catalysis is strongly supported by: (1) inhibition experiments with inert ligands that bind to Mo like triethylphosphine, cyanide, or chloride; (2) much poorer catalysis results with related homometallic Fe_4S_4 clusters; and (3) structural characterization of cubanes with hydrazine or phenylhydrazine bound at Mo. Likewise, $[VFe_3S_4]^{2+}$ clusters catalyze the reduction of hydrazine to ammonia, and the rates of reduction correlate well with the availability of labile sites at the V atom.[44,51,55] Similar studies could also be envisioned with subsite-differentiated Fe_4S_4 clusters to probe the catalytic properties of a single Fe-site of an all-iron metal–sulfur cube in relation to the modeling of the all-iron nitrogenase.[56] Other $MoFe_3S_4$ clusters with polycarboxylate ligation at molybdenum (e.g. citrate) were found to be even better catalysts than those with a more readily accessible metal site by labile solvent decoordination. This implies that the polydentate ligand partially decoordinates during catalysis and may further play the role of a proton shuttle for the bound substrate. It is tempting to relate these experimental observations to the presence of the bidentate homocitrate ligand at molybdenum in nitrogenase. More generally, this raises the question of the possible direct involvement in the biological reduction of dinitrogen (or at least at a later stage of catalysis, e.g. at the diazene or hydrazine reduction level), of the heterometal in FeMo-co and FeV-co, and perhaps as well of the corresponding apical iron atom in FeFe-co.[44,51] The possibility of partial decoordination of homocitrate from Mo, preceding N_2 coordination at this metal, has been examined by molecular mechanics studies where the surrounding protein was taken into account.[57] It was found that *R*-homocitrate in its alkoxy monodentate form, is just of the right size to hydrogen bond via its longer (C_3) free carboxylate arm to a neighboring lysine residue and to the imidazole ring from the histidine residue bound to Mo. The corresponding shorter (C_2) arm of the closely related citrate ligand would not achieve this crucial interaction. Besides, (*R*)-homocitrate is known to be highly specific for biological nitrogen fixation, and mutated strains with a nitrogenase having citrate in place of (*R*)-homocitrate are much less efficient in reducing dinitrogen. The molecular mechanics study also showed that the medium (C_2) free carboxylate arm of (*R*)-homocitrate interacts with a glycine residue, which creates a hydrogen bond path between the P-cluster and FeMo-co.[34,57] These theoretical and graphical studies of the X-ray structure of the MoFe-protein came in support of experimental stopped-flow kinetic studies of substrates binding to different types of the extracted FeMo-cofactor. One type is extracted from a wild bacterial strain where FeMo-co bears (*R*)-homocitrate at Mo. The other type is extracted from a mutated bacterial strain ($NifV^-$) with citrate at Mo. The apical iron site of the extracted cofactors is coordinated by one solvent molecule (N-methyl formamide, NMF). This site binds a thiolate ligand (PhS^-) with kinetics depending on what other ligands bind to the cluster. When cyanide, azide, or proton bind

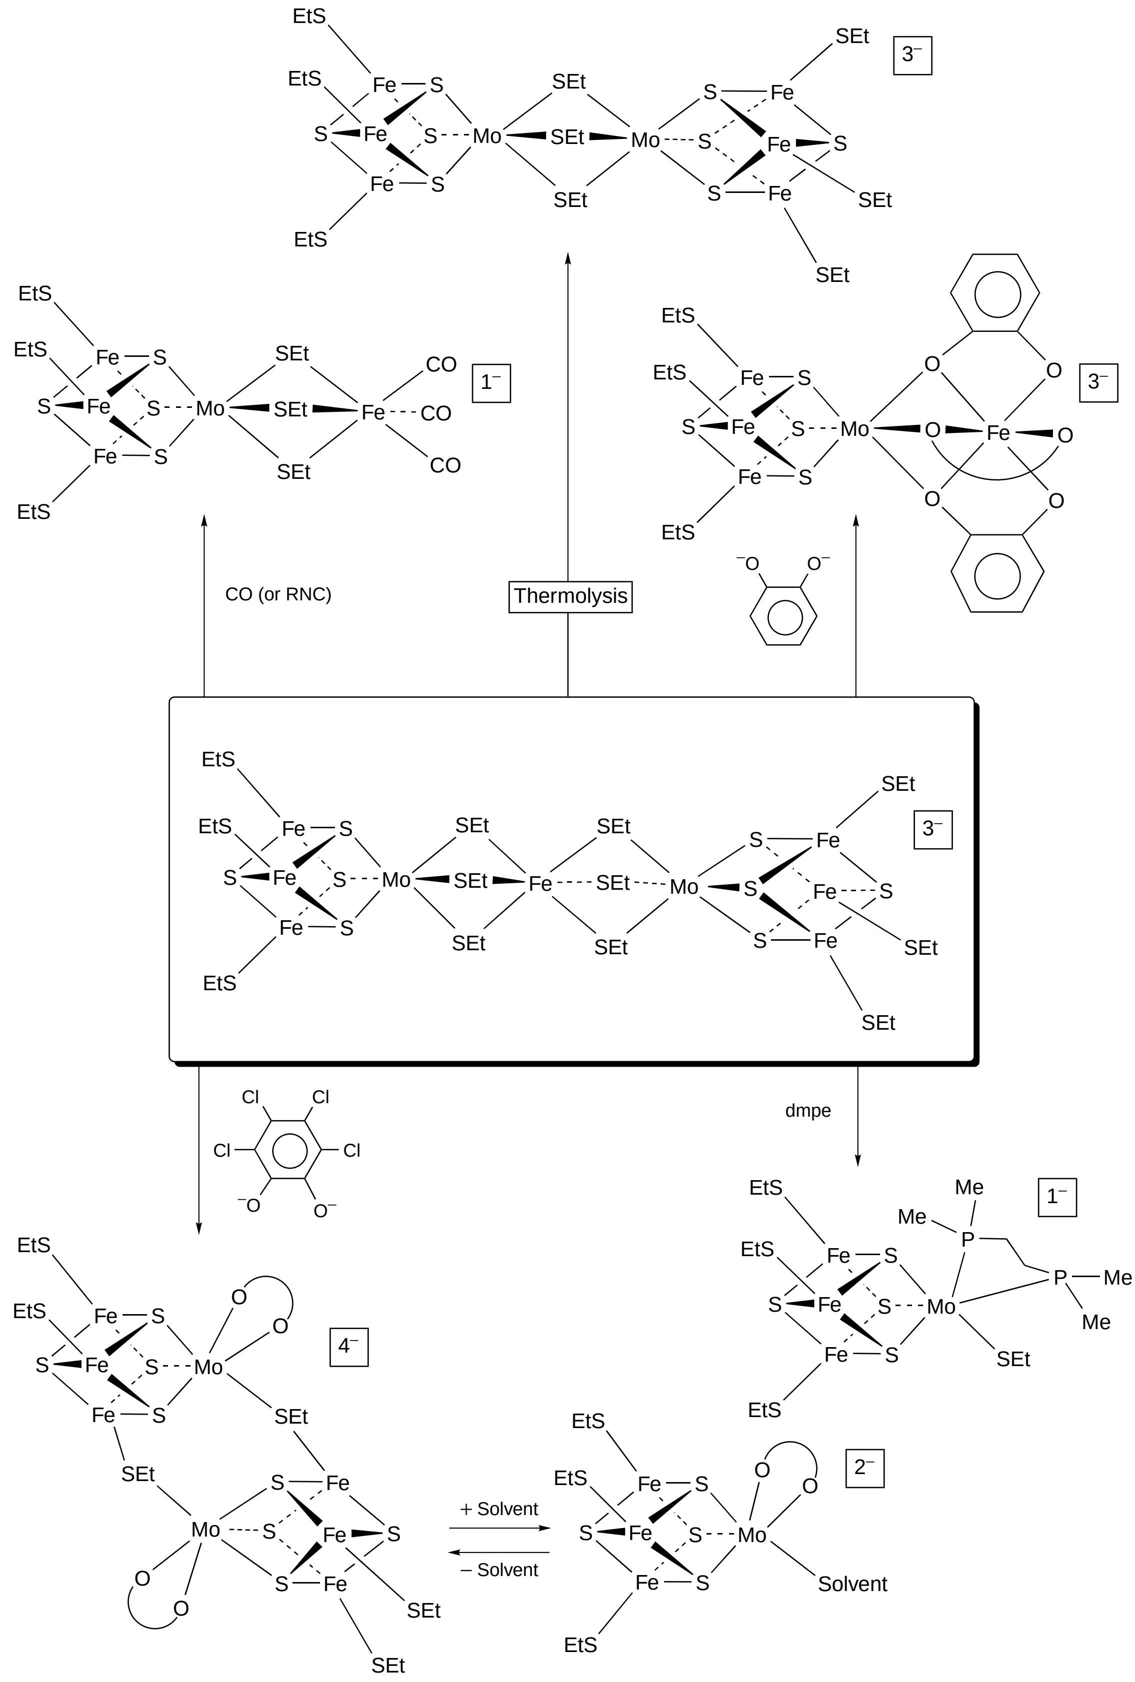

Figure 6 Reactivity of $[Mo_2Fe_7S_8(SEt)_{12}]^{3-}$. Synthesis of $MoFe_3S_4$ monocubes from $[Mo_2Fe_7S_8(SEt)_{12}]^{3-}$(bottom)

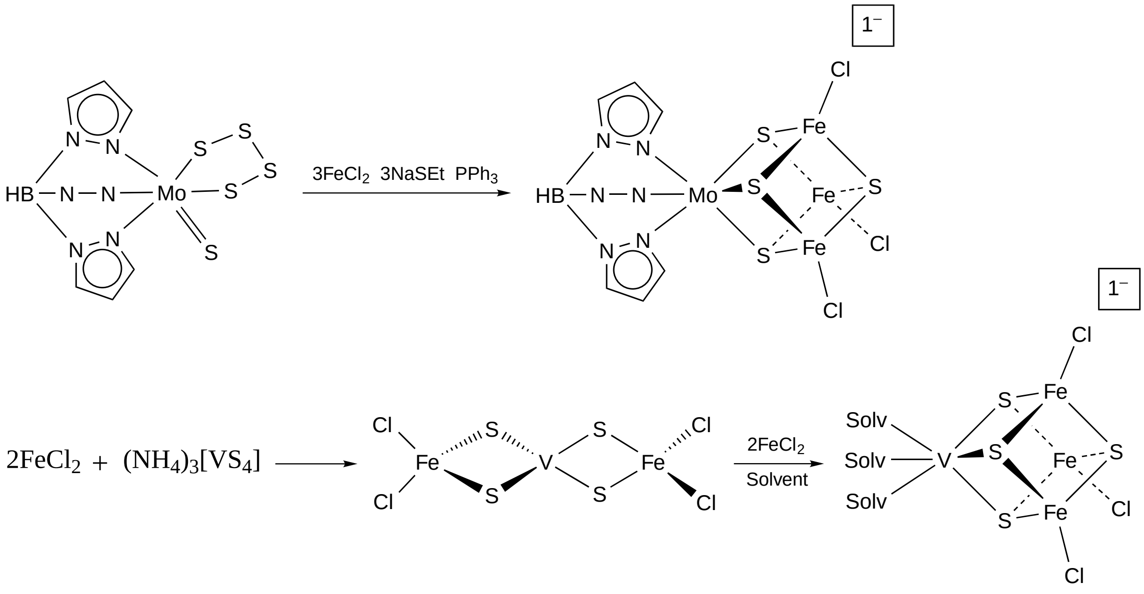

Figure 7 Direct synthesis of $MoFe_3S_4$ and VFe_3S_4 monocubes

to the cluster core, thiolate-binding kinetics to both types of cofactors are indistinguishable. However when imidazole binds to Mo, very different behaviors are observed. This was explained by specific H-bonding between (*R*)-homocitrate and imidazole. The binding of dinitrogen at the free Mo site has not been observed experimentally and remains a speculative proposal. It builds on earlier model studies with mononuclear molybdenum or tungsten phosphine dinitrogen complexes.[58] In some of these model complexes, a carboxylate ligand may act as a leaving group that opens a substrate binding site which coordinates N_2.[58]

When such molybdenum-dinitrogen complexes exist, the activation of N_2 is always stronger for the tungsten analogue. Then, if the cofactor heterometal is indeed the site of dinitrogen activation, a FeW-cofactor may be even more efficient with respect to biological nitrogen fixation. Testing this hypothesis requires the isolation of a tungsten nitrogenase. This is not an easy task because of the presence of a highly specific Mo storage protein (in *Azotobacter vilnelandii*) that contaminates with FeMo-co preparations grown on a tungstate medium, even when only traces of Mo are present. Besides, under Mo-deficient conditions, alternative nitrogenase systems may be expressed. Nevertheless, a tungsten (Mo-free) nitrogenase has recently been isolated under tungstate growth conditions from *Rhodobacter capsulatus,* that lacks a Mo-storage protein and whose mutated strain (anfA) is incapable of expressing the iron-only nitrogenase under molybdenum-deficient growth conditions.[59] The isolated tungsten-substituted nitrogenase was found to be only marginally active in reducing acetylene, and dinitrogen reduction was not observed. However, appreciable dihydrogen evolution was obtained, corresponding to a rate of ca. 25% of that observed for the native MoFe-protein. Redox titration of both proteins showed the tungsten-substituted protein midpoint potential to be at least 150 mV more negative (<-200 mV NHE) compared to that of the MoFe-protein (-50 mV NHE). Hence, the FeW-co appears to be at least partially reducible to a state where hydrogen evolution occurs (but to a lesser extent than for FeMo-co), whereas the more reduced state where substrate activation occurs is not accessed. Considering thermodynamics alone, it is interesting to note that a functional iron-protein with a $[Fe_4S_4]^0$ cluster would be a sufficiently strong reductant (ca -0.8 V NHE) to reduce a tungsten−iron protein with $E_{1/2}$ of approximately -0.3 V NHE. Decreased hydrogen evolution would be advantageous for nitrogen fixation as discussed next, however the apparent impossibility of physiologically reducing the WFe-protein to a state where N_2 would bind precludes any nitrogen fixation. This can be rationalized by two features of molybdenum and tungsten chemistry: (1) tungsten complexes or clusters are more difficult to reduce than their molybdenum analogues; (2) ligands are less labile at a tungsten center. Hence, even if FeW-co was reducible to the corresponding substrate binding redox state of FeMo-co, the partial decoordination of homocitrate from W might not occur because the breaking of a W–O bond requires more energy than for the corresponding Mo–O bond in FeMo-co.

Whether or not N_2 binds at Mo, a possible role for this metal at the active site of the enzyme has been recently pointed out and is now discussed.[60] In the absence of N_2, all conventional nitrogenases reduce protons to dihydrogen. In the presence of N_2, only a fraction of electrons are used to reduce dinitrogen while the other fraction is still involved in dihydrogen formation, and is therefore wasted. The limiting stoichiometries for all three types of nitrogenase are as follows (equivalent of dihydrogen formed per equivalent

of reduced dinitrogen): Mo(1), V(3), and Fe(7.5). Hence, notwithstanding differences in the reduction mechanism and different protein structures, the presence of a heterometal in the iron–sulfur cofactor appreciably improves the efficiency of biological dinitrogen reduction, especially when this metal is molybdenum. The effect of Mo within a Fe–S cluster has been addressed experimentally by comparing the kinetics of proton binding to a Fe_4S_4 cluster, $[Fe_4S_4Cl_4]^{2-}$, and a thiolate-bridged double $MoFe_3S_4$ cluster: $[\{MoFe_3S_4Cl_3\}(\mu\text{-}SR_3)]^{3-}$ (R = Et or Ph).[60] The chloride ligands of these clusters are labile and can be substituted by nucleophiles such as thiolates. Protonation of Fe–S clusters, probably at the basic sulfide centers, is a known common reaction of such inorganic species. In the presence of a weak acid and a strong nucleophile such as thiophenolate, protonation of the cluster following thiolate binding is the rate-limiting step of the reaction with a similar rate constant for both types of MFe_3S_4 clusters (M=Fe or Mo). The rate of proton transfer to the cluster prior to nucleophile binding can be determined by measuring the kinetics of the reaction between the MFe_3S_4 cluster and a poor nucleophile such as bromide, in the presence of a weak acid. Results show that proton transfer to any Fe–S cluster is slower in the absence of a bound nucleophile, and is about two orders of magnitude slower for $MoFe_3S_4$ compared to Fe_4S_4. A simple electron-withdrawing effect of the heterometal seems excluded as the pKa of protonated clusters falls into the narrow range of 18.9–17.9 and is little affected by the structure of the cluster. Rather, energetically more demanding bond length changes in Mo–Fe–S cluster are proposed as a possible explanation. Very interesting implications for biological dinitrogen fixation are then put forward. Because any dinitrogen binding site needs to be electron rich to ensure the ligand–metal σ-bonding and metal–ligand π-back bonding interactions, such sites may be easily protonated, which would then either decrease their affinity for dinitrogen or labilize an already bound N_2 molecule. This could be avoided if electron transfer is also coupled to protonation, however this could also favor dihydrogen formation. Since proton transfer to Mo–Fe–S clusters is appreciably slower than to Fe–S clusters, the presence of molybdenum in the FeMo-cofactor could favor nitrogen fixation by enhancing the affinity of the binding site for dinitrogen and by slowing down the protonation of the cluster, which would also diminish or suppress unwanted dihydrogen evolution. Besides, model studies have shown that Mo–Fe–S clusters have a higher affinity than Fe–S cluster for binding species such as thiolates, halides, CO, or N_2O. Irrespective of the precise N_2-binding site at FeMo-co, molybdenum would make the enzyme a good nitrogenase and a poor hydrogenase, in agreement with the limiting stoichiometries reported for the Mo- and the all Fe-nitrogenase. It would be interesting to know if similar studies with VFe_3S_4 clusters would yield a protonation rate constant in between those observed with $MoFe_3S_4$ and Fe_4S_4 clusters, which would be consistent with the known relative N_2-reduction efficiency of all three types of conventional nitrogenases (Mo > V > Fe).

Current available cofactor models are hence only partially relevant in terms of structure: only the molybdenum/heterometal end of the cluster has been accurately modeled. In terms of functional relevance, no interactions with N_2 have been obtained despite catalytic activation of reduced diazo species (e.g. hydrazine) or alternative substrates (e.g. acetylene). Considering the available biochemical data as well, one can only speculate on the precise site of N_2 binding and reduction at FeMo-co, and on the exact role of the heterometal in this reaction. Electron-rich mononuclear molybdenum and tungsten complexes have been developed that bind dinitrogen and sometimes also support ammonia synthesis.[34,58,61,62] They are however structurally very different from FeMo-co for they are mononuclear and possess abiological ligands such as phosphine, permethylated cyclopentadienyl, or triamido amine. When more relevant sulfur ligands and/or metal–metal interactions were introduced, the key interaction with dinitrogen was lost in most cases although in some instances the activation of reduced diazo species was retained.[34,62–66] Theoretical assessments of possible N_2 binding sites at FeMo-co can assist this debate, with the limitation that it is difficult to take into account theoretically the full structure of the active site (cluster, protein, and solvent molecules) and the afferent mechanistic complexity and subtleties of nitrogenase.[18–20,34,62,67] Irrespective of the N_2 binding site considered, a general trend of theoretical calculations seems to be that FeMo-co is a rather weak N_2 activator compared to well understood and efficient mononuclear systems. One must also keep in mind that the extracted FeMo-co itself does not interact with dinitrogen, which underlines the important role of the protein for N_2 reduction by this center.

Given the current absence of interaction of any synthetic metal–sulfur cluster with dinitrogen, the binding of other and more reactive substrates or inhibitors of nitrogenase, like acetylene or carbon monoxide, are of interest. We have already pointed out that the heterometal site of $MoFe_3S_4$ or VFe_3S_4 cubes can support the reduction of acetylene. However, biochemical studies have established that acetylene is reduced on a specific Fe_4 face of the central Fe_6 trigonal prism of FeMo-co.[68,75] Besides, it is not known if acetylene and dinitrogen bind to the same site at FeMo-co, and these molecules probably bind with different FeMo-cofactor redox states. In any case, the current lack of structural models of the light atom–centered Fe_6 trigonal prism precludes functional modeling of this site for the moment. Recent iron–sulfur imido chemistry might be of relevance to the activation of nitrogenous substrates by the central iron–sulfur core, but the development of iron–sulfur nitride chemistry is awaited.[31,41,69]

The future synthetic models of FeMo-co will have to closely resemble the now more accurate $MoFe_7S_9Y$ crystallographic model (with ‘Y’ probably being N). The progress made in the synthesis of P-cluster analogues, discussed in the previous

section, is encouraging since the P-cluster has a similar size and metal–sulfur content as FeMo-co, although a bit less complex. The next challenge will be the development of some functional chemistry of relevance to nitrogenase at these future accurate FeMo-co models. Interaction of dinitrogen with these centers, a property that few molecular cluster have shown so far,[3,70–72] would be a breakthrough. It is evident that the task is not obvious taking into account: (1) the original and complex FeMo-co structure; (2) the rather weak affinity of FeMo-co for N_2 compared to model systems; (3) the complex mechanism of N_2 biological reduction coupled to the evolution of H_2; and (4) the strong dependence of FeMo-co catalytic activity on the surrounding protein and specific amino acid residues, and on the (R)-homocitrate ligand. A synthetic functional peptide-FeMo-co center possessing the minimum structural and supramolecular requirements to activate N_2 could be a midterm goal.

5 CONCLUSIONS

Considerable progress in the synthesis of model clusters of nitrogenase has been made in recent years thanks to the continuous development in the laboratory of a rational and diverse iron–sulfur chemistry and to the increased knowledge of the natural systems themselves. The fact that biophysical and biochemical techniques now yield more detailed mechanistic and structural data on the enzymes may question the need for synthetic models. However, the advancement of the understanding of the mechanistic and structural complexity of the nitrogenase enzymes requires a multidisciplinary approach. Interactions and scientific debates between geneticists, biophysicists, biochemists, inorganic chemists, and theoretical chemists benefit all disciplines and scientists, and allow the knowledge of nitrogenases to advance at a faster pace. While the understanding of the enzyme advances, nitrogenase seems to challenge synthetic chemists regularly and the standards are set high. As discussed in this article, the scientific community has always taken up the challenge, sometimes brilliantly. For example, the $[Fe_4S_4]^{2+/1+}$ center of the iron-protein was thought to be well understood and modeled until this cluster was found to be stable in the $[Fe_4S_4]^0$ state within the protein. $[Fe_4S_4]^0$ synthetic models with thiolate ligands are all very unstable. Whether or not the $[Fe_4S_4]^0$ state is biologically relevant, which has to be clarified, the natural system gives the impetus to synthesize stable low-valent iron–sulfur centers and control their redox potentials by covalent and noncovalent binding. The two known structures of the P-cluster of nitrogenase show the importance of redox-linked structural flexibility of iron–sulfur clusters and the importance of the protein to stabilize them. The structure of the P-cluster in the native state can now be obtained in the laboratory by self-assembly, or topologically, in a stepwise and well-understood fashion. Taking into account its astonishing structure and function alone, the FeMo-cofactor represents evidently the greatest challenge to modeling chemistry. This cluster is now known to be centered on a light atom that is probably a nitrogen atom, waiting to be identified with certainty. FeMo-co reduces dinitrogen with the help of the protein and its heterogeneous (R)-homocitrate ligand with an unknown intimate mechanism that also produces dihydrogen. Catalytic properties are retained when molybdenum is substituted with vanadium or iron in alternative nitrogenases. Considering these facts and, despite their inherent weaknesses, the prolific synthetic structural and functional models of the metal–sulfur centers of nitrogenases developed over the years, one could sum up the work in nitrogenase model clusters by ‘a lot done, more to do.’

1 INTRODUCTION

Nitrogenases represent a class of complex metalloenzymes that catalyze the process of biological N_2 fixation, during which dinitrogen is reduced to ammonia in a nucleotide-dependent process.[1–12] The ammonia produced is subsequently used for cell growth or maintenance. The overall reaction catalyzed by nitrogenases is usually depicted as follows:[8,11,12]

$$N_2 + 8H^+ + 16MgATP + 8e^- \longrightarrow 2NH_3 + H_2 + 16MgADP + 16P_i \quad (1)$$

Nitrogenases are unique to bacteria, and animals or plants that fix N_2 must do so in association with bacteria.[13] Interest in nitrogenases arises from the importance of these enzymes to agriculture. Biological N_2 fixation provides roughly 90 million tons of N for agricultural soil each year and represents a major contributor of new N to agriculture and the food supply.[8,10] Meanwhile, attention has been drawn to the interesting chemistry involved in breaking the triple bond of the dinitrogen molecule under biological N_2 fixation conditions. How nitrogenases can carry out such an energy-demanding process under mild temperatures and pressures remains yet another driving force for research on these fascinating enzymes.

Four classes of nitrogenases have been described. They are the molybdenum nitrogenase (Sections 2–4), the vanadium nitrogenase (Section 5.1), the iron-only nitrogenase (Section 5.2), and the nitrogenase from *Streptomyces thermoautotrophicus* (Section 5.3). The major distinctive feature of the first three classes of nitrogenases, which are otherwise very similar, is the heterometal atom in the active site of the metal cluster (molybdenum, vanadium, or iron).[5,8,10] The fourth nitrogenase, however, is superoxide-dependent and apparently different from the other nitrogenase classes.[14,15]

Most of the current knowledge concerning the mechanism of nitrogenases is based upon extensive studies of the molybdenum nitrogenase; hence this enzyme will be the focus of discussion in this article. The general properties of the molybdenum nitrogenase are described in Section 2, and the catalytic and assembly mechanism of this enzyme system will be dealt with in Sections 3 and 4. The alternative nitrogenase systems will also be briefly discussed in Section 5.

2 MOLYBDENUM NITROGENASE

The molybdenum nitrogenase, undoubtedly the best-characterized form of nitrogenase, has been isolated from

a number of different microorganisms such as *Azotobacter vinelandii*, *Klebsiella pneumoniae*, and *Clostridium pasteurianum*.[9,10,16] Figure 1(a) is a schematic representation of the enzyme, which comprises two separately purifiable, oxygen-sensitive, metallosulfur proteins: the molybdenum-iron (MoFe) protein and the iron (Fe) protein, both of which are essential for enzymatic activity.[1–12] Figure 1(b) illustrates the substrate-reduction reaction of the molybdenum nitrogenase, a process in which the Fe protein forms a complex with the MoFe protein and acts as an obligate, MgATP-activated, electron donor for the MoFe protein, where the substrate is reduced (see also Section 3).[2,3,7,9]

2.1 The Fe Protein

The Fe protein, a member of the family of nucleotide-utilizing proteins (e.g. myosin, ras p21, recA),[4,9] is a homodimer of $M_r \sim 60$ kDa. The two identical subunits are encoded by the *nifH* gene, and there is a high degree of homology among the Fe proteins from a wide range of bacteria.[10] Each subunit of the Fe protein has a binding site for MgATP, and the two subunits are bridged by a [4Fe–4S] cluster (*see* ***Iron–Sulfur Proteins***).[1–4,6–9,17–20]

2.1.1 *Protein Structure*

The X-ray crystal structures of several conformations of the Fe protein, either alone or in complex with the MoFe protein, have been solved.[21–27] Figure 2 shows the MgADP-bound conformational state of the Fe protein of *A. vinelandii*,[10,26] where each subunit folds as a single α/β-type domain and the subunits together symmetrically ligate the surface-exposed [4Fe–4S] cluster through two cysteines from each subunit. Two MgADP molecules are

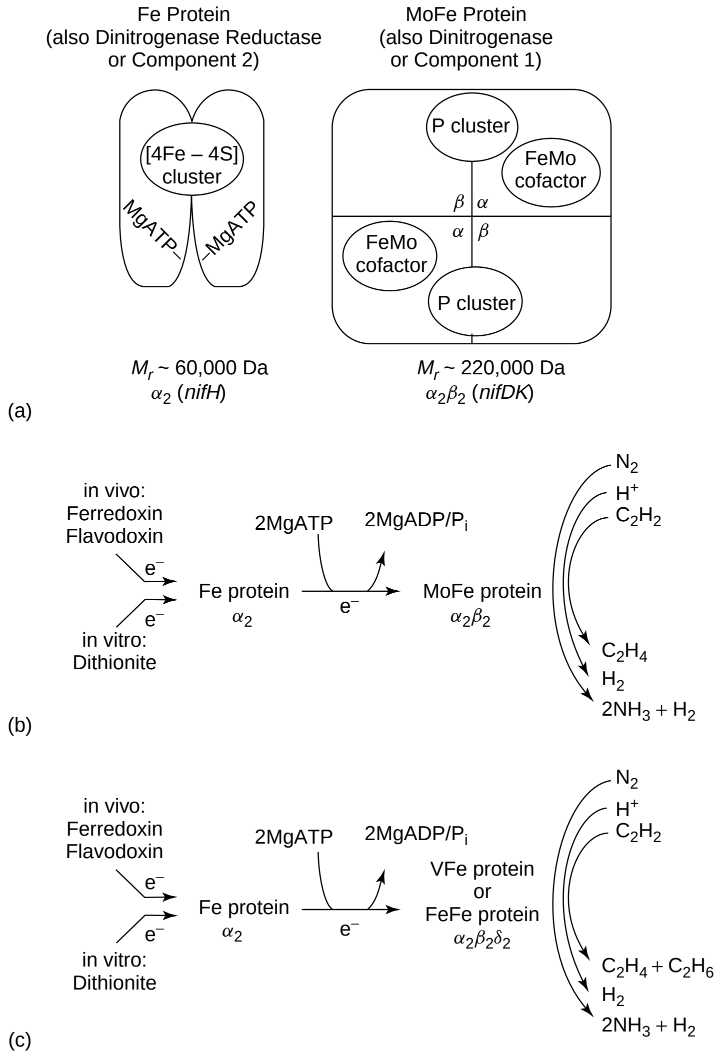

Figure 1 Schematic representation of the molybdenum nitrogenase (a) and the substrate-reduction reaction of the molybdenum nitrogenase (b) and alternative nitrogenases (c)

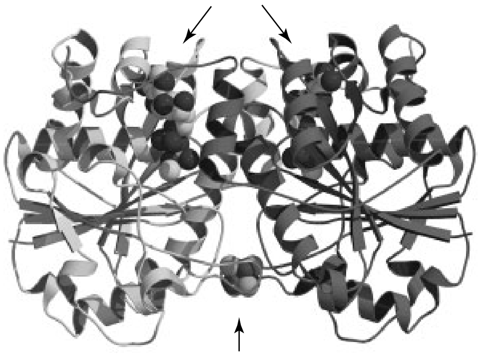

Figure 2 Structure of the α_2 homodimeric Fe protein of *A. vinelandii*, with the subunits colored in light and dark gray. The polypeptide chains are shown in ribbon presentation, and the [4Fe–4S] cluster and the two bound MgADP are shown in space-filling representation. PDB entry 1FP6 and programs MOLSCRIPT[29] and RASTER3D[30] were used to generate this figure

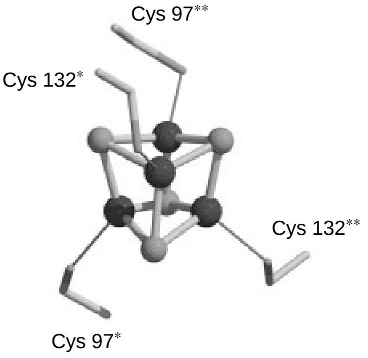

Figure 3 Structure of the [4Fe–4S] cluster of the *A. vinelandii* Fe protein including the coordinating ligands Cys97 and Cys132 from both subunits of the Fe protein (indicated as * and **). Iron and sulfur atoms are colored in dark and light gray, respectively. PDB entry 2NIP and programs MOLSCRIPT[29] and RASTER3D[30] were used to generate this figure

bound in a parallel orientation relative to each other near the dimer interface, one on each subunit. The nucleotide binding sites are located approximately 15 Å away from the [4Fe–4S] cluster and the docking surface between the Fe protein and the MoFe protein, indicating that the bound nucleotides need to exert their effects on the nitrogenase catalytic cycle from a distance through conformational changes.[6,9,19] The exact structure of the Fe protein in the MgATP-bound conformation is unknown, though X-ray scattering data have shown that the conformational changes of the Fe protein upon MgATP binding cause a contraction of the protein by 2.0 Å on average.[28] The same contraction is observed in the structure of the Fe protein in complex with the MoFe protein and MgADP·AlF_4^-,[21] suggesting that the MgATP-bound conformation of the isolated Fe protein is similar to that of the Fe protein in this complex structure. The structural details of the Fe protein involved in the catalytic mechanism will be discussed in Section 3.1.

2.1.2 The [4Fe–4S] Cluster

The [4Fe–4S] cluster is exposed to solvent and is symmetrically bridged between the two subunits of the Fe protein by the side chains of Cys97 and Cys132 (Figure 3).[3,10] The cluster ligands are located near the N termini of α-helices that are directed toward the cluster, permitting favorable electrostatic interactions between the terminal amide groups of the helices and the anionic cluster.[10] The [4Fe–4S] cluster of the Fe protein can exist in three different oxidation states,[10,25] that is, $[4Fe{-}4S]^{2+}$, $[4Fe{-}4S]^{1+}$, and $[4Fe{-}4S]^0$ (*see* ***Iron–Sulfur Proteins***). The physiological relevance of the various oxidation states of the [4Fe–4S] cluster will be discussed in greater detail in Section 3.1.

2.2 The MoFe Protein

The MoFe protein is an $\alpha_2\beta_2$ tetramer of $M_r \sim 220$ kDa, and its α and β subunits are encoded by the *nifD* and *nifK* gene, respectively (Figure 1(a) and Table 1).[7,9,10] It contains, in preparations with the highest activity, 2 molybdenum (Mo), ~30 to 34 iron (Fe), and an approximately equivalent number of acid-labile sulfur (S^{2-}) atoms (Table 1).[5,16] This metal content is consistent with the presence of two different types of unique metal clusters in the protein, that is, the [8Fe–7S] cluster (P cluster), which is bridged between each $\alpha\beta$ subunit pair, and the [Mo–7Fe–9S–homocitrate] cluster (FeMo cofactor or FeMoco), which is located within each α subunit (Figure 1a).[9,10,17]

2.2.1 Protein Structure

The X-ray crystal structures of MoFe protein, alone or in complex with the Fe protein, have been reported for *A. vinelandii*,[21,22,37–43] *C. pasteurianum*,[44,45] and *K. pneumoniae*,[46,47] and all of these structures are highly conserved on the basis of both primary sequence and three-dimensional structure. The MoFe protein of *A. vinelandii* is an $\alpha_2\beta_2$ heterotetramer consisting of a pair of $\alpha\beta$ dimers related by a molecular twofold rotation axis (Figure 4).[3,37,38] The homologous α and β subunits include three domains, designated αI, αII, and αIII and βI, βII, and βIII, respectively, all of which exhibit parallel β-sheet/α-helical type of polypeptide folds. Domains of both subunits contribute ligands to the P cluster. These ligands are located in a common core of a four-stranded, parallel β-sheet flanked by α-helices and additional β-strands.[7] The P clusters are located between

[a]Metal content in mol metal/mol protein. [b]ND = not determined. [c]Specific activities in nmol/min/mg protein. [d]These activities were originally reported in nmol/assay. The conversion of these values for the table are based on the reported assay conditions (assay time: 1 h; amount of FeFe protein: 0.92 mg).[33] Av = *Azotobacter vinelandii*; Kp = *Klebsiella pneumoniae*; Ac = *Azotobacter chroococcum*; Rc = *Rhodobacter capsulatus*; Rr = *Rhodospirillum rubum*. Note that the component proteins of the nitrogenase are often designated by the initials of the organism from which they were isolated and the arabic numeral of the component. For example, Av1 is the MoFe protein of *A. vinelandii* and Kp2 is the Fe protein from *K. pneumoniae*.[3,5,10] This nomenclature is also applied to the alternative nitrogenases, with the addition of a superscript ''V'' or ''Fe'' to indicate whether the component protein is from the vanadium or iron-only nitrogenase system. For example, $Av1^V$ is the VFe protein of *A. vinelandii* and $Rr2^{Fe}$ is the Fe protein from *R. rubum*. For the purpose of simplicity, this nomenclature is not used in this article, though readers may find it useful when reading some of the nitrogenase-related literature.

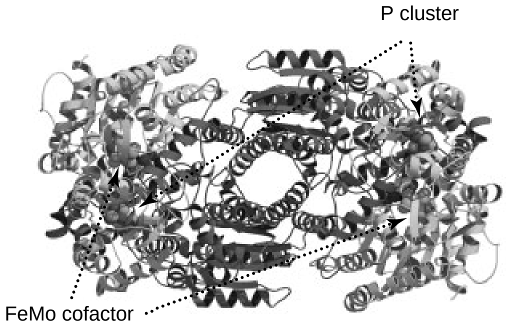

Figure 4 Structure of the $\alpha_2\beta_2$ tetrameric MoFe protein of *A. vinelandii*, with the α and β subunits colored in light and dark gray, respectively. The polypeptide chains are shown in ribbon presentation, and the FeMo cofactors and P clusters are shown in space-filling representation. PDB entry 1M1N and programs MOLSCRIPT[29] and RASTER3D[30] were used to generate this figure

domains αI and βI, whereas the FeMo cofactor occupies a cavity within the MoFe protein, formed among domains αI, αII, and αIII.

2.2.2 P Cluster

The P cluster is found at the interface between the α and β subunits, 10 Å below the surface of the protein.[7,10,48] When the MoFe protein is isolated in the presence of excess dithionite, its P cluster is in an $S = 4$, diamagnetic state (designated P^N).[4,49,50] All of the iron atoms of the P^N state are believed to be ferrous. There is some indication of the possible presence of some ferric character in this diamagnetic state, though there is no experimental evidence that the P cluster can be reduced further to an oxidation state below P^N. On the other hand, the P^N state of the P cluster can be two-electron oxidized to the P^{2+} state (designated P^{OX}) with dye oxidants thionine or indigodisulfonate (IDS).[51] This stable S = integer (3 or 4) state can be recognized by a $g = 11.8$ signal observed in the parallel mode EPR.[49,52] In addition to P^N and P^{OX}, a mixed $S = 1/2 : S = 5/2$ state of the P cluster has been characterized[53] and is believed to represent P^{1+}, the one-electron oxidation product of P^N. The P cluster is proposed to be involved in the electron transfer during the substrate-reduction reaction (see also Section 3.2), though its exact function in this process is not clear (*see* ***Iron–Sulfur Proteins***).

Figure 5 shows the structures of P^N and P^{OX}. Both states of the P cluster contain eight iron and seven sulfur atoms, which are covalently coordinated to the MoFe protein by six cysteinyl ligands, three from the α-subunit, that is, Cys α62, Cys α88, and Cys α154, and three from the β-subunit, that is, Cys β70, Cys β95, and Cys β153. In both cases, Cys α62, Cys α154, Cys β70, and Cys β153 coordinate one iron atom each,

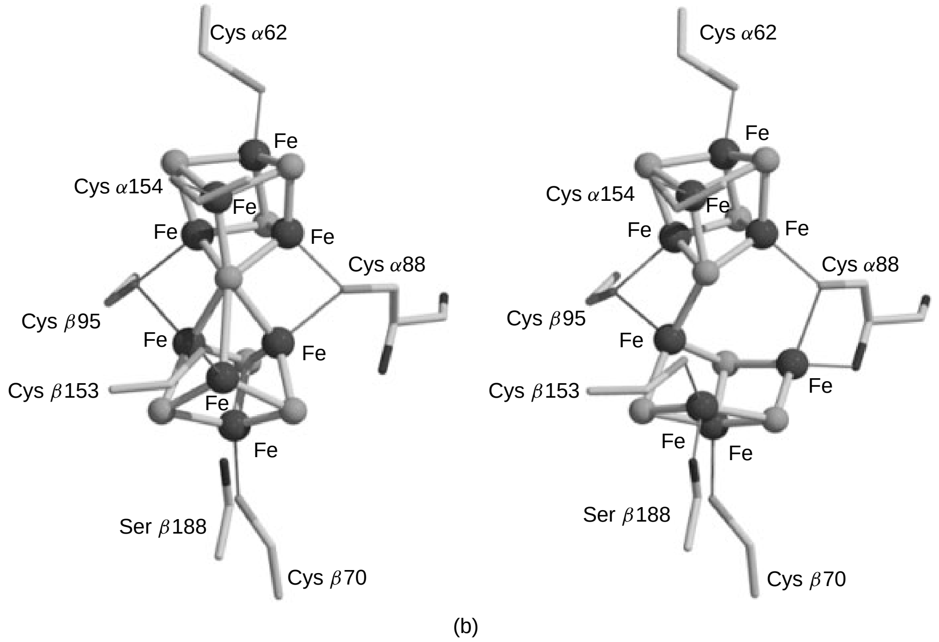

Figure 5 Structure of the (a) dithionite-reduced (P^N) and (b) two-electron–oxidized (P^{OX}) state of the P cluster of the *A. vinelandii* MoFe protein including the coordinating ligands. Iron and sulfur atoms are colored in dark and light gray, respectively. PDB entries 1M1N (P^N) and 2 MIN (P^{OX}) and programs MOLSCRIPT[29] and RASTER3D[30] were used to generate this figure

whereas Cys α88 and Cys β95 coordinate two iron atoms each.[37,38,40] However, P^N and P^{OX} are structurally different in that one half of the P cluster in the P^{OX} state is present in a more open conformation.[10] The interconversion between P^N and P^{OX} involves two iron atoms of the P cluster, and the changes in the core structure of the cluster are accompanied by the changes in the ligation between the cluster and the protein.[40] Two additional protein ligands are present in the P^{OX} state, one is the Oγ of Ser β188 that coordinates the same iron atom as the cysteinyl group of Cys β153, whereas the other is the Cys α88 that coordinates an iron with a backbone amide nitrogen ligand in addition to providing a cysteinyl ligand to the same iron atom (Figure 5).[40]

2.2.3 FeMo Cofactor

The FeMo cofactor is located within the α subunit of the MoFe protein, 14 Å away from the P cluster. It can be studied when it is buried within the MoFe protein or extracted into *N*-methylformamide (NMF).[3,4,18,54] The FeMo cofactor can undergo reversible one-electron oxidation and reduction,[4] and it is generally accepted that the FeMo cofactor provides the site for substrate reduction. The redox properties of the FeMo cofactor and their physiological relevance will be discussed further in Section 3.2.

Figure 6 shows the structure of the FeMo cofactor.[42] It has the overall stoichiometry of Mo : Fe_7 : S_9 : homocitrate and is composed of a [4Fe–3S] cluster and a [Mo–3Fe–3S] cluster bridged by three inorganic sulfide atoms.[37–39,42,44–46,48]

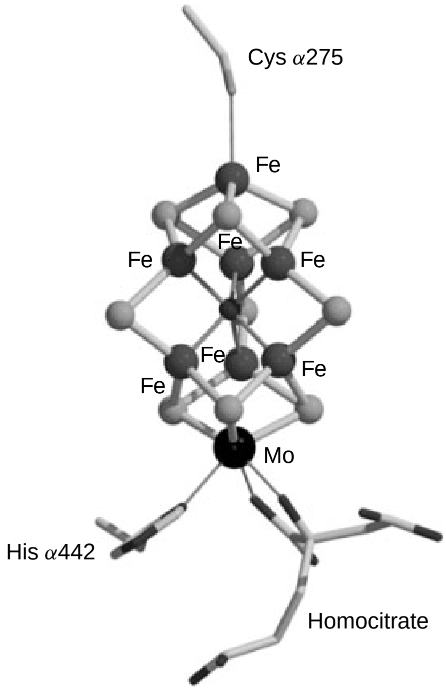

Figure 6 Structure of the FeMo cofactor of the *A. vinelandii* MoFe protein including the coordinating ligands Cys α275 and His α442. Molybdenum, iron, and the central ligand (plausibly nitrogen) are colored in dark gray, with a decrease in atomic radii in the order of Mo > Fe > central ligand. Sulfur is colored in light gray. PDB entry 1M1N and programs MOLSCRIPT[29] and RASTER3D[30] were used to generate this figure

A recently resolved high-resolution (1.16 Å) structure of the *A. vinelandii* MoFe protein revealed the possible presence of a nitrogen atom that is coordinated to six iron atoms in the center of the FeMo cofactor (Figure 6),[42] though conclusive evidence for the identity of this atom remains to be obtained. The core charge of the metals in the FeMo cofactor is proposed to be +1[55] or +3[56] in the resting state, yet the isolated FeMo cofactor is known to be anionic.[4] The overall negative charge of the FeMo cofactor is supplied by homocitrate, an organic terminal ligand of molybdenum, which is −4 if the –OH is deprotonated. The cofactor is ligated to the α subunit of the MoFe protein by just two ligands, His α442 and Cys α275 (Figure 6).

3 NITROGENASE CATALYSIS

The most comprehensive model for the function of molybdenum nitrogenase in the reduction of N_2 is that of Lowe and Thorneley, which was developed almost two decades ago.[57] This model describes two aspects of nitrogenase catalysis, the Fe protein cycle and the MoFe protein cycle.

3.1 Fe Protein Cycle: Electron Transfer from the Fe Protein to the MoFe Protein in the Nitrogenase Complex

Figure 7 shows what is believed to occur during the one-electron Fe protein cycle of the molybdenum nitrogenase, the process in which the Fe protein serves as an obligate electron donor for the MoFe protein.[4,8,10,57,58] In order to carry out the catalytic function of nitrogenase, the reduced Fe protein first binds two molecules of MgATP and undergoes a conformational change before forming a complex with the MoFe protein. Then, coupled with the hydrolysis of 2MgATP molecules to 2MgADP and $2P_i$, one electron is transferred from the $[4Fe-4S]^{1+}$ cluster of the Fe protein to the MoFe protein within the complex. This process is followed by complex dissociation, re-reduction of the oxidized Fe protein, and the dissociation of MgADP, which allows the enzyme complex to start the next cycle of electron transfer.

The distances between the nucleotide binding sites of the Fe protein, the [4Fe−4S] cluster, and the Fe protein/MoFe protein interface (Section 2.1.1) suggest that conformational changes are involved in the catalytic mechanism of the nitrogenase.[6,9,19] Mutagenic studies show that the initial conformational change of the Fe protein, which occurs upon MgATP binding, involves the Walker A motif or the phosphate-binding loop (P-loop), two switch regions (Switch I and II), and a region around residue A157. The Walker A motif and Switch I and II are characteristic of the G-protein family, whereas the area around A157 is unique to the Fe protein.[6,10,19,59–61] In the MgADP-bound conformation of the *A. vinelandii* Fe protein, the Walker A motif (residues 9−16, GKGGIGKS, consensus residues underlined) forms a loop that wraps around the phosphate groups of the nucleotide, with the hydroxyl of residue 16 coordinating the Mg^{2+} ion and the invariant lysine forming a salt bridge with the β phosphate. It is therefore proposed that Switch I (residues 38−44) provides direct communication links between the nucleotide binding site and the MoFe protein docking interface, whereas Switch II (residues 125−129) is responsible for signal transduction between the nucleotide binding site and the [4Fe−4S] cluster.[9,10]

Three oxidation states (0, +1, and +2) have been reported for the [4Fe−4S] cluster of Fe protein (Section 2.1.2).[10,25] Figure 8(a) shows the EPR spectrum of the dithionite-reduced $[4Fe-4S]^{1+}$ cluster of the Fe protein in the absence of nucleotides that exhibits an $S = 1/2$ signal in the $g = 2$ region with a rhombic line shape,[4,62,63] whereas Figure 8(b) shows the EPR-silent spectrum that arises from the diamagnetic IDS-oxidized $[4Fe-4S]^{2+}$ cluster of the Fe protein.[64] The $E^{0'}$ of the $[4Fe-4S]^{2+/1+}$ couple of Fe protein is −310 mV versus NHE, which becomes ca. 100 mV more negative in

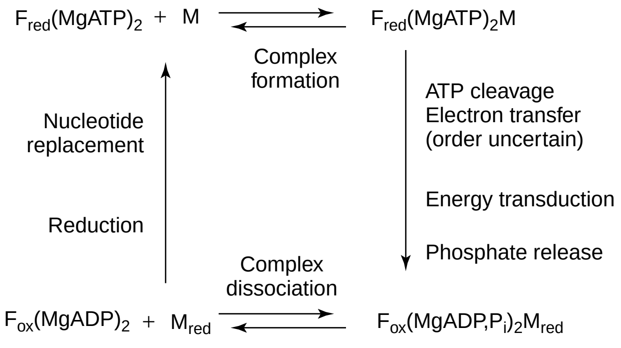

Figure 7 The Fe protein cycle of the molybdenum nitrogenase.[4,8,10,57,58] The cycle describes the MgATP-dependent electron transfer from the Fe protein (F) to one $\alpha\beta$ half of the MoFe protein (M), which is accompanied by the hydrolysis of 2MgATP to 2MgADP and $2P_i$. Subscripts: ox = oxidized and red = reduced

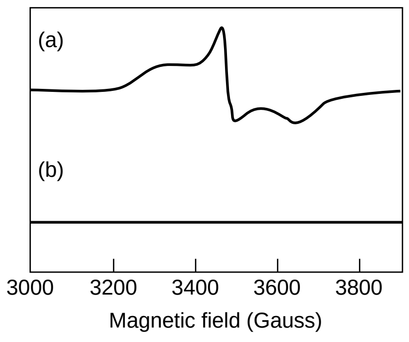

Figure 8 EPR spectra of (a) dithionite-reduced and (b) IDS-oxidized Fe protein in the absence of nucleotide.[4,62–64] The spectra were recorded at 13 K. Note that the dithionite-reduced Fe protein exists in a mixture of $S = 1/2$ and $S = 3/2$ spin states.[18] Only the $S = 1/2$ EPR signal in the $g = 2$ region is shown in the figure

the presence of MgATP.[4] It has been shown that ferredoxin or flavodoxin in vivo or dithionite in vitro can reduce the [4Fe–4S] cluster of the Fe protein to the +1 state (Figure 1b), and the $[4Fe{-}4S]^{2+/1+}$ couple is believed to be utilized in the Fe protein cycle under physiological conditions. However, it has also been demonstrated that the [4Fe–4S] cluster can be further reduced, reversibly, to the all-ferrous $[4Fe{-}4S]^0$ state[25,64] and that two electrons can be transferred from this state to the MoFe protein concomitant with the hydrolysis of two molecules of MgATP,[65] leading to the suggestion that the $[4Fe{-}4S]^{2+/0}$ couple is utilized in vivo at least under some circumstances. In addition to that, a midpoint potential of −800 mV versus NHE has been described recently for the $[4Fe{-}4S]^{1+/0}$ couple.[66] Nevertheless, the physiological relevance of the all-ferrous state of the Fe protein is yet to be established.

3.2 The MoFe Protein Cycle: Electron Transfer within the MoFe Protein and the Substrate-reduction Reaction

Figure 9 shows the MoFe protein cycle, which consists of eight one-electron transfer steps, each of which corresponds to one Fe protein cycle.[4,8,10,57,58] The reactions shown in Figure 9 are consistent with the overall stoichiometry of the enzymatic N_2 reduction, that is, $N_2 + 8H^+ + 8e^- \rightarrow 2NH_3 + H_2$.[10]

Following the transfer of one electron from the Fe protein to the MoFe protein, the FeMo cofactor, which is present in an $S = 3/2$ state with unique features at $g = 3.65$ and 2.01 (Figure 10a), is reduced to an EPR-silent but paramagnetic state.[4] The disappearance of this EPR signal, which can also be accomplished chemically by oxidation with thionine (Figure 10b),[4,64] occurs after the addition of one electron to one FeMo cofactor, indicating that the FeMo cofactor is the final location for the first electron that enters the MoFe protein

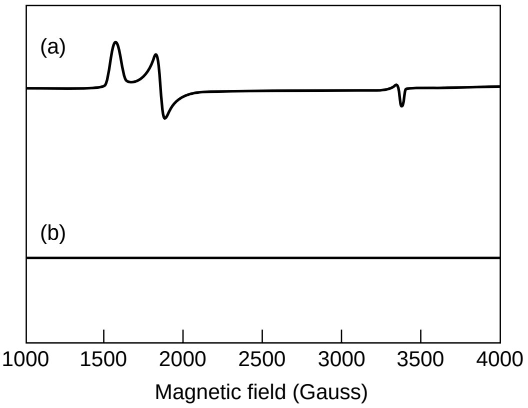

Figure 10 EPR spectra of (a) dithionite-reduced and (b) thionine-oxidized MoFe protein of *A. vinelandii*. The $S = 3/2$ EPR signal arises from the FeMo cofactor center of the protein.[4,8,10,18,64,67–69] The spectra were recorded at 10 K

from the Fe protein. The $MgADP{\cdot}AlF_4^-$-stabilized complex between the Fe protein and the MoFe protein, which is believed to represent the transition state during MgATP hydrolysis, provides some compelling evidence that the electrons are transferred from the Fe protein to first the P cluster and then the FeMo cofactor (Figure 11).[21] Following that, it is believed that electrons are transferred from the FeMo cofactor to the bound substrate, and the substrate reduction subsequently takes place. Interestingly, it has been observed that all products leaving the nitrogenase are reduced by multiples of two electrons. Therefore, the MoFe protein must be able to accumulate several electrons before products are released. Currently, it is not known whether the electrons are stored in the P cluster, the FeMo cofactor, or the enzyme-bound intermediate of substrate reduction. Also, direct evidence that suggests how

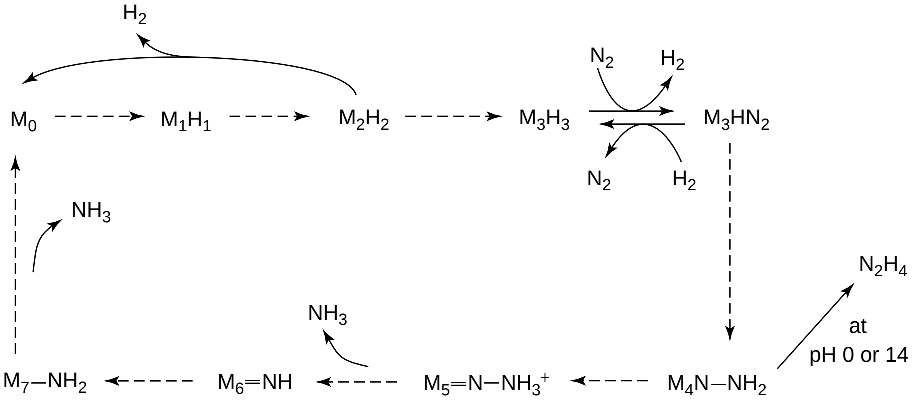

Figure 9 The MoFe protein cycle of the molybdenum nitrogenase.[4,8,10,57,58] The cycle describes a plausible sequence of events during the reduction of N_2 to $2NH_3$ and H_2. M represents one functional half of the MoFe protein, which is composed of one $\alpha\beta$ subunit pair plus one FeMo cofactor and one P cluster. Subscripts 0 to 7 indicate the number of electrons transferred to M from the Fe protein via the Fe protein cycle. It is plausibly assumed that each transferred electron is neutralized by the addition of one proton. Each dotted arrow corresponds to one completed Fe protein cycle (shown in Figure 7)

Table 2 Substrates and inhibitors of nitrogenase[4,8,58,83]

Substrate/inhibitor	Reaction catalyzed by nitrogenase
N_2	$N_2 + 8H^+ + 8e^- \longrightarrow 2NH_3 + H_2$
H^+	$2H^+ + 2e^- \longrightarrow H_2$
C_2H_2	$C_2H_2 + 2H^+ + 2e^- \longrightarrow C_2H_4$ (plus 1–5% C_2H_6 with V and Fe nitrogenases)
C_2H_4	$C_2H_4 + 2H^+ + 2e^- \longrightarrow C_2H_6$
HCN	$HCN + 6H^+ + 6e^- \longrightarrow CH_4 + NH_3$
	$HCN + 4H^+ + 4e^- \longrightarrow CH_3 + NH_2$
CH_3NC	$CH_3NC + 6H^+ + 6e^- \longrightarrow CH_3NH_2 + CH_4$
$N{\equiv}CNH_2$	$N{\equiv}CNH_2 + 8H^+ + 8e^- \longrightarrow CH_4 + 2NH_3$
	$N{\equiv}CNH_2 + 6H^+ + 6e^- \longrightarrow CH_3NH_2 + NH_3$
Cyclopropene	3 Cyclopropene $+ 6H^+ + 6e^- \longrightarrow$ Cyclopropane + 2 Propene
N_2O	$N_2O + 2H^+ + 2e^- \longrightarrow N_2 + H_2O$
NO_2^-	$NO_2^- + 7H^+ + 6e^- \longrightarrow NH_3 + 2H_2O$
N_2H_4	$N_2H_4 + 2H^+ + 2e^- \longrightarrow 2NH_3$
N_3^-	$N_3^- + 3H^+ + 2e^- \longrightarrow N_2 + NH_3$
O_2	$O_2 + 2H^+ + 2e^- \longrightarrow H_2O_2$
COS	$COS + 2H^+ + 2e^- \longrightarrow CO + H_2S$
CO_2	$CO_2 + 2H^+ + 2e^- \longrightarrow CO + H_2O$
CO	Inhibitor of all substrate reductions except H^+
H_2	Inhibitor of N_2 reduction.

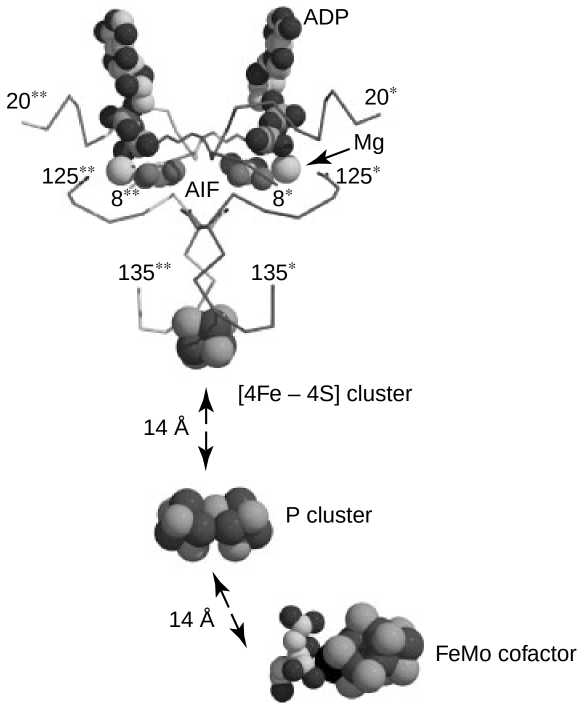

Figure 11 The relative positions of the components of the ADP·AlF_4^--stabilized complex that are involved in the electron flow during the substrate-reduction reaction. PDB entry 1M34 and programs MOLSCRIPT[29] and RASTER3D[30] were used to generate this figure. Metal clusters and ADP·AlF_4^- are shown in space-filling representation. In addition, residues 8 to 20 (including the Walker A motif) and 125 to 135 (including Switch II) from both subunits of the Fe protein are shown (indicated as * and **). Electrons flow in a MgATP-dependent reaction from the [4Fe–4S] cluster of Fe protein to first the P cluster and then the FeMo cofactor of the MoFe protein, where the reduction of dinitrogen to ammonia occurs

the substrate might bind to the FeMo cofactor site of the enzyme, where substrate reduction takes place, is limited. Furthermore, though it is known that the substrate-reduction reaction involves an equal number of electrons and protons and that the P cluster might be involved in this process,[9,40] how protons are transferred from the solvent to the FeMo cofactor site has not been established.

What is known, though, is that in addition to its physiological substrates, that is, N_2 and H^+, nitrogenase is able to reduce a large variety of small doubly and triply bonded substrates (Table 2). Progress has been made in understanding the interaction of the FeMo cofactor site with such substrates or inhibitors as C_2H_2, CS_2, or CO,[55,70–75] as well as that of the isolated FeMo cofactor with CN^- and CO.[76–80] Also, on the basis of a molecular biology approach, it has been suggested that the substrate might bind to the [4Fe–4S] face of the FeMo cofactor, which is capped by Val α70 and Arg α96 of the MoFe protein.[81,82] In addition, as mentioned in Section 2.2.3, a high-resolution (1.16 Å) structure of the nitrogenase MoFe protein has been obtained recently, which indicates the possible presence of a nitrogen atom that is coordinated to six iron atoms in the center of the FeMo cofactor.[42] This interesting finding may in time provide us with significant insight into the mechanism of dinitrogen reduction.

4 NITROGENASE ASSEMBLY

The biosynthesis of nitrogenase is arguably one of the most complex processes in the field of bioinorganic chemistry, requiring the participation of at least 15 different gene

products. Like Section 3, this section will only discuss the assembly mechanism of the molybdenum nitrogenase, which is the best-characterized nitrogenase system.

4.1 Fe Protein Assembly

The assembly of the Fe protein involves the biosynthesis of the structural polypeptides and the biosynthesis and insertion of the [4Fe−4S] cluster into the Fe protein. Substantial progress has been made in understanding the assembly of the molybdenum nitrogenase Fe protein and its [4Fe−4S] cluster, a process that involves the *nifH* gene that encodes for the subunits of the Fe protein and at least *nifS*, *nifU*, and *nifM* gene products that are implicated in the [4Fe−4S] cluster assembly (Table 3 and Figure 12).[8,11,84] It was initially proposed that NifS (*nifS* gene product) and NifU (*nifU* gene product) have complementary functions related to the general mobilization of S and Fe for nitrogenase metallocluster formation. This suggestion was supported by experiments that demonstrated that NifS is a pyridoxal-dependent cysteine desulfurase and that NifU provides an in vitro scaffold for the formation of [2Fe−2S] clusters destined for nitrogenase metallocluster formation.[85–87] A likely pathway involves the formation of a protein-bound cysteine persulfide on NifS that is subsequently donated to NifU, upon which, in the presence of Fe, a labile [2Fe−2S] cluster is formed.[88] The exact mechanism concerning the assembly of [2Fe−2S] units on the NifU scaffold is not clear, nor is the issue of whether [2Fe−2S] or [4Fe−4S] units are ultimately formed on the NifU scaffold prior to their release for Fe protein maturation. In contrast to the emerging information of the role of NifS and NifU in the Fe protein assembly, little is known about the function of NifM (*nifM* gene product), which has been shown to be essential for the process.[8]

4.2 MoFe Protein Assembly

The assembly of the MoFe protein involves the biosynthesis of the FeMo cofactor, and in a separate pathway, the biosynthesis of a P cluster−containing yet FeMo cofactor−deficient species of the MoFe protein and the insertion of the completed FeMo cofactor into the FeMo cofactor−deficient MoFe protein.[2,8,18,67,69,89]

4.2.1 Biosynthesis of the FeMo Cofactor

Figure 12 illustrates the current model of FeMo cofactor biosynthesis, a process independent of the production of MoFe protein polypeptides,[91–93] which starts with the mobilization of iron and sulfur and the assembly of Fe/S fragments by NifS and NifU.[11] These Fe/S fragments are transferred to NifB (*nifB* gene product),[84] which is subsequently involved in the production of the Fe/S core of the FeMo cofactor (designated NifB cofactor) that probably contains all of the iron and sulfur that ends up in the FeMo cofactor (Table 3).[94,95] Following that, the NifB cofactor, probably bound to an ‘escort’ protein designated NifX (*nifX* gene product), binds to a scaffold $NifN_2E_2$ protein (encoded by the *nifN* and *nifE* gene products).[84,96–100] It is possible that molybdenum and homocitrate could be incorporated into the NifB cofactor while it is attached to NifX in a process that possibly involves NifW and NifV[84,101,102] (*nifW* and *nifV* gene products, respectively). Subsequently, at the transient $NifN_2E_2$ scaffold, the NifB cofactor is rearranged by an unknown mechanism and forms the completed FeMo cofactor. The process of FeMo cofactor formation also requires the Fe protein, MgATP, and reductant,[103–105] though their exact functions in the process have not been established. The completed FeMo cofactor is then transferred to another ‘escort’ protein, probably NifY that is encoded by the *nifY* gene in *K. pneumoniae*[106] or the non-*nif*−encoded protein called gamma (γ) in *A. vinelandii*,[107] which delivers the FeMo cofactor to the FeMo cofactor−deficient MoFe protein (see also Section 4.2.3). However, the exact function of γ in the MoFe protein assembly remains unknown, and the essential role of γ in the process was questioned very recently.[108]

4.2.2 Biosynthesis of a P Cluster−containing, FeMo Cofactor−deficient MoFe Protein

As shown in Figure 12, the biosynthesis of the P cluster−containing yet FeMo cofactor−deficient MoFe protein involves *nifD* and *nifK*, which encode the α and β subunit of the MoFe protein, respectively, and at least the *nifS* and *nifU* gene products, in addition.[8] Expression of the molybdenum nitrogenase is activated by molybdenum and regulated by *nifA* and *nifL* (Table 3). Little is known about the assembly mechanism of the P cluster. Nonetheless, such a P cluster−containing but FeMo cofactor−deficient MoFe protein is obtained from a *nifB* deletion strain of *A. vinelandii*, and an isolated FeMo cofactor can be readily inserted into this MoFe protein.[109] The X-ray crystal structure of this cofactor-deficient protein provides interesting insights into the FeMo cofactor insertion and MoFe protein maturation process[43] and will be discussed in greater detail in the following section.

4.2.3 Insertion of the FeMo Cofactor into the FeMo Cofactor−deficient MoFe Protein

Like the biosynthesis of the FeMo cofactor (Section 4.2.1), the insertion of the FeMo cofactor into the FeMo cofactor−deficient form of the MoFe protein also requires the presence of the Fe protein.[2,4,8,18,67,69,89] This final maturation process of the MoFe protein most likely occurs in a series of steps, which are shown in Figure 12. Initially, the FeMo cofactor site is not accessible to FeMo cofactor insertion (‘closed’ conformation).[105,110,111] The conversion of this site to another form with the FeMo cofactor site accessible to

Table 3 The *nif* gene products and functions[1,4,8,10,11,69,82–84,87,89,90]

Gene	Product/function
(a) Structural genes	
nifH	Product: Fe protein subunit. Forms homodimer ($M_r \approx 60\,000$ Da). A single [4Fe–4S] cluster is bridged between the two identical subunits. Binds two molecules of MgATP. Function: ATP-dependent electron transfer to the MoFe protein, FeMo cofactor biosynthesis, and insertion of the FeMo cofactor into the MoFe protein. Possible function: P cluster assembly and regulation of the alternative nitrogenases.
nifD	Product: MoFe protein α subunit. Forms $\alpha_2\beta_2$ tetramer ($M_r \approx 220\,000$ Da) with β subunit. Holoprotein contains two FeMo cofactors and two P clusters. Function: Contains substrate-reduction site (FeMo cofactor).
nifK	Product: MoFe protein β subunit. Function: See *nifD*.
(b) Processing genes	
nifQ	Product: NifQ. Function: Involved in FeMo cofactor biosynthesis, maybe at an early step. The *nifQ*$^-$ phenotype can be suppressed by elevated levels of Mo or cysteine.
nifB[a]	Product: NifB. Function: NifB is involved in the production of an Fe/S-containing FeMo cofactor precursor, designated NifB cofactor.
nifV[a]	Product: Homocitrate synthase. Function: Formation of homocitrate, which is the organic component of the FeMo cofactor.
nifX	Product: NifX. Possible function: NifX can bind the FeMo cofactor or NifB cofactor. Might be an intermediate carrier in FeMo cofactor biosynthesis.
nifY	Product: NifY. Possible function: NifY attaches to the FeMo cofactor-deficient, NifB$^-$ MoFe protein in case of Kp. Might be an intermediate carrier in FeMo cofactor biosynthesis.
nifN	Product: NifN. Forms $\alpha_2\beta_2$ tetramer ($M_r \approx 210\,000$ Da) with the *nifE* gene product ($NifN_2E_2$). Each tetramer contains two identical redox-active [4Fe–4S] clusters. NifN bears significant sequence identity when compared with the β subunit of the MoFe protein. Function: Required for FeMo cofactor biosynthesis. $NifN_2E_2$ appears to provide a transient site upon which one or more events related to FeMo cofactor assembly occurs.
nifE	Product: NifE. Forms $\alpha_2\beta_2$ tetramer ($M_r \approx 210\,000$ Da) with the *nifN* gene product ($NifN_2E_2$). NifE bears significant sequence identity when compared with the α subunit of the MoFe protein. Function: See *nifN*.
nifM[a]	Product: NifM. Function: Required for activation of the Fe protein.
nifU[a]	Product: NifU. Provides an in vitro scaffold for the formation of [2Fe–2S] clusters destined for nitrogenase metallocluster assembly. Functions: Complements NifS in the mobilization of Fe and S for metallocluster assembly. Required for the activity of the Fe protein and the MoFe protein.
nifS[a]	Product: Pyridoxal-dependent cysteine desulfurase. Functions: Complements NifU in the mobilization of Fe and S for metallocluster assembly. Required for the activity of Fe protein and MoFe protein.
nifW	Product: NifW. Function: Required for full activity of the MoFe protein. Possible function: Might be related in coupling Mo and homocitrate.
nifZ	Product: NifZ. Function: Required for full activity of the MoFe protein. Possible function: Related to FeMo cofactor formation or insertion.
nifT	Product: NifT. Function: Unknown.
(c) Electron transfer genes	
nifF	Product: Flavodoxin. Function: Physiological electron donor of the Fe protein.
nifJ	Product: Pyruvate: flavodoxin oxidoreductase. Composed of two identical $M_r \approx 120\,000$ Da subunits. Function: Couples the oxidation of pyruvate to the reduction of flavodoxin.
(d) Regulatory genes	
nifA	Positive regulatory element.
nifL	Negative regulatory element.

[a]Also required for the vanadium and iron-only nitrogenases, which are encoded by *vnf* and *anf* genes, respectively.

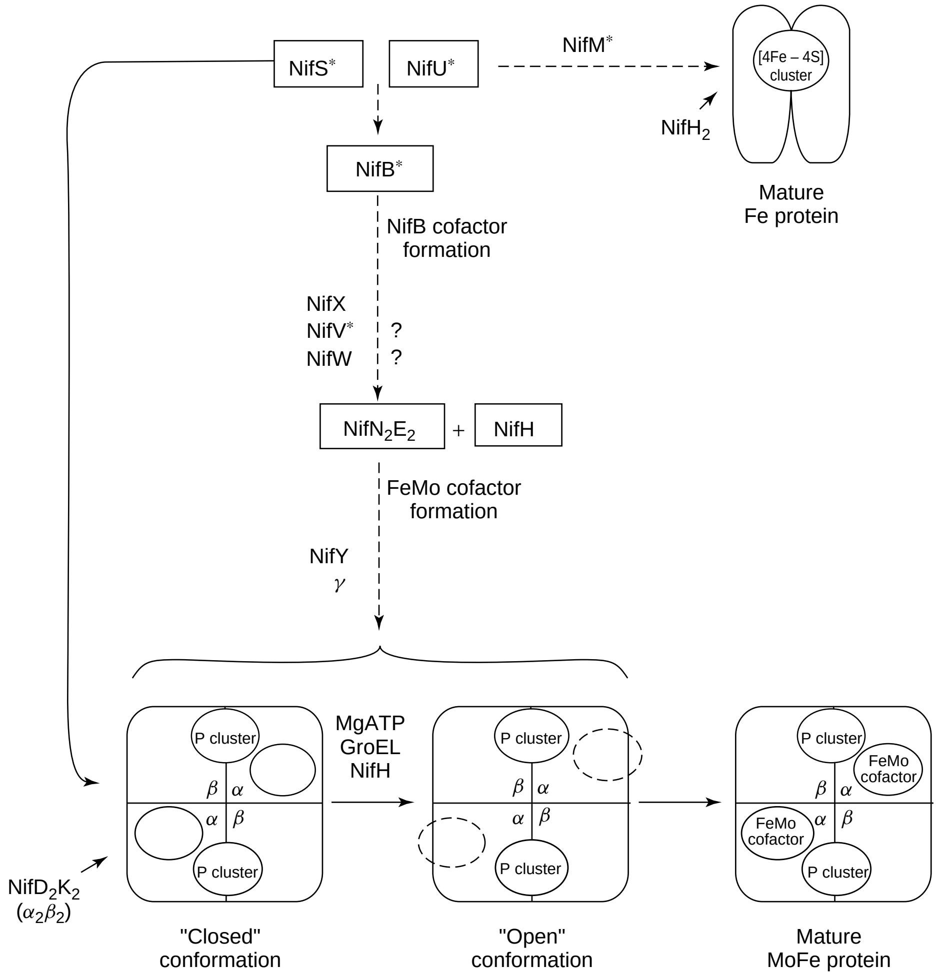

Figure 12 Assembly of the molybdenum nitrogenase. Pathways of FeMo cofactor biosynthesis, Fe protein maturation, and MoFe protein assembly are indicated in dotted, dashed, and solid arrows, respectively. The *nif* gene products that are also required for the vanadium and iron-only nitrogenase systems are indicated by *

FeMo cofactor insertion ('open' conformation) involves at least the combined action of Fe protein, GroEL, MgATP, and possibly γ.[106–108,110,112] Once the FeMo cofactor site is accessible, the FeMo cofactor is inserted, γ dissociates, and the assembly process of the mature nitrogenase is completed.

As mentioned above, a FeMo cofactor–deficient MoFe protein was obtained from a *nifB* deletion strain of *A. vinelandii*, and its X-ray crystal structure has been resolved at 2.3 Å.[43] Like the wild-type *A. vinelandii* MoFe protein (see Section 2.2), this MoFe protein (designated $NifB^-$ MoFe protein)[43] is an $\alpha_2\beta_2$ tetramer consisting of a pair of $\alpha\beta$ dimers that are related by a molecular twofold rotation axis, and each subunit consists of three domains, designated αI, αII, and αIII and βI, βII, and βIII, respectively. In the dithionite-reduced state, the P cluster of the $NifB^-$ MoFe protein, like that of its wild-type counterpart, is assigned to the P^N state and is located between domains αI and βI. However, the FeMo cofactor of the wild-type MoFe protein, which occupies a cavity formed between domains of the α subunit, is not present in the $NifB^-$ MoFe protein (Figure 13). Accompanying the absence of the FeMo cofactor, domain αIII of the $NifB^-$ MoFe protein undergoes substantial structural rearrangements, whereas domains αI and αII as well as the β subunit of the $NifB^-$ MoFe protein remain mostly unchanged relative to those of the wild-type MoFe protein. The structural rearrangements of domain αIII in the $NifB^-$ MoFe protein create a FeMo cofactor insertion funnel, which is not present in its wild-type counterpart. Despite the prevailing negative surface charge of the $NifB^-$ MoFe protein, there is an evident accumulation of positive surface charge lining the funnel the entire way from the entrance down to the FeMo cofactor binding site.[43] Since the FeMo cofactor is overall negatively charged owing to the dominant contribution of homocitrate,[4] this electrostatic feature of the insertion funnel presumably helps to steer the FeMo cofactor down the funnel into its correct position in the holoprotein. Given the instability of the isolated FeMo cofactor, the biosynthetic pathway likely involves the protein-bound FeMo

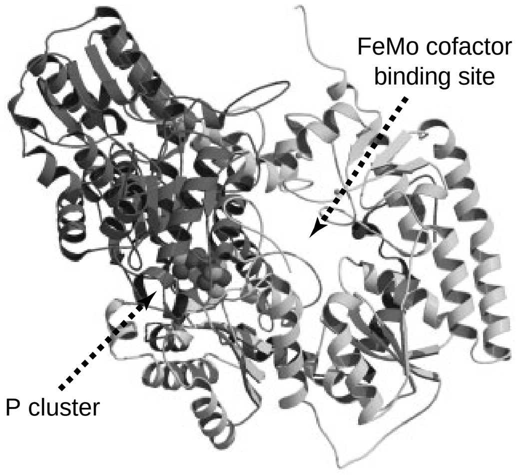

Figure 13 Front-side view of one $\alpha\beta$ subunit pair of the $NifB^-$ MoFe protein of *A. vinelandii*, with the α and β subunits colored in light and dark gray, respectively. The polypeptide chains are shown in ribbon presentation, and the P cluster is shown in space-filling representation. The FeMo cofactor binding site is indicated. PDB entry 1L5H and programs MOLSCRIPT[29] and RASTER3D[30] were used to generate this figure

cofactor instead of the free cofactor. Although the penultimate carrier of the FeMo cofactor preceding its incorporation into the MoFe protein has not been conclusively identified, the rearrangement of the αIII domain might create a potential interaction domain for the docking of the FeMo cofactor donor, in addition to generating the opening for FeMo cofactor insertion.

5 ALTERNATIVE NITROGENASES

5.1 Vanadium Nitrogenase

5.1.1 General Properties

The vanadium nitrogenase has been isolated from *A. vinelandii* and *A. chroococcum* (Table 1). With the molybdenum in the protein replaced by vanadium, the vanadium nitrogenase resembles its molybdenum counterpart.[5,8,10,16] It has the molybdenum–iron (MoFe) protein equivalent in the vanadium–iron (VFe) protein, as well as the iron (Fe) protein equivalent.

In contrast to the $\alpha_2\beta_2$ tetrameric MoFe protein, the VFe protein isolated from *A. chroococcum* is an $\alpha_2\beta_2\delta_2$ hexamer under optimal experimental conditions.[5,16] The VFe protein from *A. vinelandii*, however, shows variable subunit composition.[32] Two species of the *A. vinelandii* VFe protein, that is, $\alpha\beta_2(\delta)$ and $\alpha_2\beta_2(\delta)$, have been characterized[32] (Table 1). The exact stoichiometry between the α, β, and δ subunits has not been established in this case, and the suboptimal subunit composition was speculated to be a result of the weak interactions between the subunits.[36] Other than the subunit composition, the VFe proteins from *A. vinelandii* and *A. chroococcum* have similar properties, which is consistent with the sequence homology of their structural genes. The α and β subunits of the VFe protein, encoded by *vnfD* and *vnfK* genes, respectively, are homologous to the *nifD*-encoded α and *nifK*-encoded β subunits of the MoFe protein;[8,10] whereas the additional small δ subunit of the VFe protein is encoded by *vnfG* (Table 3).[5,8,16,31–36] The VFe protein contains, in preparations with the highest activity, up to 2 vanadium (V) atoms, ∼20 iron atoms, and ∼20 acid-labile sulfur atoms (Table 1). These metal contents are lower than those typically determined in MoFe protein preparations, which is most likely not significant since comparable values were commonly obtained in earlier studies of the MoFe proteins, but have increased with time.[36] Although no X-ray crystallographic data are currently available for the VFe proteins, EPR, MCD, Mössbauer, EXAFS, and cofactor extrusion studies indicate that the VFe proteins from both *A. vinelandii* and *A. chroococcum* contain redox centers that are respective homologues to the P cluster and FeMo cofactor,[5,8,36] leading to the hypothesis that the structure of the VFe protein resembles that of the MoFe protein apart from the presence of the additional δ subunit in the VFe protein. The homologue of the FeMo cofactor in the VFe protein is the designated FeVa cofactor or FeVaco.

The Fe protein of the vanadium nitrogenase, encoded by *vnfH*, shares a high degree of homology with the *nifH*-encoded Fe protein of the molybdenum nitrogenase.[8] Like its counterpart in the molybdenum enzyme, the Fe protein of the vanadium nitrogenase has an α_2 homodimeric composition and contains an [4Fe–4S] cluster.

5.1.2 Catalysis and Assembly

The requirements for vanadium nitrogenase activity are very similar to those of the molybdenum nitrogenase in that both the Fe protein and the VFe protein are essential, MgATP hydrolysis is required, dioxygen needs to be absent, and a reductant like ferredoxin or flavodoxin in vivo or dithionite in vitro is necessary (Figure 1c).[5,8,16] However, there are clear differences in the substrate-reducing profiles of the two enzymes.[5,8,10,16] First, the vanadium nitrogenase fixes N_2 less efficiently than the molybdenum nitrogenase at 30 °C (Table 1). This relationship is reversed at low temperatures. Secondly, in contrast to the molybdenum nitrogenase, hydrazine is a side product of N_2 reduction in the case of the vanadium nitrogenase. Thirdly, the vanadium nitrogenase reduces acetylene, relatively poorly than the molybdenum enzyme, to not only ethylene, which is the only product generated by the molybdenum

enzyme, but also to small amounts of ethane (Tables 1 and 2).

As indicated in Table 3 and Figure 12, some *nif* gene products, for example, NifS, NifU, NifM, NifB, and NifV are also required for the biosynthesis of the vanadium nitrogenase of *A. vinelandii*. However, the expression of the vanadium nitrogenase is regulated by a different activator (i.e. *vnfA*) than the molybdenum enzyme.[8] Molybdenum inhibits the expression of the vanadium nitrogenase. Therefore, in the presence of molybdenum, only the molybdenum nitrogenase is expressed, whereas in the absence of molybdenum, vanadium activates the expression of the vanadium nitrogenase.

In the case of the molybdenum nitrogenase, $NifN_2E_2$ is believed to be critical for the biosynthesis of the FeMo cofactor and functions as a transient scaffold on which modifications of the NifB cofactor occur (Section 4.2.1). Since the vanadium nitrogenase contains respective homologues to the *nifN* and *nifE* genes of the molybdenum nitrogenase, namely, *vnfN* and *vnfE*,[8,84] it is possible that *vnfN* and *vnfE* encode a similar transient scaffold protein complex for the biosynthesis of FeVa cofactor. Given that NifB is also required for the assembly of the vanadium nitrogenase, it is likely that the NifB cofactor binds to $VnfN_2E_2$ during the biosynthesis of FeVa cofactor in a fashion similar to that when it binds to $NifN_2E_2$. In addition, homocitrate synthesized by NifV might be added to the FeVa cofactor at a similar step in the biosynthesis pathway that is analogous to the FeMo cofactor biosynthesis (see Figure 12). Furthermore, NifS and NifU are most likely important for the mobilization of iron and sulfur and the assembly of Fe/S fragments for the vanadium nitrogenase, and NifM is likely required for the maturation of VnfH.

5.2 Iron-only Nitrogenase

5.2.1 General Properties

The iron-only nitrogenase has been isolated from *A. vinelandii, R. rubum*, and *R. capsulatus* (Table 1). It is also similar to the molybdenum nitrogenase except that the molybdenum is replaced by iron in the protein.[5,8,10,16] It has the molybdenum–iron (MoFe) protein equivalent in the iron–iron (FeFe) protein and the iron (Fe) protein equivalent.

As shown in Table 1, like the VFe protein, the FeFe protein has an $\alpha_2\beta_2\delta_2$ hexameric subunit composition under optimal conditions. The α, β and δ subunits of the FeFe protein are encoded by *anfD, anfK*, and *anfG*, respectively. Earlier efforts to purify the FeFe protein suffered from low activities, though progress has been made and recent preparations of the FeFe protein from *R. capsulatus* have activities comparable to that of the VFe protein and do not contain molybdenum or vanadium but high levels of iron (Table 1).

Recent EPR,[35] Mössbauer, and EXAFS[113] studies of the FeFe protein from *R. capsulatus* have provided spectroscopic evidence that the metal clusters of the FeFe protein bear a certain degree of structural homology to those present in the MoFe and VFe proteins. Therefore, it is likely that the FeFe protein contains redox centers that are homologous to the P cluster and FeMo or FeVa cofactor, respectively. The FeMo or FeVa cofactor homologue in the FeFe protein is termed FeFe cofactor or FeFeco.

The *anfH*-encoded Fe protein of the iron-only nitrogenase is very homologous to the *nifH*-encoded Fe protein of the molybdenum nitrogenase and the *vnfH*-encoded Fe protein of the vanadium nitrogenase.[8] This Fe protein also has an α_2 homodimeric composition and contains a [4Fe–4S] cluster.

5.2.2 Catalysis and Assembly

The requirements for the substrate-reduction activity of the iron-only nitrogenase are similar to those of the vanadium nitrogenases (Figure 1c).[8,10] The expression of the iron-only nitrogenase is only activated in the absence of both molybdenum and vanadium and regulated by a different activator (i.e. *anfA*) than the molybdenum or vanadium enzyme.[8] In contrast to the vanadium nitrogenase, the iron-only nitrogenase does not contain homologues to the *nifN* and *nifE* genes. Therefore, the biosynthesis of FeFe cofactor relies on not only the *nif* gene products (i.e. NifS, NifU, NifM, NifB, and NifV), but also on the *vnf* gene products (i.e. VnfN and VnfE). The $VnfN_2E_2$ complex might act as a transient scaffold for the biosynthesis of both the FeVa cofactor and the FeFe cofactor.[8]

5.3 *Streptomyces thermoautotrophicus* Nitrogenase

S. thermoautotrophicus was isolated from the covering soil of a burning charcoal pile.[14,15] The bacterium uses gases as sources of energy, carbon, and nitrogen (hence designated gasotrophy) and is able to fix N_2 with CO or H_2 plus CO_2 as growth substrate under aerobic conditions.[14] N_2 fixation by *S. thermoautotrophicus* exhibits features that are not present in other nitrogen-fixing bacteria. N_2 reduction in this case is coupled with the oxidation of carbon monoxide (CO) by a molybdenum-containing CO dehydrogenase (designated ST3) that transfers the electrons derived from CO oxidation to O_2, thereby producing superoxide anion radicals ($O_2^{\bullet-}$). A manganese-containing superoxide oxidoreductase (designated ST2) reoxidizes $O_2^{\bullet-}$ to O_2 and transfers the electrons to a MoFeS-dinitrogenase (designated ST1), where the reduction of N_2 occurs. Among the most striking properties of the *S. thermoautotrophicus* nitrogenase system are the dependence of the enzyme on O_2 and $O_2^{\bullet-}$, the complete insensitivity of all components involved toward O_2 and H_2O_2, the inability of the enzyme

to reduce ethyne or ethene, and a low MgATP requirement for enzymatic activities. In addition, the subunit structure of the *S. thermoautotrophicus* nitrogenase components and the polypeptides involved seem to be dissimilar from the known nitrogenases.[15]

6 SUMMARY

Nitrogenases are a class of metalloenzymes that catalyze biological N_2 fixation, the overall reaction of which is usually depicted as: $N_2 + 8H^+ + 16MgATP + 8e^- \rightarrow 2NH_3 + H_2 + 16MgADP + 16P_i$. Four classes of nitrogenases, that is, the molybdenum nitrogenase, the vanadium nitrogenase, the iron-only nitrogenase, and the *S. thermoautotrophicus* nitrogenase, have been described. The first three classes of nitrogenases are very similar except for the heterometal atom in the active site of the metal cluster (molybdenum, vanadium, or iron), whereas the fourth is superoxide-dependent and apparently different from the other nitrogenases.

The best-characterized molybdenum nitrogenase comprises two metallosulfur proteins, that is, the molybdenum-iron (MoFe) protein and the iron (Fe) protein, both of which are essential for the enzymatic activity. The Fe protein is an α_2 homodimer (encoded by *nifH*) of $M_r \sim 60$ kDa. The two subunits are bridged by a [4Fe–4S] cluster and each has a MgATP binding site. The MoFe protein is an $\alpha_2\beta_2$ tetramer (encoded by *nifD* and *nifK*) of $M_r \sim 220$ kDa. It contains the [8Fe–7S] cluster (P cluster) that is bridged between each $\alpha\beta$ subunit pair and the [Mo–7Fe–9S–homocitrate] cluster (FeMo cofactor or FeMoco) that is located within each α subunit.

The catalysis of molybdenum nitrogenase occurs in a series of steps. First, the reduced Fe protein binds two molecules of MgATP and undergoes a conformational change before forming a complex with the MoFe protein. Then, coupled with the hydrolysis of two MgATP molecules to 2MgADP and $2P_i$, one electron is transferred from the Fe protein to the MoFe protein within the complex. This is followed by complex dissociation, re-reduction of the oxidized Fe protein, and the dissociation of MgADP, which allows the enzyme to start the next cycle of electron transfer. Once a sufficient amount of electrons is accumulated in the MoFe protein, reduction of the bound substrate takes place.

The assembly of the molybdenum nitrogenase Fe protein involves the *nifH* gene and at least the *nifS, nifU,* and *nifM* gene products that are implicated in the [4Fe–4S] cluster assembly, while the assembly of MoFe protein requires at least 15 *nif* gene products and involves the biosynthesis of FeMo cofactor and FeMo cofactor–deficient MoFe protein in separate pathways and the insertion of FeMo cofactor into the MoFe protein.

1 INTRODUCTION

In the early 1890s, Lord Rayleigh discovered that nitrogen obtained by removal of the gases O_2, CO_2, H_2O from an air sample was denser than nitrogen obtained by chemical procedures. Among other theories for this discrepancy was the idea that some heavier unknown gas was present in the air. In 1894, Lord Rayleigh and William Ramsay discovered that this unknown gas was a new element.[1] Because the gas was shown to be chemically inert, they named it argon, from Greek, *argon*, meaning inactive. The other members of the noble gas (Ng) series were discovered and isolated in the subsequent years up to 1900 by William Ramsay and his assistant Morris Travers. They used a new experimental technique, low-temperature distillation.

The element helium, from Greek *helios*, the sun, had already been noted in the Sun's spectrum in 1868, but was not isolated as a terrestrial element until 1895, when Ramsay obtained it by heating the mineral uraninite in which the helium was physically trapped. With an improved technique of liquid air distillation, Ramsay and Travers isolated neon (Greek, *neos*, new), krypton (Greek, *kryptos*, hidden), and xenon (Greek, *xenon*, stranger). An excellent account of the discovery of the noble gases and the early controversy regarding the discovery of argon is given by Travers.[2]

The last of the family of the noble gases was found in 1900 by Owens and Rutherford. This was radon-220, a product of the *Radioactive Decay* of thorium. Also in the same year, radon-222, which is a product of the radioactive decay of radium, was discovered by Dorn.

This article will cover the general chemistry of some of the more common noble gas species, including fluorides, oxides, transition metal salts, and derivatives of carbon and nitrogen.

2 THE NOBLE GAS ELEMENTS

Helium is the second most abundant element in the universe. In the Earth, it is continuously formed by radioactive decay, mostly of uranium and thorium. Its present concentration in the atmosphere is probably the equilibrium concentration between the amount being released from the Earth's crust and the amount of helium escaping from the atmosphere into space. The atmosphere represents the major source for neon, argon, krypton, and xenon. They are produced as by-products during fractional distillation of liquid air. Radon is obtained from the radioactive decay of radium.

The noble gases have closed-shell electronic structures ($1s^2$ for helium and ns^2np^6 for the other noble gases) (*see* ***Electronic Structure of Main-group Compounds***) and are extremely stable, as shown by the high ionization energies, especially of the lighter members: He, 24.58; Ne, 21.56; Ar, 15.76; Kr, 14.00; Xe, 12.13; Rn, 10.75 eV. They are all colorless, odorless, tasteless, low-boiling, monoatomic gases whose physical properties vary systematically with atomic number.[3] The boiling point of helium is the lowest of any known substance. The weak forces between noble gas atoms are proportional to the *Polarizability* element and increase with the increasing size of the electron clouds.

The ability of these gases to form true chemical compounds with other atoms is limited to the heavier members of the group, krypton, xenon, and radon, where the first ionization energies are reduced to a level comparable with other chemically active elements. Theoretical studies, however, have indicated that it may be possible to isolate helium derivatives, such as MeBeHe.[4] Many of the compounds are prepared at low temperature and characterized through spectroscopic techniques. More recently, multinuclear NMR has emerged as an extremely useful characterization technique.[5]

3 WEAKLY BONDED SPECIES OF NOBLE GASES

The species known before 1962 that contained noble gases combined with other elements and molecules were

cationic species, observed only in the gas phase, or inclusion compounds. The latter involve noble gas atoms held in host crystal lattices, with only weak London exchange interactions helping to fix the gases in the lattice cage.

Emission spectra from discharge tubes or from mass spectrometric studies containing a single gas or mixtures of pure noble gases give evidence for the presence of diatomic molecules. Usually, it is not clear if these are neutral molecules or ions. Ions are more likely to exist because chemical bond formation seems more likely when the closed-shell arrangement is destroyed by removal of an electron. There is also spectroscopic evidence for diatomic molecules between noble gas atoms and other atoms (e.g. H, O, N, Hg) or molecules (e.g. CO_2, N_2, SF_6, etc.). All these species have exceedingly short lifetimes.

Inclusion compounds, or clathrates, are known where the noble gas is present within a crystalline framework of water (general ideal formula $8\,Ng{\cdot}46H_2O$) or hydroquinone ($Ng{\cdot}3C_6H_4(OH)_2$). There are no chemical bonds holding the guest atoms or molecules to the host molecules. Because it is difficult to define exactly what is and what is not a chemical bond, it is better to compare the energies involved.[6] The energies with which noble gas atoms are bound in clathrates are 10 times higher than the van der Waals energies between the noble gas atoms probably owing to the permanent dipoles possessed by the host molecules. By comparison, the energies in common chemical bonds are 10 times higher than bonding energies in clathrates. There are extensive reviews of weakly bound species of noble gases by Holloway[7] and Bartlett and Sladky.[8]

4 THE PREPARATION OF THE FIRST TRUE CHEMICAL COMPOUND OF A NOBLE GAS

After argon was isolated as the first member of the noble gas group in 1894 by Rayleigh and Ramsay, they tried various chemical reagents to form compounds of the new element, but without success. Ramsay also sent a 100-mL sample of the gas to his friend Moissan, the discoverer of fluorine, so that he could attempt to prepare a fluoride. His unsuccessful experiment was considered the ultimate test for the chemical inertness of argon. Unfortunately, some years later, the electronic theory of valence reinforced the notion of the chemical inertness of the noble gases. The noble gas valence-electron configuration was defined as the configuration to which other elements tend in their chemical bonding.

In 1933, besides some theoretical speculations that noble gas compounds should exist, some new reports of unsuccessful experiments to prepare noble gas compounds were published. The most promising experiment was carried out by Yost and Kaye[9] at the suggestion of Pauling, who was convinced that at least the heavier noble gases, for example, xenon, should react with the most electronegative elements, for example, fluorine (*see* ***Fluorine: Inorganic Chemistry***). The failure of Yost and Kaye was really very unfortunate, since a similar experiment, carried out 32 years later, using sunlight in place of their electrical discharge, was successful.

Bartlett and Lohmann proved that an oxyfluoride of platinum, made by fluorination in the presence of oxygen, was the salt $O_2^+PtF_6^-$. This indicated that PtF_6 was an oxidizer of unexpected power. Bartlett immediately noted that the ionization potential of the xenon atom is almost identical to that of the oxygen molecule ($I(O_2) = 12.2$ eV, $I(Xe) = 12.13$ eV). He tried the reaction of xenon gas with PtF_6 vapors. Yellow–orange xenon fluoroplatinate(V) was obtained.[10] This and the subsequent studies at Argonne National Laboratory, where PtF_6 had first been prepared in 1957, started a new era of inorganic chemistry. Interest was so wide that a special meeting on noble gas compounds was organized at Argonne eight months after the first preparation of the true xenon compound.[11] Since then, many books and reviews treating the developments in noble gas chemistry have been published.[8,12–16]

5 THE CHEMISTRY OF XENON

5.1 Xenon Fluorides

Three binary fluorides of xenon are known: XeF_2, XeF_4, and XeF_6. XeF_8 is not known (*see* ***Fluorides: Solid-state Chemistry***). The fluorides are readily prepared from the elements and are thermodynamically stable. Full characterization data is available for these compounds, including gas-phase ^{129}Xe and ^{19}F NMR data.[17] The commercial availability of XeF_2 has greatly increased the study and use of this reagent.[18]

5.1.1 Xenon Difluoride

Xenon difluoride was prepared for the first time from a xenon–fluorine gas mixture using an electric discharge.[19] Other kinds of energy, such as heat, UV light, sunlight, high-intensity γ-radiation, irradiation by electrons from a van de Graaff accelerator, irradiation by 10 MeV protons and so on, are also effective. A convenient preparation using very simple apparatus, and affording a pure product, is the exposure of a xenon–fluorine gas mixture to sunlight. Very pure XeF_2 in greater quantities (up to 1 kg) can be best prepared by UV irradiation (*see* ***Photosynthesis***) of a gaseous xenon–fluorine mixture in the mole ratio 1:2, with addition of about 1 mol% of HF in the fluorine as a catalyst. The thermal reaction between xenon and fluorine to form xenon difluoride is heterogeneous and takes place on the prefluorinated walls of the reaction vessel and/or the surface of an added fluoride, such as NiF_2. In the presence of NiF_2, it is possible to synthesize even XeF_6 at

393 K, starting with the gaseous mixture $Xe:F_2 = 1:5$. Xenon difluoride is colorless as solid, liquid, or gas. The vapor pressure of the solid at 298 K is 6.0×10^2 Pa, and therefore at room temperature large crystals are usually formed. The ΔH_f (solid) is $-163\,kJ\,mol^{-1}$.

In crystalline XeF_2, the linear molecules are aligned parallel in a body-centered tetragonal array (Figure 1). Each xenon atom has two bound fluorine atoms at 2.00 Å and eight fluorine atoms from fluorine ligands of the eight nearest XeF_2 neighbors at 3.42 Å. It is evident that there are strong interactions between XeF_2 molecules. This structural arrangement is compatible with the high enthalpy of sublimation of XeF_2 ($55.7\,kJ\,mol^{-1}$) and the assumed charge distribution in each molecule ($^{-05}F–Xe^{+1}–F^{-05}$). It is further evident from the packing arrangement that the equatorial region of each XeF_2 molecule is avoided by fluorine ligands of neighboring molecules because the nonbonding valence electrons of the xenon atom effectively shield the positive charge on the xenon.

Xenon difluoride dissolves in the halogen fluorides BrF_3, BrF_5, and IF_5 and in AHF (anhydrous hydrogen fluoride) as monomolecular species geometrically similar to the gas-phase species. XeF_2 sometimes forms complexes with the solvents (e.g. BrF_3 and IF_5). XeF_2 is also soluble in MeCN and other organic solvents.

XeF_2 is potentially a strong oxidizer, but is frequently unreactive for kinetic reasons. Its stability in aqueous solution is an example of this kinetic inertness. XeF_2 dissolves in water ($\approx 25\,g\,L^{-1}$ at 273 K) with only slight decomposition. XeF_2 may be recovered by extraction with CCl_4 or by fractional distillation. The equilibrium constant for equation (1) has been estimated to be about 10^{40}. This explains the observation that the fluorination of uranium and zirconium oxides by XeF_2 is initiated by the addition of water to the reaction mixture.[20] XeF_2 is, generally, a very good fluorinating agent for a wide range of substrates.[21]

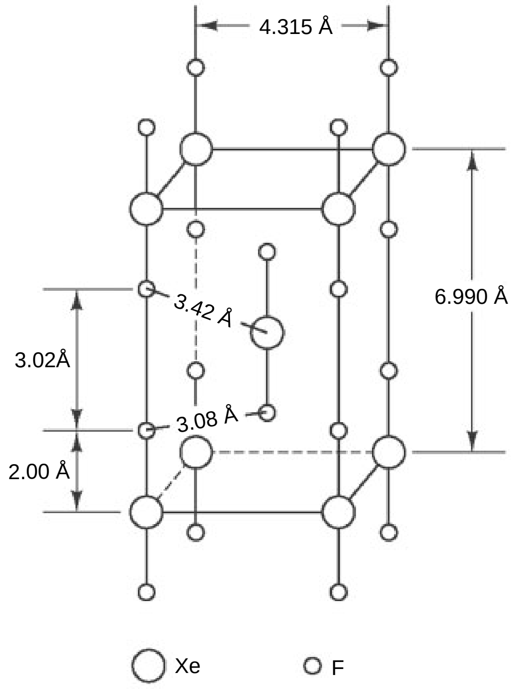

Figure 1 Unit cell of xenon difluoride

$$XeF_2(aq) + H_2O \longrightarrow Xe(g) + 0.5\,O_2(g) + 2HF(aq) \qquad (1)$$

Neutral and acid aqueous solutions of XeF_2 decompose rather slowly (half-life being $\approx$7 h at 273 K), while the decomposition in basic solution is fast, the base catalytic effect being roughly in the order of the base strength. XeF_2 is stable in dried propylene carbonate.[22]

5.1.2 *Xenon Tetrafluoride*

Xenon tetrafluoride was the first noble gas binary fluoride to be synthesized. It was prepared by heating a gaseous mixture of xenon and fluorine in the mole ratio 1:5 at a total pressure of 0.6 MPa at 673 K in a closed nickel can.[23] These conditions are close to the optimum for XeF_4 preparation.[24] Low temperatures and high-fluorine pressures favor XeF_6 formation, while low fluorine pressures and high temperatures favor XeF_2 formation. If high purity XeF_4 is desired, it is necessary to purify it by chemical methods because it is nearly impossible to separate xenon difluoride from the tetrafluoride by physical means (the two have similar vapor pressures and also form a 1:1 adduct). A general chemical purification method that can be used for any mixture of xenon fluorides exploits the inferior fluoride ion donor ability of XeF_4 compared to XeF_2 or XeF_6 (equation 2).[25]

$$\left.\begin{matrix} XeF_2 \\ XeF_4 \\ XeF_6 \end{matrix}\right\} \text{in } BrF_5 \text{ soln.} + AsF_5(\text{excess}) \xrightarrow[273\,K]{-AsF_5,\ -BrF_5}$$

$$XeF_4 + (Xe_2F_3)^+AsF_6^- + XeF_5^+AsF_6^- \xrightarrow[293\,K]{\text{vacuum}} XeF_4 \qquad (2)$$

Other preparative methods include the photochemical reaction between xenon and excess of fluorine in the presence of NiF_2 as catalyst, thermal decomposition of XeF_6 in the presence of NaF (this method is also convenient for the preparation of pure fluorine) and the pyrolysis of some XeF^+ salts such as $XeF^+PtF_6^-$ or $XeF^+Pd_2F_9^-$ at 423 K (equations 3 and 4).

$$2XeFPtF_6(c) \longrightarrow XeF_4(g) + XePt_2F_{10}(c) \qquad (3)$$

$$XePd_2F_{10}(c) \longrightarrow XeF_4(g) + Pd_2F_6(c) \qquad (4)$$

XeF_4 is colorless as crystals, liquid, or vapor. The vapor pressure of the solid at 298 K is 3.4×10^2 Pa and the ΔHf is $-266\,kJ\,mol^{-1}$. Vibrational spectroscopic and electron diffraction data have proven that the XeF_4(g) molecule is

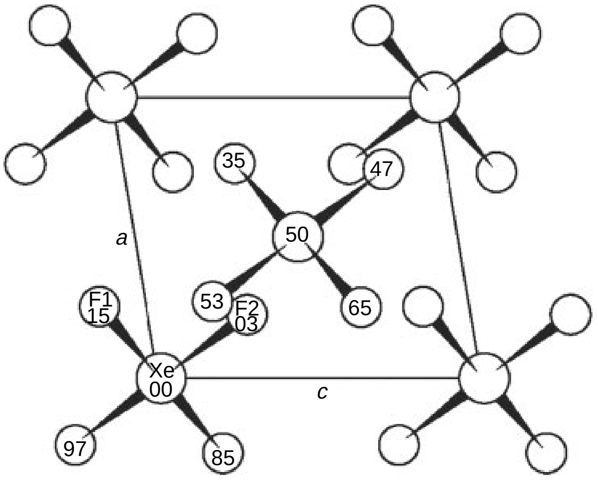

Figure 2 Molecular packing in XeF_4 as seen in projection down the *b* axis. The numbers on some of the atoms are *b* coordinates ($\times 100$)

square-planar (D_{4h}) with a Xe–F bond length of 1.94 Å (*see* ***Diffraction Methods in Inorganic Chemistry***). The size and the shape of XeF_4 in the crystal is not significantly different from the gas-phase molecule (see Figure 2). The Xe–F bond length in the solid is 1.953 Å and the F–Xe–F angle is 90.0°. The enthalpy of sublimation of XeF_4 ($61\,kJ\,mol^{-1}$) indicates strong electrostatic interactions between XeF_4 molecules, as in the case of XeF_2.

XeF_4 can be kept in thoroughly dried glass or quartz and can be stored indefinitely in Kel-F (polyfluorotrichloroethylene), nickel, or monel containers. XeF_4 hydrolyzes very rapidly, with one-third of the xenon remaining in the solution as the trioxide (equation 5).

$$3XeF_4 + 6H_2O \longrightarrow XeO_3 + 2Xe + 1.5O_2 + 12HF \qquad (5)$$

The low bond energy of XeF_4 causes it to be a strong oxidative fluorinator (comparable with BrF_3), but it has high-kinetic inertness like XeF_2.

5.1.3 Xenon Hexafluoride

The first synthesis of XeF_6 was also reported in 1962.[26] All syntheses are best carried out in nickel or monel reaction vessels. From the equilibrium constants for the formation of xenon fluorides,[24] it is evident that an excess of fluorine is necessary to minimize the formation of XeF_4. In addition, the reaction temperature should be as low as possible, yet consistent with a reasonable reaction rate. In the presence of NiF_2 as catalyst the activation energy for the xenon–fluorine reaction is lowered and the reaction proceeds rapidly at 393 K, in contrast to 523 K without catalyst.

XeF_6 may be purified from other xenon fluorides and $XeOF_4$ by its complexation with sodium fluoride at 323 K. Impurities ($XeOF_4$, XeF_2, XeF_4) may be removed under vacuum at 323 K, the Na_2XeF_8 complex being stable at that temperature. XeF_6 is recovered by decomposing the complex at 398 K. Solid XeF_6 is colorless below the melting point, while the liquid and vapor are yellow–green. XeF_6 is much more volatile than XeF_2 or XeF_4, although much less so than other hexafluorides. Its ΔH_f is $-338\,kJ\,mol^{-1}$.

The crystal structure of solid XeF_6 is complex. The solid assumes at least four distinct crystalline polymorphic forms (*see Polymorph*). The existence of three modifications was shown by heat capacity measurements.[27] These polymorphic phases were designated I, II, and III in order of decreasing temperature, with transitions at 291.8 K and 253.8 K. The phase IV is a cubic phase that exists from the melting point of XeF_6 to at least 93 K. Phase I is a high-temperature monoclinic modification, phase II is the orthorhombic form, and phase III is a low-temperature monoclinic form. The phases I, II, and III all contain tetrameric rings that approximate to F^--bridged XeF_5^+ clusters. Transformations between these three phases occur relatively easily, since all contain only tetramers. Solid–solid transformations seem to occur only when both phases contain the same structural units. Solid–solid transformations are not observed between these tetramer-based phases and the cubic phase, which contains both tetramers and hexamers. The crystal structure of the cubic modification (phase IV)[28] is shown in Figure 3. The hexameric clusters, like the tetramers, can also be viewed as F^--bridged clusters of XeF_5^+ species. Clearly, this phase cannot transform to the tetramer-based forms without breakup of the hexameric units, which must require considerable reorganization energy.

A comparison of the density of liquid XeF_6 with the densities of all the other hexafluorides shows that its density is unexpectedly high. This is linked with the association of the molecules in the liquid phase and may well involve aggregations similar to those observed in the crystal phases. The unusually large heat capacity of the liquid is in accord with this. Near the melting point the heat capacity of the liquid is almost twice as great as that of the solid. This places XeF_6 not only in a unique position among the other hexafluorides, but also among all other liquids in general. The entropy of vaporization of XeF_6 at its boiling point has the extraordinarily high value of $136.9\,J\,K^{-1}\,mol^{-1}$. This seems to be the highest entropy of vaporization observed for any known liquid. The association of molecules in the liquid phase must be caused by intermolecular forces beyond those of the van der Waals type. Strongly interacting XeF_5^+ and F^- species in tight clusters may be the cause. The gas-phase XeF_6 molecule has no dipole moment, but the autoionization observed in the solid state provides for the required strong association.

XeF_6 is a much more powerful oxidizer and fluorinator than the lower xenon fluorides. It also has lower kinetic stability than XeF_2 and XeF_4. Thus XeF_6 cannot be stored in glass or quartz, but reacts with them by exchanging fluorine for oxygen to yield initially $XeOF_4$, subsequently XeO_2F_2, and finally xenon trioxide (see Sections 5.2.1 and 9).

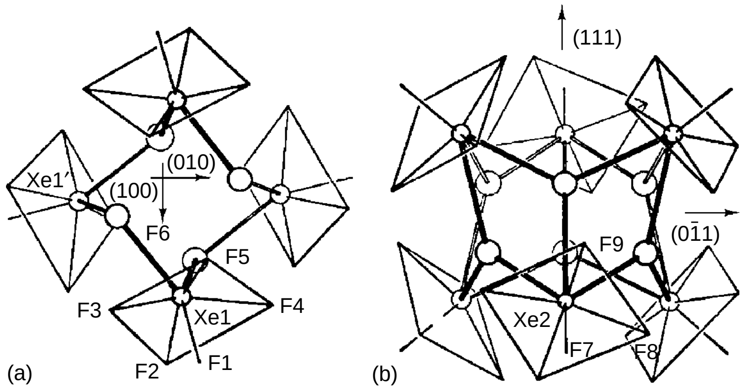

Figure 3 (a) Tetramer of $XeF_5{}^+F^-$, (b) hexamer of $XeF_5{}^+F^-$. Xenon atoms are indicated by small circles and bridging fluoride ions by large circles; $XeF_5{}^+$ ions are drawn in skeletal form

5.2 Xenon Oxides

Among xenon oxides only XeO_3 and XeO_4 have been definitively isolated and characterized. XeO is known, as a gas-phase species, to be bound with respect to a $^1D(0)$ atom but not with respect to ground-state $^3P(0)$. There is no evidence for a condensed phase XeO species. Recently, however, the unique radical, HXeO, has been isolated by UV photolysis of either H_2O/Xe or N_2O/HBr/Xe solid mixtures as 7 K. The compound was characterized by IR and its intrinsic stability supported by ab initio calculations.[29]

5.2.1 *Xenon Trioxide*

XeO_3 may be prepared by controlled hydrolysis of XeF_6 at low temperature (equation 6).[30] It can also be derived from XeF_4 as already described. The best hydrolysis is performed in the presence of sufficient magnesium oxide (MgO) to rapidly neutralize all the hydrogen fluoride (HF) produced. Aqueous XeO_3 solutions are indefinitely stable if reducing impurities and light are excluded. If the solution is evaporated to dryness the solid oxide may detonate.

$$XeF_6(g) + 3H_2O(l) \longrightarrow 6HF(aq) + XeO_3(aq) \qquad (6)$$

XeO_3 is a colorless, hygroscopic, detonatable solid with a low vapor pressure at room temperature. Its ΔH_{sub} is 126 (42) kJ mol^{-1} and ΔH_f is 402 kJ mol^{-1}.

5.2.2 *Xenon Tetroxide*

XeO_4 was first prepared by the reaction of concentrated sulfuric acid with xenates(VIII) at room temperature or lower.[31] When the reaction is carried out slowly, about one-third of the xenon is converted to XeO_4. The tetroxide is purified by vacuum sublimation. XeO_4 is a pale yellow solid that, at 273 K, has a vapor pressure of about 33×10^2 Pa, while at 195 K its volatility is still high enough for mass spectrometric detection. Usually, decomposition to xenon and oxygen occurs before the sample reaches 273 K. The decomposition is often violent in accord with the enthalpy of formation of XeO_4 (642 kJ mol^{-1}). XeO_4 is an oxidizing agent of great power. Its structure has been investigated in the gas phase by electron diffraction and shown to be tetrahedral with Xe–O = 1.74 Å.

5.3 Xenon Oxyfluorides

All possible xenon(IV) and xenon(VI) oxyfluorides are known. Among the xenon(VIII) oxyfluorides, only $XeOF_6$ is not yet isolated.

5.3.1 *Xenon Oxide Difluoride*

$XeOF_2$ has been prepared in the reaction of XeF_4 with water in HF solvent at 210 K.[32] $XeOF_2$ presumably decomposes slowly even at 210 K to yield XeF_2 and oxygen. After the reaction is completed, the product is washed with HF at 195 K to remove traces of unreacted water and XeF_2. $XeOF_2$ is a light-yellow solid that decomposes explosively at ca. 273 K On slow warming from 210 to 273 K over a period of 20 h, $XeOF_2$ decomposes to XeF_2 and XeO_2F_2. The solid $XeOF_2$ is characterized by its Raman spectrum (in cm^{-1}) (relative intensities in parentheses): 732 (8), 496 (100), 285 (4), 186 (8), 197 (1).

5.3.2 *Xenon Oxide Tetrafluoride*

$XeOF_4$ was first detected as an impurity by mass spectrometry among the xenon fluorides prepared by thermal methods. It was obtained in macroscopic quantities by the partial hydrolysis of xenon hexafluoride (equation 7).[33] Unreacted XeF_6 and HF formed in the reaction are removed

by treatment with NaF.

$$XeF_6 + H_2O \longrightarrow XeOF_4 + 2HF \quad (7)$$

$XeOF_4$ is known from NMR, vibrational, and *Microwave Spectroscopy* to be a square-based pyramid with an oxygen ligand at the apex (C_{4v}). The microwave data show the xenon and four fluorine atoms to be nearly in the same plane. The Xe–F bond length (1.903 Å) is very similar to that found for XeF_6 (1.890 Å). The Xe–O bond length (1.706 Å) is shorter than in XeO_3 (1.76 Å) or XeO_4 (1.74 Å). The observed geometry is consistent with location of the nonbonding electron pair on the fourfold molecular axis trans to the oxygen atom.

$XeOF_4$ is colorless as solid, liquid, and gas. It has a low-melting point (226.95 K) and is quite volatile (11×10^2 Pa at 273 K). The liquid is nonassociated and the low-electrical conductivity of the pure liquid indicates that autoionization is not significant. The liquid has, at 297 K, a dielectric constant of 24.6 and dissolves alkali fluorides with considerable enhancement of its electrical conductivity. $XeOF_4$ is the most stable molecular compound containing a Xe–O bond. It is thermally stable to nearly 573 K, where it starts to decompose slowly to XeF_4 and oxygen.

5.3.3 *Xenon Dioxide Difluoride*

XeO_2F_2 was observed in the early mass spectra of xenon fluorides and can be obtained by hydrolysis of XeF_6. The best method for its preparation in macroscopic quantities is by the reaction of XeO_3 and $XeOF_4$.[34] The $XeOF_4$ and XeF_2 impurities may be removed by fractional distillation. Xenon dioxide difluoride forms colorless crystals at room temperature, which have a vapor pressure between that of XeO_3 and $XeOF_4$ and melts at 303.95 K to give a colorless liquid. It can decompose to XeF_2 and O_2.

5.3.4 *Xenon Dioxide Tetrafluoride*

XeO_2F_4 was made by the reaction of XeO_3F_2 (see Section 5.3.5) and XeF_6 in $XeOF_4$ as solvent.[35] It was identified by *Mass Spectrometry*. XeO_2F_4 is the most volatile of all known xenon compounds and may therefore possess the symmetrical, nonpolar, D_{4h} symmetry.

5.3.5 *Xenon Trioxide Difluoride*

XeO_3F_2 was the first oxyfluoride of octavalent xenon to be prepared. It was made by reaction of XeF_6 with sodium perxenate solid at room temperature.[36] XeO_3F_2 is, like XeO_4, sufficiently volatile to distil at 195 K. The much greater volatility of XeO_3F_2 as compared to XeO_2F_2 indicates that the molecule of XeO_3F_2 is more symmetrical and probably nonpolar (D_{3h}).

XeO_3F_2 can be prepared in much better yield by the reaction of XeF_6 with XeO_4. Because XeO_3F_2 is rapidly destroyed by XeF_6 with formation of $XeOF_4$, special care must be taken to remove XeO_3F_2 (under vacuum) from the reaction vessel at 195 K immediately after all XeO_4 has been consumed. Structural information has been derived only from vibrational spectroscopy. On this basis, it has been concluded that the molecule XeO_3F_2 has the symmetry D_{3h}. The melting point of XeO_3F_2 is 219.05 ± 0.5 K. The vapor pressure of XeO_3F_2 as a function of temperature is (in 10^2 Pa) 5 at 222.75 K, 7 at 222.35 K, 16 at 236.25 K, 13 at 236.35 K, 29 at 243.85 K, and 32 at 245.15 K.[37] Its heat of vaporization is $33.0 \pm 3.0\ \mathrm{kJ\ mol^{-1}}$. The extrapolated boiling point is 313 K.

5.4 The Dixenon Cation

Green Xe_2^+ is formed either by oxidation of gaseous xenon, for example, with $O_2^+Sb_2F_{11}^-$ salt, or by reduction of XeF^+ salt with water or other reducing agents.[38] Xe_2^+ was also identified by the resemblance of its spectrum to the spectrum of the isoelectronic I_2^- anion. The Xe_2^+ cation has a Raman band at $123\ \mathrm{cm^{-1}}$.

5.5 Xenon(II) Compounds

XeF_2 forms many compounds with binary fluorides, oxide tetrafluorides, and some anhydrous acids. Strong fluoride ion acceptors, for example, such as AsF_5 and SbF_5, can withdraw a fluoride ion from XeF_2 forming XeF^+ species[38,39] or, in the case of excess XeF_2, also $Xe_2F_3^+$ species. The increase in the Xe–F bond energy in the cation formation ($133.9\ \mathrm{kJ\ mol^{-1}}$ in XeF_2, $195.9\ \mathrm{kJ\ mol^{-1}}$ in the cation) contributes to the fluoride ion donor ability of the difluoride. A study focusing on the Lewis acid reactivity of $XeF+$ with various bases in the gas phase determined the bond dissociation enthalpy to be 188 kJ mol 1.[39] Xenon difluoride also forms molecular adducts in which the negatively charged F ligands of XeF_2 are attracted by the positive center of the partner molecule of the adduct.

Xenon(II) compounds can be prepared by fusing stoichiometric amounts of the component fluorides in an atmosphere of a dry inert gas or by dissolving them in a nonoxidizing or reducing solvent. One component can also be used in excess and removed by vacuum distillation to constant weight. Some reactions between binary fluorides in lower oxidation states and XeF_2 have also been carried out in a melt of XeF_2. Under these conditions, the oxidizing as well as the fluorobasic properties of XeF_2 are revealed, and Xe^{II} complexes of higher oxidation state fluorides are formed.

5.5.1 *Compounds with Hexafluorides*

In the system XeF_2–MF_6, only the adducts XeF_2MoF_6, XeF_2WF_6, and XeF_2UF_6 have been claimed. The existence

of these adducts was established only from the melting point–composition diagrams. They are not stable at room temperature and they decompose readily into their component compounds.

5.5.2 Compounds with Pentafluorides

This type of xenon(II) compound is the most common. With pentafluorides, XeF_2 forms three types of compounds: $2XeF_2{\cdot}MF_5$, $XeF_2{\cdot}MF_5$, and $XeF_2{\cdot}2\,MF_5$. It is also possible that compositions richer or poorer in XeF_2 content exist. Both saltlike and fluorine-bridged formulations were suggested to explain the bonding in these compounds. The degree of ionic character in the compounds varies depending on the Lewis acid properties of the pentafluorides involved (*see Lewis Acids & Bases*). The stronger the Lewis acid, the more ionic the compound. $XeF^+Sb_2F_{11}^-$ (Figure 4) is considered to be the most ionic compound. Xenon(II) compounds with pentafluorides, claimed in the literature, are given in Table 1.

The isolation of the compounds $2XeF_2{\cdot}VF_5$ and $2XeF_2{\cdot}TaF_5$ was not confirmed. Stable 2:1 compounds were not obtained either in the XeF_2–NbF_5 nor in the XeF_2–TaF_5 systems.[40] The compound $XeF_2{\cdot}2OsF_5$ was not prepared. Even the 1:1 compound is thermally unstable at room temperature and decomposes to $2XeF_2{\cdot}OsF_5$, xenon, and osmium hexafluoride.

In the case of AuF_5, other compounds with a higher content of AuF_5 could probably also be synthesized. Probably because PF_5 is a relatively weak fluoroacid the

$2XeF_2{\cdot}RuF_5$	$XeF_2{\cdot}RuF_5$	$XeF_2{\cdot}2RuF_5$
$2XeF_2{\cdot}OsF_5$	$XeF_2{\cdot}OsF_5$	–
$2XeF_2{\cdot}RhF_5$	$XeF_2{\cdot}RhF_5$	$XeF_2{\cdot}2RhF_5$
$2XeF_2{\cdot}IrF_5$	$XeF_2{\cdot}IrF_5$	$XeF_2{\cdot}2IrF_5$
$2XeF_2{\cdot}PtF_5$	$XeF_2{\cdot}PtF_5$	$XeF_2{\cdot}2PtF_5$
$2XeF_2{\cdot}AuF_5$	–	–
$2XeF_2{\cdot}PF_5$	$XeF_2{\cdot}PF_5$	–
$2XeF_2{\cdot}AsF_5$	$XeF_2{\cdot}AsF_5$	–
$2XeF_2{\cdot}SbF_5$	$XeF_2{\cdot}SbF_5$	$XeF_2{\cdot}2SbF_5$
$2XeF_2{\cdot}BiF_5$	$XeF_2{\cdot}BiF_5$	$XeF_2{\cdot}2BiF_5$
–	–	$XeF_2{\cdot}2BrF_5$
–	$XeF_2{\cdot}IF_5$	$XeF_2{\cdot}2IF_5$

compounds $2XeF_2{\cdot}PF_5$ and $XeF_2{\cdot}PF_5$ were not established with certainty. All efforts to prepare a phase richer in AsF_5 than $XeF_2{\cdot}AsF_5$ failed. Even the 1:1 compound loses AsF_5 at room temperature to yield $2XeF_2{\cdot}AsF_5$. In the system XeF_2–SbF_5 a set of additional compounds was postulated ($2XeF_2{\cdot}3SbF_5$, $XeF_2{\cdot}3SbF_5$, $XeF_2{\cdot}6SbF_5$) on the basis of the melting point–composition diagram. The molecular adducts, $XeF_2{\cdot}2BrF_5$ and $XeF_2{\cdot}9BrF_5$, were also postulated on the basis of the melting point–composition diagram. The compound $XeF_2{\cdot}IF_5$ is a molecular adduct. The compound $XeF_2{\cdot}2IF_5$ was not confirmed.

Single-crystal structures of the types $XeF^+MF_6^-$ and $XeF^+M_2F_{11}^-$ are shown in Figure 4. The structures in Figure 4 confirm that xenon difluoride donates a fluoride ion to the metal pentafluoride to generate the MF_6^- or $M_2F_{11}^-$ salt, depending on the mole ratio of the reactants. When XeF_2 is in excess, the $Xe_2F_3^+$ cation (Figure 5) is formed. The V-shaped $[F–Xe–F–Xe–F]^+$ cation is planar and symmetrical about the bridging fluorine atom. The intermolecular separations suggest that $F–Xe^+F^-Xe–F^+$ is the major canonical form in the cation.

XeF^+ species in the $XeF^+MF_6^-$ and $XeF^+M_2F_{11}^-$ salts are characterized by a band or pair of bands in the Raman spectrum in the 596–619 cm^{-1} region, and in the IR spectrum in the 600–626 cm^{-1} region. $Xe_2F_3^+$ is characterized by strong Raman bands in the Xe–F stretching region at $\approx$593 and 580 cm^{-1}, and in the bending region at 160 cm^{-1}.

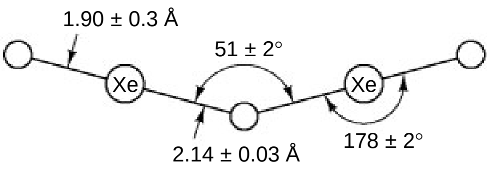

Figure 5 Bond lengths and angles in $Xe_2F_3^+$

5.5.3 Compounds with Tetrafluorides

In the system XeF_2–tetrafluorides, the set of compounds in Table 2 was claimed to exist. The existence of the compounds $2XeF_2{\cdot}MF_4$ (M = Ti, Zr, Hf, Sn) was not confirmed.[40] Tetrafluorides are not sufficiently strong Lewis fluoroacids to stabilize compounds of the type $(Xe_2F_3{}^+)_2MF_6{}^{2-}$. There is some evidence in the case of palladium of the possible existence of such a salt,[41] but it readily loses XeF_2. Even compounds of the type $(XeF^+)_2MF_6{}^{2-}$ have not been isolated. There are several stable polymeric compounds of the type $(XeF^+)_x(MF_5{}^-)_x$ (see Figure 6) and the type $(XeF^+)_x(M_2F_9{}^-)_x$.

Crystal structures have been determined only in the case of $XeF_2{\cdot}CrF_4$ (Figure 6) and $XeF_2{\cdot}XeF_4$. Vibrational spectra show $XeF_2{\cdot}CrF_4$ to be only partially on the ionization pathway towards an XeF^+ salt. The $XeF_2{\cdot}XeF_4$ is an adduct in which the component molecules closely resemble the molecules in the component fluoride crystals.

5.5.4 Compounds with Trifluorides, Difluorides, and Monofluorides

The compounds $2XeF_2{\cdot}BF_3$ and $XeF_2{\cdot}BF_3$ were reported in the literature, but they have not been confirmed.

5.5.5 Compounds with Oxide Tetrafluorides

XeF_2 adducts with the weak fluoride ion acceptor species WOF_4 and $MoOF_4$ have been prepared with the stoichiometry $XeF_2{\cdot}MOF_4$ and $XeF_2{\cdot}2MOF_4$ (M = Mo, W). Fluorine-19 NMR spectroscopy has been used to investigate their solution structures in different solvents. In SO_2ClF solution, $XeF_2{\cdot}nMOF_4$ ($n = 1–4$) species were observed at low temperatures. The structures contain Xe–FL·M bridges that are nonlabile on the NMR timescale at low temperatures. In the adduct $XeF_2{\cdot}nWOF_4$ (n = 2, 3), isomerization between oxygen and fluorine-bridged Xe–F groups was observed for the first time. $XeF_2{\cdot}MOF_4$ adducts solvolyze in HSO_3F at 193 K, yielding a new species, the fluorosulfate-bridged structure $FXeSO_3FMOF_4$, which is in equilibrium with $FXeSO_3F$ and MOF_4.[42]

A molecular adduct $XeF_2{\cdot}XeOF_4$ is formed by the reaction between XeF_2 and $XeOF_4$.[43] It is a white solid with a melting point of 302 K. The 'semi-ionic' lattice is similar to that of $XeF_2{\cdot}IF_5$.

5.5.6 Compounds with Fluorosulfate and Related Groups

The preparation of monosubstituted XeF_2 derivatives has generally involved the reaction between XeF_2 and an appropriate anhydrous acid, according to equation (8). The driving force for equation (8) is the considerable exothermicity of formation of HF ($\Delta H_f^\circ = -271.6\,\mathrm{kJ\,mol^{-1}}$). The first compound of this type was $FXeSO_3F$, but later a whole set of these compounds was isolated. The ligands involved were $-OTeF_5$, $-OSeF_5$, $-OC(O)CF_3$, $-OPOF_2$, and $-OClO_3$. The pentafluorotellurate is the most stable, but the perchlorate and the trifluoroacetate are kinetically unstable and detonate readily.

$$XeF_2 + HL \longrightarrow FXeL + HF \qquad (8)$$

Disubstituted derivatives of XeF_2 have also been isolated. These compounds are obtained by treating XeF_2 with two moles of an anhydrous acid or by reacting FXeL with one mole of acid. The bis compounds are less stable than the monosubstituted species.

The bonding in $FXeOSO_2F$ is essentially covalent, with little ionic contribution to the bonding. Mixed compounds of the type $R^2O–Xe–OR^1$ have been detected in the ^{129}Xe NMR spectra. The compound $F_5SeO–Xe–OTeF_5$ exists only in equilibrium with the derivatives $Xe(OSeF_5)_2$ and $Xe(OTeF_5)_2$.

Some monosubstituted derivatives of XeF_2 can also form salts with strong Lewis acids. Unusual cations have been formed using this synthetic route. The reaction between xenon(II) fluoride orthopentafluorotellurate ($FXeOTeF_5$) and AsF_5 yields a bright-yellow solid $XeOTeF_5{}^+AsF_6{}^-$ melting at 433 K. $FXeOTeF_5$ is a poorer donor of F^- than XeF_2.

By reacting $XeF^+AsF_6{}^-$ with KSO_3F in the mole ratio 2:1, the salt $(FXe)_2SO_3F^+AsF_6{}^-$ was formed. The $(FXe)_2SO_3F^+$

cation is not stable in excess HSO_3F at room temperature and slowly decomposes, liberating xenon gas.

5.5.7 *Molecular Adducts of XeF_2*

Several adducts of XeF_2 have been prepared in which the XeF_2 molecule is indistinguishable from the molecule in crystalline XeF_2. The following adducts were isolated: $XeF_2{\cdot}XeF_4$, $XeF_2{\cdot}IF_5$, $XeF_2{\cdot}XeOF_4$, $XeF_2{\cdot}(XeF^+Sn_2F_9^-)_2$, $2XeF_2{\cdot}XeF_5^+AsF_6^-$, $XeF_2{\cdot}XeF_5^+AsF_6^-$, and $XeF_2{\cdot}(XeF_5^+AsF_6^-)_2$. The adducts may be prepared by mixing the starting compounds in the appropriate molar proportions, or by fusing their mixture, or dissolving them in a suitable solvent.

All XeF_2 molecular complexes owe their existence to appreciable coulombic interactions between the negatively charged F ligands and the positive center of the partner molecule.

5.6 Xenon(IV) Compounds

The fluorine ion donor ability of XeF_4 has been shown to be less than that of XeF_2 and XeF_6: $XeF_6 > XeF_2 \gg XeF_4$.[25] These findings are in agreement with the enthalpies of ionization[44] derived from photoionization studies (equations 9–11).

$$XeF_2(g) \longrightarrow XeF^+(g) + F^-(g) \qquad \Delta H^\circ = 9.45\,\text{eV} \tag{9}$$

$$XeF_4(g) \longrightarrow XeF_3^+(g) + F^-(g) \qquad \Delta H^\circ = 9.66\,\text{eV} \tag{10}$$

$$XeF_6(g) \longrightarrow XeF_5^+(g) + F^-(g) \qquad \Delta H^\circ = 9.24\,\text{eV} \tag{11}$$

The enthalpy of ionization of XeF_6 is more than 0.6 eV lower than that anticipated on the basis of XeF_2 and XeF_4 data. This is compatible with the greater stability of XeF_5^+ salts compared with XeF^+ and XeF_3^+. It seems that the pseudooctahedral geometry of the XeF_5^+ ion is especially favorable.

Although there is no doubt that XeF_6 is the strongest fluoride ion donor, there is disagreement as to the relative fluoride ion donor abilities of XeF_2 versus XeF_4. On the basis of the length, direction, and number of fluorine bridges in XeF^+ and XeF_3^+ salts, it has been concluded that the order of fluoride ion donor ability is $XeF_2 < XeF_4 < XeF_6$. That very few XeF_3^+ salts have been isolated, and that those known are thermally less stable than their XeF_2 relatives, contradicts this conclusion and supports the F^- donor strength being in the sequence $XeF_4 < XeF_2 < XeF_6$.

5.6.1 *Compounds with XeF_4*

XeF_4 only forms compounds with the strongest Lewis acids (SbF_5 and BiF_5). The compounds $XeF_4{\cdot}MF_5$ and $XeF_4{\cdot}2\,MF_5$ (M = Sb, Bi) have been isolated at room temperature, while the existence of the compound $XeF_4{\cdot}AsF_5$ has been claimed at low temperatures and in the presence of an excess of AsF_5. The compounds can be presented as XeF_3^+ salts on the basis of the first crystal structure obtained in this system (Figure 7). The XeF_3^+ cation is T-shaped and coordinated to the anion via a fluorine bridge, the length and polar character of which is determined by the Lewis acidity of the anion. The totally symmetric stretching vibration ν_1 of XeF_3^+ is $\approx$643 cm^{-1}.

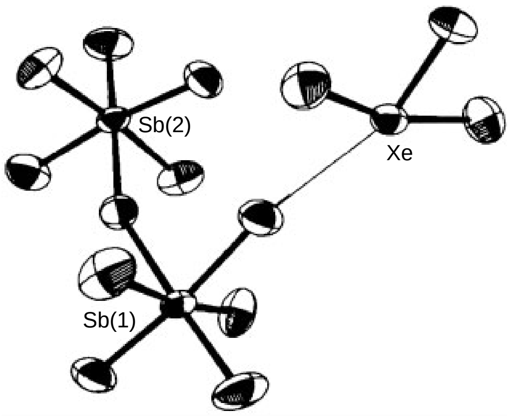

Figure 7 The $XeF_3^+Sb_2F_{11}^-$ structural unit

5.6.2 *Compounds with $XeOF_2$*

Cesium fluoride (CsF) was added at 77 K to solid $XeOF_2$ under a layer of HF. CsF dissolved upon warming to 195 K, forming $Cs^+\ (HF)_xF^-$, which reacted with $XeOF_2$ upon slow warming to 273 K. Under a dynamic vacuum to remove HF, the bright-yellow salt $Cs^+XeOF_3^-$ was obtained. It is stable at room temperature for several hours. The Raman spectrum of $XeOF_3^-$ has been assigned on the basis of C_{2v} symmetry.[32] Attempts to prepare the $XeOF^+$ cation have failed. Addition of AsF_5 to $XeOF_2$ under a layer of HF resulted in the decomposition to O_2 and $XeF^+AsF_6^-$.[32]

5.7 Xenon(VI) Compounds

The compounds obtained by the reaction of XeF_6 or xenon(VI) oxide fluorides with Lewis acids and bases are described here.

5.7.1 *XeF_5^+ and $Xe_2F_{11}^+$ Salts*

Many synthetic routes have been used for the preparation of xenon(VI) fluoro complexes.

1. *Direct method*. The interaction of a binary fluoride with an excess of XeF_6 in its melt. Several compounds have been prepared by using XeF_6 not only as a fluorobase but

also as an oxidizing and fluorinating agent. In some cases, the xenon(VI) compounds have been prepared by mixing the component fluorides in a nonreducing solvent.

2. *Indirect method.* The corresponding binary fluoride is synthesized in situ in a very reactive 'molecular form'. In this case, XeF_6 acts as a fluorinating agent by fluorine/oxygen exchange ($XeOF_4$ formed) and in some cases also as an oxidizing agent. Hydrazinium or ammonium salts or oxides have been used as starting materials.
3. *Combined method.* In this case, KrF_2 and XeF_6 have been used simultaneously. This synthetic route is efficient in cases where the parent binary fluoride acceptor is itself thermodynamically unstable in the oxidation state in which the xenon(VI) fluoro compound is expected (e.g. $(XeF_5^+)_2NiF_6^{2-}$), or in cases where the binary fluoride exists in the appropriate oxidation state but XeF_6 is not strong enough to oxidize it to this state (e.g. $XeF_5^+AgF_4^-$).

Xenon hexafluoride forms compounds with monomeric and polymeric anions. In the case of monomeric anions we have the following set of compounds: $Xe_2F_{11}^+MF_6^-$, $XeF_5^+MF_6^-$, $XeF_5^+M_2F_{11}^-$, $(Xe_2F_{11}^+)_2MF_6^{2-}$, $(XeF_5^+)_2MF_6^{2-}$, $(Xe_2F_{11})_3^+MF_6^{3-}$ and $(XeF_5^+)_3MF_6^{3-}$. In the case of polymeric anions, with tetravalent fluorides, we have the following mole ratios: XeF_6: MF_4 = 4:3, 3:4, 1:2, 1:4, and with MF_3 1:1 and 1:2. The compounds between XeF_6 and F^- acceptors are given in Table 3. Estimates of stability, reaction activity, and solubility of (XeF_5^+) (MF_6^-) (M = P–Bi, V–Ta) have been made based upon ab initio calculations.[45]

The adducts $2XeF_6{\cdot}MoF_6$ and $XeF_6{\cdot}MoF_6$ were established only from melting point–composition diagrams. The 4:1 compounds are $Xe_2F_{11}^+$ salts, while the 1:4 compounds are XeF_5^+ salts with polymeric anions. The compounds $XeF_6{\cdot}MF_4$ (M = Zr, Hf), $XeF_6{\cdot}MF_3$ (M = Sc, Fe, Ga, In), and $XeF_6{\cdot}2MF_3$ (M = Al) are derived by the indirect synthetic route. The compounds $6XeF_6{\cdot}MF_3$ (M = Y, Ho, Er, Tm, Yb, Lu) and $3XeF_6{\cdot}MF_3$ (M = Y, Dy, Ho) are the first known monomeric salts of $Xe_2F_{11}^+$ and XeF_5^+, respectively, with a metal in the 3+ valence state. The compound $XeF_6{\cdot}AuF_3$,[46] together with $XeF_6{\cdot}AuF_5$, represents the first instance of XeF_5^+ occurring with two different valence states of a metal.

As may be seen from the structures of $(Xe_2F_{11}^+)$ AuF_6^- and $(Xe_2F_{11}^+)_2NiF_6^{2-}$ (Figure 8), the group $Xe_2F_{11}^+$ consists of two similar XeF_5^+ groups linked by a bridging F species (formally F^-). It should be noted that the XeF_5^+ species occurring in the structures of $Xe_2F_{11}^+$ or XeF_5^+ salts are similar in shape but the total coordination of the cation varies from one salt to another. The xenon atom in XeF_5^+ retains a nonbonding valence-electron pair that is evidently sterically active so that the Xe atom is pseudooctahedrally coordinated with five fluorine atoms and the sterically active valence-electron pair. Negatively charged species are attracted most strongly when positioned off axis, as shown in Figure 9.

This model does not explain why certain anions (like RuF_6^-, AuF_6^-, and PtF_6^-) provide four F ligands (Figure 10) to coordinate to XeF_5^+, whereas PdF_6^{2-}, NiF_6^{2-}, and AsF_6^- provide only three, and NiF_6^{2-} in the structure $(Xe_2F_{11}^+)_2NiF_6^-$ (Figure 8) only two. When XeF_5^+ makes three bridging linkages to two different anions, the ring

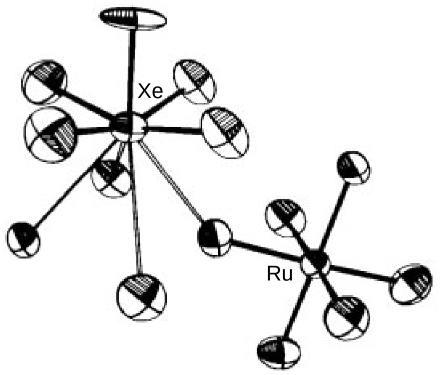

Figure 10 The XeF_5^+ and RuF_6^- structural units and the coordination of XeF_5^+

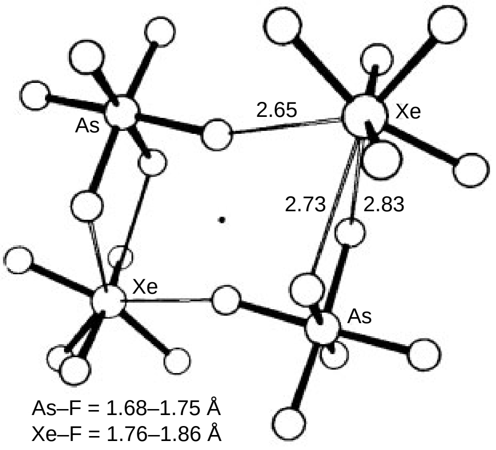

Figure 11 Configuration and bond distances for $XeF_5^+AsF_6^-$

system shown for $XeF_5^+AsF_6^-$ in Figure 11 occurs. That same ring appears repeatedly in the $(XeF_5^+)_2PdF_6^{2-}$ structure (Figure 12a), where each XeF_5^+ is similarly connected to two separate anions. In the $(XeF_5^+)_2NiF_6^{2-}$ structure (Figure 12b), however, one of the cations is coordinated to two separate anions to again generate the $XeF_5^+AsF_6^-$-type ring, but the other XeF_5^+ makes its three bridge bonds to one octahedral face of one anion. This creates discrete $(XeF_5)_4(NiF_6)_2$ clusters. The structure of $(XeF_5^+CrF_5^-)_4XeF_4$ shows that this is an XeF_4 molecular adduct of a XeF_5^+ salt (Figure 13). This

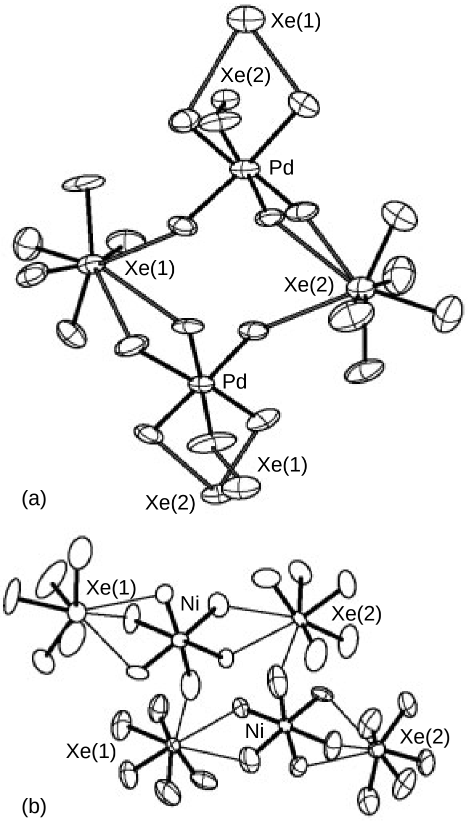

Figure 12 The structural units (a) $(XeF_5^+)_2PdF_6^{2-}$ and (b) $(XeF_5^+)_2NiF_6^{2-}$

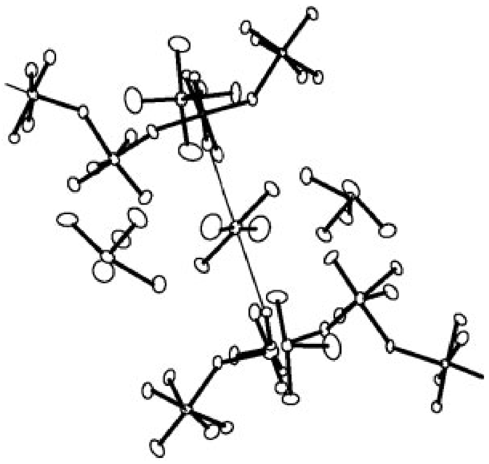

Figure 13 XeF_4 environment in $(XeF_5^+CrF_5^-)_4XeF_4$

structure is of particular interest in showing for the first time an appreciable deformation of the XeF_5^+ cation. In addition, the anion consists of an infinite chain of distorted $CrF_4(F_{0.5})_2^-$ octahedra that alternately share *cis* and *trans* vertices.

Vibrational spectroscopy (especially Raman) has been an important tool in the characterization of $Xe_2F_{11}^+$ and XeF_5^+ salts. The $Xe_2F_{11}^+$ species behave vibrationally like two weakly coupled XeF_5^+ species. The F bridging of the two XeF_5^+ groups in the $Xe_2F_{11}^+$ cation is characterized by a 'bridge stretch' at $\approx$360 cm^{-1}. The full assignments for the fundamentals is available.[47,48]

5.7.2 *XeF_7^- and XeF_8^{2-} Salts*

Complexes of XeF_6 with fluoride ion donors, for example, NO_2F, NOF, and alkali metal fluorides (with the exception of LiF), are listed in Table 4. On the basis of Raman spectroscopy, the compound 2NOF·XeF_6 could be written as $(NO^+)_2XeF_8^{2-}$. This is supported by its crystal structure. The anion XeF_8^{2-} can be described as a slightly distorted Archimedean antiprism with Xe–F distances ranging from 1.946 to 2.099 Å. The steric activity of the nonbonding xenon valence-electron pair is not convincingly present. $NF_4^+XeF_7^-$ decomposes to NF_3, F_2, and XeF_6. Evidence for $(NF_4^+)_2XeF_8$ as an intermediate has been given.

5.7.3 *Xenon(VI) Oxyfluoro Cations: $XeOF_3^+$, XeO_2F^+*

$XeOF_4$·2SbF_5 was prepared by the reaction of $XeOF_4$ with an excess of SbF_5 at temperatures higher than room temperature, followed by removal of volatiles to constant weight at room temperature. A colorless solid with mp 334–338 K was obtained. $XeOF_4$·SbF_5 was obtained by the reaction of $XeOF_4$·2SbF_5 with an excess of $XeOF_4$ at temperatures a little above room temperature and removal of volatiles to constant weight at room temperature. A colorless solid with mp 377–378 K was obtained.[49] On the basis of their Raman spectra, it has been concluded that the compounds are ionic and contain the $XeOF_3^+$ cation. The structure of $XeOF_3^+$ is represented on a trigonal bipyramidal model with the nonbonding valence-electron pair and the oxygen ligand in equatorial sites. It is a geometric relative of XeF_3^+.

SbF_5 and XeO_2F_2 in the mole ratio 2:1 were allowed to react in HF solution. A white solid was obtained after removal of the solvent. XeO_2F_2·2SbF_5, is unstable at room temperature, decomposing to $XeF^+Sb_2F_{11}^-$ and oxygen. The Raman spectrum of the compound XeO_2F_2·2SbF_5 is consistent with the 'ionic' formulation $XeO_2F^+Sb_2F_{11}^-$. Vibrational spectroscopic evidence is consistent with the cation XeO_2F^+ having a pyramidal (pseudotetrahedral) geometry. No direct evidence for fluorine bridging was obtained. The Raman spectrum is available.[50]

Table 4 Xenon(VI) compounds with F^- donors

2NaF·XeF_6	NO_2F·XeF_6
2KF·XeF_6	$(NO^+)_2$·XeF_8^{2-}
2RbF·XeF_6	NF_4^+·XeF_7^-

2CsF·XeF_6	
CsF·XeF_6	

5.7.4 *Xenon(VI) Oxyfluoro Anions: $XeOF_5^-$, $(XeOF_4)_3F^-$, $XeO_2F_3^-$, and XeO_3X^- (X = F, Cl, Br)*

CsF reacts with an excess of $XeOF_4$ at room temperature yielding CsF·3$XeOF_4$, a white solid. This product is stable in a dynamic vacuum at 273 K when the excess $XeOF_4$ is pumped away, but decomposes at room temperature in a static vacuum to CsF·$XeOF_4$ and $XeOF_4$.[51] On the basis of the Raman spectra, CsF·$XeOF_4$ is best formulated as the salt $Cs^+XeOF_5^-$. The presence of a single, sharp Xe=O stretching mode at ca. 900 cm^{-1} in CsF·3$XeOF_4$ indicates that all three $XeOF_4$ molecules are equivalently bonded to a central fluorine ion, thus implying an anion $(XeOF_4)_3F^-$.

On slow warming of a solution of $XeOF_2$ in HF from 210 to 273 K over a period of 20 h, pure $XeOF_2$ decomposes to XeF_2 and XeO_2F_2, which can further react with Cs^+ $(HF)_xF^-$ dissolved in HF yielding $Cs^+XeO_2F_3^-$. The probable structure of $XeO_2F_3^-$ is pseudooctahedral, with both oxygens in the axial positions and with the three fluorine atoms and the sterically active lone pair in equatorial positions.[32]

Hydrolysis of $Cs^+XeOF_5^-$ or $CsXeF_7^-$ leads to the compound CsF·XeO_3. Single-crystal structure analysis of $KFXeO_3$ showed that the compound is a polymer, $[K^+]_n[XeO_3F^-]_n$. A more convenient method of preparation mixes appropriate amounts of the aqueous solutions of XeO_3 and metal fluoride (MF), subsequent evaporation yielding crystals of the salts. A series of compounds of the type M^+ $[XeO_3X^-]$ with M = Cs, Rb, K and X = F, Cl, Br is known. The thermal stability of these salts decreases with increasing atomic weight of the halogen. The fluoride salts are stable to 473 K, but decompose to xenon, oxygen, and alkali fluoride above 533 K. The chloride xenates begin to decompose at 423 K, while the bromo salt is unstable even at room temperature.

5.8 Xenon(VIII) Compounds

Xenon(VIII) oxyfluoro anions or cations have not yet been isolated.

5.9 Xenon Compounds with Bonds to Nitrogen and Carbon

5.9.1 *Xe–N Bonding*

The reaction of XeF_2 with $HN(SO_2F)_2$ proceeds at 273 K, yielding $FXeN(SO_2F)_2$ and HF.[52] $FXeN(SO_2F)_2$ was the first

compound prepared with a Xe–N bond. The Xe–N and Xe–F distances are 2.200(3) and 1.967(3) Å, respectively with an F–Xe–N angle of 178.1(1)°. Like its XeF_2 precursor, the molecule exhibits fluoride ion donor properties. In reactions with Lewis acids, for example, AsF_5, SbF_5, and so on, the following salts have been obtained: $XeN(SO_2F)_2^+AsF_6^-$, $XeN(SO_2F)_2^+Sb_3F_{16}^-$, and $F[XeN(SO_2F)_2]_2^+AsF_6^-$. These cations are less stable than their XeF^+ and $Xe_2F_3^+$ counterparts. The reaction to prepare the disubstituted compound $Xe[N(SO_2F)_2]_2$ is much slower and should be performed at lower temperatures because $Xe[N(SO_2F)_2]_2$ decomposes rapidly near room temperature to xenon and $[N(SO_2F)_2]_2$.

A new class of Xe–N bonded compounds is obtained by the interaction of the electron lone pair of a nitrile with the Lewis acid XeF^+.[53] The cationic adducts RC ≡N–XeF^+ with R = H, Me, CH_2F, Et, C_2F_5, C_3F_7, and Ph have been isolated by the reaction of the appropriate nitrile with $XeF^+AsF_6^-$ or $Xe_2F_3^+AsF_6^-$ in AHF at low temperatures.

Two additional xenon−nitrogen bonded cations represent unique examples of noble gas atoms functioning as aromatic ring substituents.[54] Equimolar amounts of $XeF^+AsF_6^-$ and 4-RC_5F_4N (R = F or CF_3) react in AHF at 243−253 K, yielding 4-RC_5F_4N–$XeF^+AsF_6^-$. Low-temperature Raman and ^{129}Xe, ^{19}F, and ^{14}N NMR spectroscopic results are consistent with planar cations in which the xenon atom is coordinated to the aromatic ring through the lone pair of electrons on the nitrogen ligand.

5.9.2 Xe–C Bonding

Compounds with bonding between carbon and Xe (II, IV) rely upon the maintenance of a partial positive charge on the Xe atom. A recent review detailed the full range and reactivity of these compounds so only a representative group will be described here.[55,56] The first established stable system with a xenon−carbon bond is the salt $[C_6F_5Xe]^+$ $[C_6F_5BF_3]^-$.[57] It can be prepared by nucleophilic displacement of fluorine in XeF_2 using $B(C_6F_5)_3$ as an aryl-transfer reagent. The product is a colorless solid, stable at temperatures lower than 243 K. Other aryl groups (e.g. monosubstituted phenyl groups, XC_6H_4) can be used to synthesize salts of the type $[XC_6H_4Xe]^+$ $[(XC_6H_4)_2BF_2]^-$. However, salts with the $[C_6F_5Xe]^+$ cation are significantly more stable and useful than those with $[XC_6H_4Xe]^+$.[58] The stability of the latter salts increases with decreasing F^- donor ability of the anion. In the absence of nucleophilic aryl groups in the anion, the thermal stability increases significantly. $[C_6F_5Xe]^+AsF_6^-$ melts without decomposition at 370−371 K and the viscous melt is stable to 398 K. Recently, $C_6F_5XeO_2CC_6F_5$ was reported.[59] Xe is linearly bonded by C (2.122 Å) and O (2.367 Å) and an intramolecular Xe–O contact of 3.142 Å is formed by the acyloxy group. Intermolecular Xe–O bridges (3.237 Å) form pairs of the molecules in the solid.

Of related interest is a recent study indicating that SiF_3^+ combines with Xe, Kr, and Ar in the gas phase to form the complexes $FNgSiF_3$.[60] Experimental and theoretical results indicated that $FXeSiF_3$ might be stable. Interestingly, similar reactions with CF_3^+ did not form noble gas compounds.

5.10 Xenates and Perxenates

Xenates are salts of xenic acid, (hypothetically $Xe(OH)_6$). Aqueous XeO_3 solutions (xenic acid) are prepared by hydrolysis of XeF_6 (see Section 5.2.1). XeO_3 is one of the strongest known oxidants in aqueous media. The monoalkali xenates $MHXeO_4 \cdot 1.5H_2O$ (M = Na, K, Rb, Cs) are prepared by titration of xenic acid with alkali hydroxide solution. Species such as $HXeO_4^-$ and $H_5XeO_6^-$ are possibly produced in this titration. The xenates(VI) are reported to be stable at room temperature in an inert atmosphere, but they disproportionate to xenon(0) and xenon(VIII) in air. They are thermally stable up to 373 or even 423 K. In some cases, they detonate.

$CsHXeO_4$ has been prepared by the reaction of xenon trioxide with aqueous cesium hydroxide in the presence of fluoride ion. The role of the fluoride ion in the preparation of $CsHXeO_4$ is not clear, but it seems that it prevents the formation of perxenate. In the absence of the fluoride ion, xenon trioxide and cesium hydroxide form a mixed perxenate and xenate salt. $CsHXeO_4$ is stable in air.

Perxenates were not prepared by oxidizing xenon with powerful oxidizers in aqueous media. The only preparative routes are by way of the xenon fluorides (XeF_6 or XeF_4). Hydrolysis of XeF_6 in strongly alkaline media generates xenon gas and hydrated perxenate as a precipitated solid (equation 12). The most efficient synthesis of perxenate was by using ozone to oxidize XeO_3 in a solution of 1 M alkali hydroxide. Na_4XeO_6 is a colorless solid, nearly insoluble in water. It contains 0.6 to 9 molecules of H_2O per xenon atom, depending on the drying procedure.

$$2XeF_6 + 4Na^+ + 16OH^- \longrightarrow Na_4XeO_6 + Xe + O_2 + 12F^- + 8H_2O \qquad (12)$$

The perxenates are colorless, thermally stable solids. Anhydrous sodium perxenate can be obtained at 373 K. It decomposes at 633 K. The corresponding barium salt decomposes at about 570 K. Perxenate solutions are powerful and rapid oxidizing agents. Xenon(VIII) is reduced to xenon(VI). Oxidation processes in acid media are more effective, but they must be fast enough to compete with decomposition of the perxenate, which is also rapid in acid.

The crystal structures of $Na_4XeO_6 \cdot 6H_2O$, $Na_4XeO_6 \cdot 8H_2O$, and $K_4XeO_6 \cdot 9H_2O$ have been determined. The perxenate ion is octahedral. The water of the hydrates is coordinated to the cations and hydrogen-bonded to the perxenate oxygen ligands. The Xe–O bond lengths in the octahedra are in the

range 1.84–1.88 Å. This is much longer than in tetrahedral XeO_4 (1.74 Å) or pseudotetrahedral XeO_3 (1.76 Å).

5.11 Xenon Chlorides and Bromides

$XeCl_2$ has been prepared by high-frequency discharge of the mixture of Xe, F_2, and $SiCl_4$ or CCl_4 in the mole ratio 1:1:1 at 193 K.[61] The compound has also been prepared using the matrix-isolation technique and microwave discharge of a xenon–chlorine mixture.[62] $XeCl_2$ is characterized by IR absorption at 313 cm^{-1} (ν_3, asymmetric Xe–Cl stretch), observed in the spectrum of the matrix-isolated material at 20 K, and matrix Raman at 253 cm^{-1} (ν_1, symmetrical Xe–Cl stretch). The greater bond energy of Cl_2 relative to F_2 (242 vs. 158 kJ mol^{-1}) and the lower thermochemical bond energy of chlorides relative to fluorides account for the low thermodynamic stability of $XeCl_2$.

Xenon tetrachloride and xenon dibromide have been detected by (*see Mössbauer Spectroscopy*) as products of the β-decay of their ^{129}I relatives (equation 13).

$$^{129}ICl_4^- \xrightarrow{-\beta} {}^{129}XeCl_4$$
$$^{129}IBr_2^- \xrightarrow{-\beta} {}^{129}XeBr_2 \quad (13)$$

More recently, the matrix isolation of the linear, centrosymmetric, compounds, HNgX (where Ng = Xe, Kr, Ar and X = halide) has been achieved.[63,64] A theoretical study reveals that HF hydrogen bonding will be fairly strong to the fluoride of HNgF.[65]

6 THE CHEMISTRY OF KRYPTON

Compounds of Kr are currently only known for the 2+ oxidation state.[66]

6.1 Krypton Difluoride

Krypton difluoride was first prepared by Turner and Pimentel[67] by UV photolysis of fluorine suspended in a solid mixture of argon and krypton at 20 K. Because krypton difluoride is thermodynamically unstable, all effective syntheses have to be carried out at low temperatures (e.g. 77 K). Methods used for the preparation of KrF_2 in the laboratory include electric discharge of a gaseous mixture of krypton and fluorine at low temperature and pressure (yield 250 mg h^{-1}), high-frequency discharge in a mixture of krypton and CF_2Cl_2, irradiation of fluorine–krypton mixtures with 1.5 MeV electrons, or 10 MeV protons, thermal decomposition of F_2 at 950 K on a nickel wire (yield 6 g h^{-1}), and, less efficiently, by exposure to sunlight.

A very efficient method for the preparation of KrF_2 on a larger scale has been developed (30–40 g per batch).[68] It is based on the irradiation of a liquified mixture of fluorine and krypton with near-UV light at 77 K. The mole ratio of the krypton–fluorine mixture is 4:1 and the yield about 1 g h^{-1} of KrF_2.

Krypton difluoride is colorless in the solid and vapor phase and it decomposes at temperatures above 250 K. The rate of decomposition is dependent upon the pretreatment of the reaction vessel. Because KrF_2 has some vapor pressure even at temperatures between 220 and 230 K, it will start to react if the reaction vessel has not been thoroughly pretreated with KrF_2. Krypton difluoride has the lowest average bond energy of any known fluoride. The atomization energy of KrF_2 ($\Delta H_{at} = 98$ kJ mol^{-1}) is smaller than the dissociation energy of elemental fluorine ($\Delta H_{diss} = 158$ kJ mol^{-1}), thus indicating that krypton difluoride is closest in activity to atomic fluorine. Its $\Delta Hf = 60$ kJ mol^{-1}.

KrF_2 is a symmetrical linear molecule ($D_{\infty h}$). In the crystal, KrF_2 molecules are aligned in planes perpendicular to the tetrad axes of the unit cell. Within these sheets, nearest neighbor molecules are aligned roughly perpendicular to one another, thus placing the negatively charged F ligands close to the positively charged krypton atoms of neighboring molecules (Figure 14).

Hydrolysis of KrF_2 proceeds analogously to the hydrolysis of XeF_2 in basic solution (equation 14). This same reaction occurs rapidly in acid solution, in contrast to the behavior of XeF_2, which dissolves and may persist unhydrolyzed for an extended period of time. No ionic species containing krypton remain in solution after hydrolysis.

$$KrF_2 + H_2O \longrightarrow Kr + 0.5O_2 + 2HF \quad (14)$$

6.2 Krypton Oxide

No krypton oxide has yet been isolated and characterized. When KrF_2 is hydrolyzed slowly with moist air, it is possible

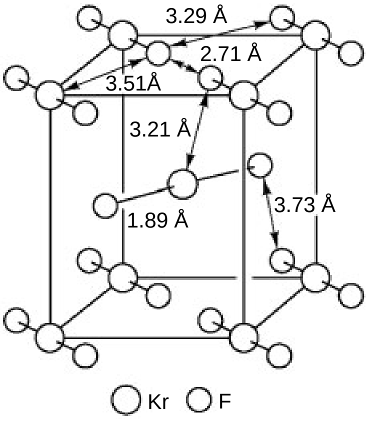

Figure 14 Unit cell of KrF_2

that some very unstable KrO is formed, which decomposes explosively.

6.3 Krypton(II) Compounds

Krypton(II) compounds are those krypton–fluorine compounds which exhibit a significant amount of ionic character and can be described either as KrF^+ and $Kr_2F_3^+$ salts, KrF_2 adducts with these salts, or molecular adducts of KrF_2 with certain binary fluorides. All known krypton(II) compounds are listed in Table 5.

Krypton complexes may be prepared directly by the reaction of KrF_2 with the appropriate binary fluoride, neat or in solution. In some cases, binary fluorides have been prepared in situ using KrF_2 as the fluorinating agent. So far, no X-ray crystal structure of any KrF_2 complex has been determined, and the characterization of the complexes has rested largely on vibrational spectroscopy. Raman spectroscopy has been especially valuable in studies of these compounds, all of which are of low thermal stability.

Observed Raman and IR frequencies for Kr^{II} compounds are best assigned on the basis of ionic formulations: $KrF^+M_2F_{11}^-$, $KrF^+MF_6^-$, and $Kr_2F_3^+MF_6^-$. The appearance of KrL·F and ML·F bridge-stretching and F–KrL·F bending modes points to a strong interaction between the cation and anion, indicative of some covalent character in that bonding. For the KrF^+ salts, the stretching vibration is in the range from 626 cm^{-1} (in the case of $KrF^+Sb_2F_{11}^-$) to 597 cm^{-1} (in the case of $KrF_2{\cdot}2NbF_5$).

The spectra of the $Kr_2F_3^+$ cation have been correlated with those of the $Xe_2F_3^+$ species, but additional peaks, which have no equivalents in the xenon spectra, suggest that $Kr_2F_3^+$ is less symmetrical than its xenon analog, with one longer and weaker Kr–F bond and one shorter and stronger Kr–F bond. An alternative interpretation is that this cation involves a distorted KrF_2 molecule fluorine-bridged to a KrF^+ cation.[20]

Krypton difluoride forms complexes mostly with Lewis acid pentafluorides in the mole ratio 2:1, 1:1, and 1:2. In addition, there are a number of compounds in which additional KrF_2 appears to be weakly associated, probably with the cationic part of the compound. Recently, the first adducts of KrF_2 with tetravalent fluorides have also been isolated and characterized: $2KrF_2{\cdot}MnF_4$ and $KrF_2{\cdot}MnF_4$. The 1:1 compound is most probably $KrF^+MnF_5^-$ with a polymeric anion.[69] Claims for the compounds $2KrF_2{\cdot}TiF_4$ and $2KrF_2{\cdot}SnF_4$ have not been supported by any characterizational evidence.

The highly polar bonds of KrF_2 also give rise to adducts with other molecules possessing highly polar bonds; compounds include $KrF_2{\cdot}BrF_5$ and $KrF_2{\cdot}XeF_6$.

The first krypton difluoride–metal oxide fluoride adducts have been prepared by reaction of KrF_2 with MOF_4 (M = Mo, W) in SO_2ClF solution at low temperatures. Raman spectra of the solid $KrF_2{\cdot}MoOF_4$ and $KrF_2{\cdot}WOF_4$ indicate that these compounds are not KrF^+ salts, but are more covalent fluorine-bridged structures. The ^{19}F NMR spectra of $KrF_2{\cdot}nMoOF_4$ ($n = 1–3$) and $KrF_2{\cdot}WOF_4$ indicate also that these complexes are best formulated as essentially covalent structures containing KrL·FL·M bridges and mononuclear or polynuclear metal oxide fluoride species.

Table 5 Krypton(II) compounds

$2KrF_2{\cdot}TiF_4$	$(xKrF_2{\cdot}KrF)^+Nb_2F_{11}^-$
$2KrF_2{\cdot}MnF_4$	$KrF^+Nb_2F_{11}^-$
$KrF_2{\cdot}MnF_4$	$(xKrF_2{\cdot}KrF^+){\cdot}Ta_2F_{11}^-$
$2KrF_2{\cdot}SnF_4$	$Kr_2F_3^+TaF_6^-$
$KrF_2{\cdot}VF_5$	$KrF^+TaF_6^-$
$KrF_2{\cdot}9BrF_5$	$KrF^+Ta_2F_{11}^-$
$KrF_2{\cdot}2BrF_5$	$(xKrF_2{\cdot}Kr_2F_3^+)\ AsF_6^-$

$KrF^+BF_4^-$	

6.4 Krypton Compounds with Bonds to Oxygen and Nitrogen

$Kr(OTeF_5)_2$ is the first krypton compound containing a krypton–oxygen bond. It was prepared by the reaction between KrF_2 and $B(OTeF_5)_3$ at 183–161 K in SO_2ClF as solvent.[70]

It is interesting that the compound containing the first krypton–nitrogen bond was synthesized before a compound with a krypton–oxygen bond. The first compound with a krypton–nitrogen bond was synthesized at low temperatures in BrF_5 solvent according to a general synthetic approach (equation 15). Each nitrogen base found capable of bonding with KrF^+ is oxidatively resistant and possesses a first adiabatic ionization potential close to or exceeding the estimated *Electron Affinity* of KrF^+ (13.2 eV). The first adiabatic ionization potential of HC≡N is 13.59 eV. The low basicity of the nitrogen atoms in these bases gives the krypton–nitrogen bond significant ionic character. This is important for the thermal stability of such a cation.[71] Compounds with krypton–carbon bonds have not yet been isolated.

$$R_fC{\equiv}N\text{–}AsF_5 + KrF_2 \longrightarrow R_fC{\equiv}N\text{–}KrF^+AsF_6^- \quad (15)$$

$$R_f = H, CF_3, C_2F_5, n\text{-}C_3F_7$$

7 THE CHEMISTRY OF RADON

There are no stable isotopes of radon and the longest lived 'natural' isotope, ^{222}Rn, has a half-life of only 3.83 days. Experimental difficulties arise not only from the radiation hazard, but also from the decomposition caused by the radiation. The most detailed review of radon chemistry, to early 1981, was written by Stein.[72]

Radon forms a series of clathrate compounds similar to those of krypton, xenon, and argon (e.g. $Rn\cdot 6H_2O$, $Rn\cdot 3C_6H_5OH$, $Rn\cdot 3p\text{-}ClC_6H_4OH$).

^{222}Rn decays by α emission and exhibits only slight γ activity when freshly separated from radium. The short-lived β- and γ-emitting daughters ^{214}Pb and ^{214}Bi, as well as the short-lived α-emitting daughters ^{218}Po and ^{214}Po, grow into equilibrium with ^{222}Rn within 4 h. The energetic (1.8 MeV) γ-ray of ^{214}Bi is frequently used to trace ^{222}Rn.

Millicurie and curie amounts of radon react spontaneously with gaseous fluorine at room temperature and with liquid fluorine at 77 K. ^{222}Rn, owing to its intense α-radiation, produces large numbers of ions and excited atoms. Therefore, for fixation of radon as the fluoride it is necessary to mix a millicurie or larger amounts of the element with gaseous or liquid fluorine in a small volume (25–50 cm^3) and let the mixture stand for 0.5 h. Radon behaves as activator and reactant. In this way, RnF_2 is produced.

The first ionization potential of radon (10.7 eV) is smaller than the first ionization potential of xenon, and therefore similar reactions are expected. Thus radon reacts with a number of oxidizing cations such as ClF_2^+, BrF_2^+, BrF_4^+, O_2^+, N_2F^+, $N_2F_3^+$, IF_6^+, and so on, and it is believed that it forms RnF^+ salts. Radon also reacts to some extent with compounds that contain oxidizing anions such as ClF_4^-, BrF_4^-, and BrF_6^-.

Stable solutions of RnF_2 have been prepared through spontaneous reactions of ^{222}Rn with liquid ClF, ClF_3, ClF_5, BrF_3, BrF_5, and IF_7 at 298 K or lower temperatures.

RnF_2 is hydrolyzed by water in a reaction analogous to the reactions of KrF_2 and XeF_2 with water. Higher-valent xenon compounds, such as XeF_4 and XeF_6, yield soluble oxygenated xenon species (XeO_3 and XeO_6^{4-}) on hydrolysis with solutions of appropriate acidity. No corresponding radon species have been observed after hydrolysis of simple or complex radon fluorides. In all cases, only gaseous radon was obtained. Reported preparations of RnF_4 and RnF_6 and, by hydrolysis, also RnO_3 have not been sustained. Because of the chemical similarity of radon with xenon and its lower first ionization potential, a number of other compounds such as RnF_4, RnF_6, $RnCl_2$, $RnCl_4$, RnO, RnO_2, RnO_3, and $RnOF_4$ might be expected. The characterization of these compounds is very difficult because of their radioactivity, decay, short-lived isotopes, and so on. So far, no complex compounds of RnF^+, $Rn_2F_3^+$, or Rn^{2+} have been fully characterized.

8 THE CHEMISTRY OF THE LIGHTER NOBLE GASES

The first ionization potentials of the lighter noble gases Ar (15.76 eV), Ne (21.56 eV), and He (24.59 eV) show that these gases will remain difficult to incorporate into compounds. Nevertheless, the first stable neutral argon compound, HArF, has been isolated in a solid argon matrix, characterized by IR, and analyzed by ab initio calculations.[63] The calculations indicate that the compound is 'intrinsically stable' with ionic and covalent contributions to the bonding. Furthermore, a wide range of helium compounds, $[XBeHe]^+$ (where $X = NH_2$, CH_3, Ph, etc.) are calculated to be thermodynamically stable.[4] This is likely due to the presence of the covalency-inducing beryllium cation.

9 EXPLOSION HAZARDS WITH NOBLE GAS COMPOUNDS

Some noble gas compounds are explosive, so special care should be taken during their manipulation. The most dangerous is XeO_3, which can be obtained from XeF_4, XeF_6, any XeF_3^+ or XeF_5^+ salts when moisture is present, or by the reaction between XeF_6 and oxides. XeO_3 is comparable in detonation sensitivity to nitrogen triiodide and in explosive force to TNT. Detonation may be induced by mild heating, by mild mechanical disturbance, by pouring, or may take place spontaneously.

Beside XeO_3 and XeO_4, some xenon oxyfluorides are also thermally unstable compounds. They may detonate, particularly at higher temperatures. Other derivatives of the xenon and krypton fluorides involving ligands less electronegative than fluorine should also be assumed to be of low thermodynamic stability. Many derivatives such as perchlorates and trifluoroacetates are known to be explosive.

10 BONDING IN NOBLE GAS COMPOUNDS

For xenon fluorides and oxides, for example, the same models can be applied as for interhalogen and halogen oxy species. Furthermore, the very successful valence shell electron pair repulsion (VSEPR) rules[73] for molecule and ion shapes are as effective for noble gas compounds and their relatives as for classical 'octet' compounds.

All acceptable theories should account for the following facts: only the heavier, more readily ionizable noble gases form compounds and only the most electronegative atoms or groups are satisfactory ligands for the noble gases. Two theories of bonding in noble gas compounds are discussed here (*see also* ***Molecular Orbital Theory*** and *Valence Shell Electron Pair Repulsion Model*).

10.1 Molecular Orbital Theory

This model does not involve the outer, or higher valence shell orbitals of the noble gas atom, at least not to an extent that could significantly affect the bond energy. The xenon atom orbitals of prime importance are 5p, and less importantly 5s, and for fluorine 2p. It is interesting that Pimentel's[74] bonding model of 1951 for trihalide ions can be extended to the noble gas dihalides without modification. In this case, we have three three-center MOs generated from the Xe $5p_x$ and two fluorine $2p_x$ orbitals. The best net bonding for the three atoms occurs when the arrangement is centrosymmetric. The molecular symmetry of XeF_2 ($D_{\infty h}$) is in agreement with this requirement. The xenon atom contributes two electrons and each fluorine ligand one electron to this σp molecular orbital (MO) system. Two electrons are in the bonding MO and two in the nonbonding MO. The antibonding MO is empty. The xenon does not contribute to the nonbonding orbital; therefore the electrons of this orbital are concentrated on the fluorine ligands, thus restoring the fluorine ligand electron density. The bonding electron pair is responsible for binding together all three atoms. Delocalization of the electron pairs of this orbital results in a net negative charge on each fluorine ligand and a positive charge on the Xe atom. The charge distribution is close to the representation $F^{0.5-}{-}Xe^{1+}{-}F^{0.5-}$. This representation fits most of the physical and chemical properties of XeF_2.

Bonding in XeF_4 can be described in a similar way, having two such three-center systems at right angles. This simple three-center four-electron MO approach is in accord with the near equality of mean thermochemical bond energy in the three xenon fluorides and with the greater bond energy in XeF^+, but it predicts XeF_6 to be octahedral, which it is not.

10.2 Valence Shell Electron Pair Repulsion Theory

This theory implies outer orbital involvement in the bonding. It assumes that each bond between the ligand and the central atom involves an electron pair. A double bond involves four electrons. Further, it assumes that all nonbonding valence electrons have a steric effect. These lone pairs repel other electron pairs more than do bonding electron pairs and have about the same steric requirements as a double bond. Gillespie[75] predicted the shape of unknown species using this theory; all later isolated species conformed to his predictions.

The three-center, four-electron MO approach is as successful as the VSEPR approach for less than six coordination. The VSEPR correctly predicted that XeF_6 should be nonoctahedral and applies straightforwardly to seven and higher coordination numbers, in a way that the simple MO theories cannot.

11 RECENT DEVELOPMENTS IN TRANSITION METAL DERIVATIVES

Beyond the relatively simple transition metal salts described previously, many more interesting and esoteric compounds have been discovered in combinations of the noble gases with the transition metals. The broad range of these exciting new compounds warrants a separate in-depth review, so only representative examples will be provided here. Matrix isolation has been used to create the new class of organometallic compounds, $M(CO)_xNg$ where Ar and Xe act as weakly bound ligands.[76] Another emerging class of compounds are of formula NgMX, (Ng = Ar or Kr, M = Cu, Ag, Au, X = F, Cl, Br), prepared by laser ablation of the metal followed by reaction with the noble gas and halide source.[77] In these linear compounds, the Ng–M bonds are short and range from 2.3 Å for Ar–Cu to 2.7 Å for Kr–Ag. Theoretical calculations have been used to predict the bond lengths of the compounds for which no experimental data is available.[78] The laser ablation of uranium with CO in the presence of Ar, Kr, and Xe lead to the formation of the compounds, (C)U(O)(Ng), which have been characterized by IR spectra and CO and Ng isotopic substitution.[79] The compound, $[AuXe_4]^{2+}\ 2[Sb_2F_{11}]^-$, was discovered in a study aimed at creating AuF.[80] In the crystal structure, the cation forms a regular square, with Au–Xe bond lengths ~2.7 Å. This compound is a clear indication of the remarkable discoveries waiting to be made in combinations of the noble gases with transition metals.

12 APPLICATIONS

In addition to the synthetic uses mentioned previously, such as in oxidizing[81] and fluorinating agents, the noble gases and their compounds have a very broad, and growing, range of applications. With two NMR-active nuclei, ^{129}Xe and ^{131}Xe, xenon has found increasing use as an indirect structural probe in a broad range of substances.[82–86] Xenon has been found to prevent hypoxia-induced neuronal damage.[87] Additionally, it has been proposed as a replacement for nitrous oxide, once an economic means of providing the gas is found.[88] Dating methods are being developed using 20Ne/22Ne ratios[89] and the fractional yield of ^{136}Xe produced by the spontaneous fission of ^{238}U.[90] Jets of Ne and Ar are used to help tokamak nuclear reactors run more efficiently.[91]

Glossary

Critical cooling rate, R_c: minimum quenching rate of a melt that results in a glassy product
Glass transition temperature, T_g: temperature at which the viscosity of a glass begins to decrease continuously
Optical attenuation: continuous decrease of light intensity when propagating in a glass

1 THE GLASSY STATE

1.1 Introduction

Solids originating from the three-dimensional regular repetition of an elementary cell are described as crystalline. This situation can lead to poorly crystalline solids when the final size of the crystal is very small. This is the case for fine grain materials having nanometer or submicron dimension sizes, often called amorphous because the coherently X-ray diffracting domains are very small. Crystals can also be grown to centimeter size, for example, for jewelry or optoelectronics applications. In both cases, those solids have reached their thermodynamic equilibrium. In contrast, there is a limited but important class of materials that, when prepared from the melt, have no time to arrange and to connect periodically when crossing the strategic liquidus to solidus line. Solids that are obtained in this way are not in equilibrium. They are regarded as frozen liquids because they retain the structure of this disordered state. The corresponding materials are then in the 'glassy' or 'vitreous' state.

The metastable solids discussed in this article will correspond to this definition; the word glass is preferred to noncrystalline solids that have a connotation that is too negative and inexact. It must also be appreciated that this state of matter suffers in that it is without a clear descriptive image as is possible, for example, for the crystalline state. Nevertheless, vitreous materials research has become an increasingly active field since the emergence of high technology applications of glasses; examples are fiber optics for telecommunication and medicine, glass lasers, sophisticated optics for telescopes and ophthalmology, and sunglasses.

1.2 Conditions of Glass Formation

Noncrystalline solids formation needs to be clarified by reference to the nature of the final product. Several methods lead to amorphous fine particles, for instance, in solution by controlled precipitation. Through gel formation, poorly crystalline TiO_2 can be obtained according to the process $Ti(OR)_4 + H_2O \rightarrow Ti(OH)_4$ gel $\rightarrow$ amorphous $TiO_2 + H_2O$. In this case, the compound obtained is thermodynamically stable, as when amorphous films are obtained by chemical vapor deposition, sputtering, flash evaporation, and so on.

The noncrystalline solids described here are amorphous and metastable. This specific thermodynamic property is because they all originate from the liquid state. The corresponding glassy or vitreous materials are not very common in solid-state chemistry, and only a limited number of molten salts or molten alloys have the characteristics necessary to produce glasses when cooling.

The formation of glass is a kinetically controlled phenomenon and is directly associated with atomic or ionic diffusion within the melt. This controls the formation and growth of microcrystals when the temperature of the liquid reaches the solidus line (i.e. the crystallization temperature).

Some melts show unexpectedly high viscosities, indicating a large degree of association within this disordered state. This is due to the formation of strong chemical bonds in the liquid, leading to polymerized forms where individual atoms are no longer free to move. The effect of thermal agitation is to maintain the disordered state by bending or rotating the bonds linking the different building elements. Cooling the melt results in an increase of the viscosity and makes the formation of individual small crystallites difficult, owing to poor atomic diffusion. Finally, the melt becomes sufficiently viscous that a point is reached where it has to be considered as a solid, but retains the structure of the mother melt. Such a metastable solid is a glass.

Glass formation or the absence of crystallite nucleation and growth is also dependent on the 'confusion principle'. This is an empirical observation which suggests that, in a multicomponent melt, several crystalline forms are in competition in the crystallization process; the confused situation that results acts as a barrier to microcrystal growth and enhances the formation of the vitreous state.

Although glasses have been known for more than 4000 years, the number of chemical combinations leading to stable vitreous solids is very limited. In addition, most glasses

have a poor behavior towards devitrification and humidity corrosion and are not suitable for industrial applications.

The most interesting glass compositions are derived from the elements of groups 6 and 7 of the periodic table, that is, the oxides, chalcogenides, and halides. A very specific class of vitreous materials is represented by a new family of noncrystalline solids, the so-called ‘metglasses’ or metallic glasses; their production is special in the sense that they require very rapid quenching of an alloy melt.

In the oxide family of glasses, the situation is largely dominated by silica (SiO_2): however, the oxides P_2O_5, B_2O_3, Al_2O_3, and so on are also known to generate vitreous phosphates, borates, and aluminates. Commercial glasses as used in everyday applications always have complex compositions involving several of these oxides.

The general feature of all chemical combinations that give rise to glass formation is that they correspond to a composition very close to the eutectic region, leading to a liquidus with a low-melting point.

1.3 Glass: A Very Special Solid

As previously mentioned, a glass is a liquid which has reached an infinite viscosity without crystallizing. In this sense, this solid is out of equilibrium and will have very specific and unique properties.

In optics, for instance, a glass is an ideal medium for photon propagation. This is because glass is a homogeneous solid without grains and grain boundaries, so that the scattering of light is minimized. For telecommunications, optical fiber technology has been developed to such a degree that the SiO_2 glasses used can propagate light for more than a hundred kilometers with weak attenuation.

The thermal behavior of a glassy solid is also unique in the sense that all the glasses are characterized by their so-called glass transition temperature, T_g. Above T_g a glass cannot be considered as a real solid with infinite viscosity. The relaxation phenomena happening at T_g correspond to an abrupt change in the viscosity η. This decreases linearly with temperature from T_g where η is typically 10^{13} P. From this point, the glass becomes a plastic solid that possesses unique properties, allowing shaping such as glass blowing, fiber drawing, and so on. The composition of a glass is often characterized by the softening temperature T_s, which corresponds to a viscosity of about 10^7 P, while the drawing temperature for optical fiber preparation corresponds to a viscosity close to 10^5 P.

Another property, characteristic of glassy materials, takes place above T_g when individual atoms begin to have a certain mobility owing to the decrease in viscosity and increase in thermal agitation. From this point, the solid tends towards its thermodynamic equilibrium by generating ordered crystalline phases; this is the domain of microcrystallite nucleation and crystal growth. The control of this phenomenon is essential in glass technology: devitrification can be detrimental, in optics for instance, because this generates scattering centers that are a major cause of optical loss. In other cases, the precise control of microcrystallization leads to very interesting composite materials, the vitroceramics, which consist of a glassy matrix in which submicronic crystals of consistent size are nucleated. The Vision range of cookware developed by Corning is a good example of this kind of product, characterized by an acceptable transparency in the visible region together with a high resistance to thermal shock. In this application, the presence of microparticles is also beneficial in decreasing and attenuating the propagation of mechanical and thermal phonons. The control of glass ceramics preparation at an industrial scale is a difficult challenge, especially when additional nucleating agents such as nanosize ZrO_2 have to be dispersed inside the silica-based matrix. This has been accomplished by Schott with the development of the Zerodur glass ceramic that is insensitive to temperature and is used as substrate for the very large mirrors of the astronomical telescopes. Recently complex silicate compositions containing a significant amount of rare earth and fluorine have been investigated with the aim of taking advantage of a glassy matrix containing low phonon RE doped fluorides crystallites, for laser or optical amplification.[1]

The glass–crystal competition, which is a permanent phenomenon in glass technology, is illustrated in Figure 1 by a typical thermal analysis, recorded for a fluoride glass.

More complex phenomena can also occur, especially when the glass is prepared from complex melt compositions containing several glass-forming components. In this event, subliquidus immiscibility is possible, giving rise to phase separation between two interconnecting glass frameworks usually of very different chemical compositions. One of them can be leached, for example, while the other forms a 3-D porous skeleton. The Vycor® glass developed by Corning is based on this phenomenon. As a frozen liquid, the vitreous state is a unique, homogeneous medium for light transmission. The absence of scattering loss due to grains, grains boundaries,

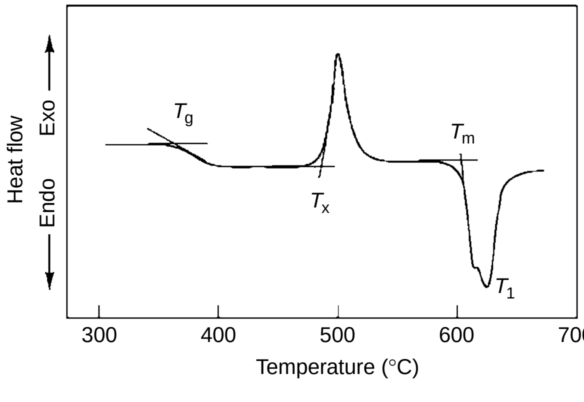

Figure 1 Thermal analysis of a fluoride glass showing characteristic temperatures: T_g is the glass transition temperature; T_x corresponds to the beginning of the crystallization; T_m is where the crystalline phase starts to melt; T_l is the liquidus temperature corresponding to the end of the melting process

the easy shaping above Tg explains why glass is a dominating materials for windows, bottles, optical fibers, and so on.

2 OXIDE GLASSES

2.1 Glass Formation in Oxide Systems

Oxide glass is one of the oldest materials made by man and vitreous objects are associated with the oldest civilizations. Halfway between art and technology, the development of glass making has been for many centuries essentially empirical. Most glasses have been of the soda-lime–silica type, SiO_2 being the major component. The conditions of glass formation in SiO_2-based systems have been extensively investigated and the generally recognized key factors are (1) formation of a 3-D aperiodic framework of SiO_4 tetrahedra sharing corners, (2) thermal motion easily causing rotation or bending of the strong Si–O–Si covalent bond leading to lack of periodicity, and (3) the skeleton can also be a giant negative anion if glass modifier oxides, such as Na_2O, CaO, and so on, are combined with SiO_2. In the latter case, the SiO_4 unit can contain two kinds of oxygen environment: bridging and covalently connected with two Si atoms; nonbridging, bonded on one side to Si atoms and having an ionic interaction on the other side, with the alkali ions statistically distributed inside the framework. Figure 2 illustrates a two-dimensional representation of a SiO_2-based glass.

The same type of strong covalent network with a large degree of freedom between the connected units is also found in a few other glass-forming oxides such as B_2O_3, P_2O_5, As_2O_3, GeO_2, and so on. The vitreous oxides strongly dominate glass science because they offer a large variety of materials with good thermomechanical properties, high resistance to devitrification, and good chemical durability.

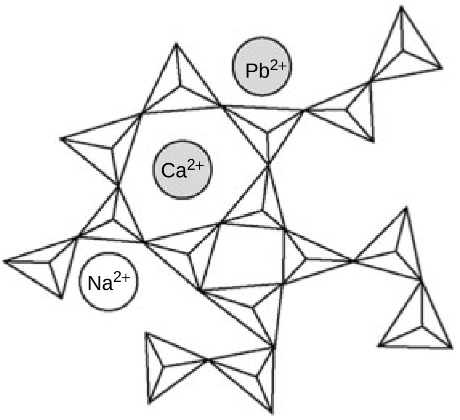

Figure 2 Structural representation of a SiO_2-based glass. The giant 3-D aperiodic skeleton is formed by SiO_4 tetrahedra sharing corners. The addition of glass modifier oxides such as PbO, Na_2O, and CaO results in nonbridging oxygen atom sites and a statistical distribution of the cations Pb^{2+}, Na^+, or Ca^{2+} throughout the lattice

2.2 Vitreous Silica and Silicate Glasses

2.2.1 Vitreous Silica

Silica glass, SiO_2, was initially prepared by fusion of natural crystalline SiO_2, such as quartz or sand. At temperatures above 1750 °C the melt is viscous enough to prevent any crystallization upon cooling. Much purer material, made to meet the requirements of optical fiber technology (e.g. ultralow-loss waveguides) is produced by the vapor phase oxidation[2] of ultrapure $SiCl_4$, following the reaction $SiCl_4 + O_2 \rightarrow SiO_2 + 2Cl_2$. The recent structural information obtained by Elliot[3] and Wright[4] confirms the initial model of Warren.[5] The basic unit of the framework is a very regular tetrahedron with an Si–O bond of 1.608 Å and an O–Si–O angle of 109.7°. Instead of being collinearly connected, the tetrahedra form a spectrum of intertetrahedral angles distributed around the average value of Si–O–Si ∼150°. With a very low thermal expansion coefficient ($\alpha = 5 \times 10^{-7}$ °C^{-1}), SiO_2 glass shows a strong resistance to thermal shock. On the other hand, with a T_g close to 1200 °C, this glass necessitates a very high temperature (>1700 °C) for blowing or fiber drawing. However, silica is highly resistant to devitrification, so that shaping and fiber drawing at such high temperature do not induce any crystallization. Silica is also highly resistant to corrosion, which makes this glass of large interest for long-term applications such as in optical fiber telecommunications.

As far as optical properties are concerned, vitreous silica is highly transparent from nearly 160 nm (8 eV) in the UV to 3 μm in the infrared (IR), as shown in Figure 3.

In the fiber form, silica exhibits a minimum optical loss of nearly 0.2 dB km^{-1} at 1.55 μm, that is far away from the UV and IR absorption edges. Attaining such a low attenuation is possible because of the use of the modified chemical vapor deposition (MCVD) process that eliminates metallic impurities during preform preparation. The usable transmission range of silica fibers utilized in telecommunications is typically from 1.3 μm to 1.6 μm as shown in the attenuation curve in Figure 4. In that range, the remaining losses are due to intrinsic factors: Rayleigh scattering combined with multiphonon absorption, and to extrinsic absorption due to the presence of residual hydroxyl OH groups responsible for the band at 1400 nm. This band corresponds actually to the first overtone of the fundamental O–H vibration. (see also Section 4.3.1)

The typical constitution of an optical fiber is shown in Figure 5. Determined by the initial preform geometry, the core diameter is a few micrometers while the cladding is ≈125 μm. The overall diameter for coated fibers is around 250 μm. With core diameters of the order of magnitude of the propagating wavelength, only the fundamental mode is

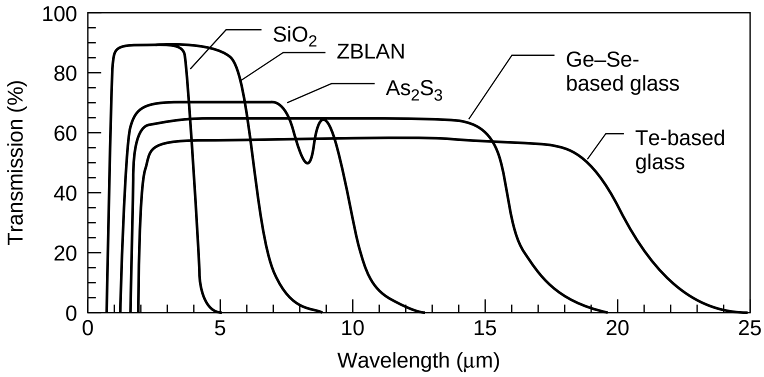

Figure 3 Optical transmission spectra of silica and nonoxide glasses. ZBLAN glass composition is given in Figure 12

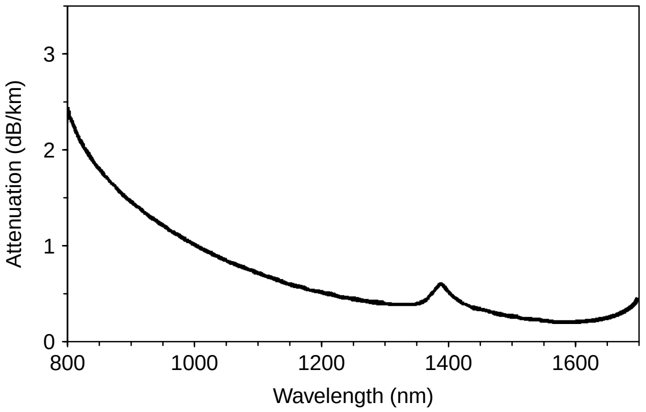

Figure 4 Optical attenuation curve of a single-mode commercial silica fiber

guided in fibers, which are then designated as single-mode fibers.

Because of basic optical principles, the light injected into the fiber must belong to a geometrical acceptance cone in order to be guided within the core. This condition is given by the numerical aperture, defined as $NA = \sin\theta_m = (n_1{}^2 - n_2{}^2)^{1/2}$ with θ_m, the maximum angle of the cone, and n_1 and n_2 the refractive indices of the core and cladding, respectively. Numerical apertures are usually between 0.1 and 0.3 for telecommunication applications, with the refractive index of pure silica equal to 1.4586 at sodium D-line.

For further reading and references on the preparation of silica preforms and fibers, on light propagation and optical losses in fibers, see Ref. 6.

Recently, large-scale research has been devoted to a novel type of silica optical fiber, named photonic crystal fiber, whose structure is very different from that of the conventional fiber described above. The cross section of a photonic crystal fiber is shown in Figure 6. The cladding is made of glass with periodic air holes surrounding a full glass-core. This results in a cladding region with average refractive index lower than that of the core, and light can propagate by total internal reflection, like in a conventional fiber. Among other advantages, photonic crystal fibers possess the potential for broad-band single-mode guiding and high nonlinearities. Further reading is available in Ref. 7

2.2.2 Alkali and Other Binary Silicate Glasses

Glasses can be made in all the alkali silicate systems over a range of composition, from SiO_2 itself up to about 30 mol % Li_2O, 50 mol % Na_2O, or 50 mol % K_2O. The first observation is a large drop in the liquidus temperature and a drastic modification of some properties. For example, T_g falls from 1200 °C for SiO_2 to 350 °C for the 45% Na_2O-containing glass. Over the same composition range the thermal expansion increases almost linearly, from $\alpha = 5 \times 10^{-7}$ °C^{-1} to $\alpha = 200 \times 10^{-7}$ °C^{-1}. For comparison, a typical commercial container glass has an α of 90×10^{-7} °C^{-1} and a T_g around 520 °C. The second tendency of alkali silicate glasses is to give rise to subliquidus immiscibility, leading to glass-phase separation; the same materials are also sensitive to moisture and water corrosion, especially in the alkali-rich region.

In most of the other binary silicate systems, involving oxides such as BaO, CaO, MgO, Al_2O_3, and so on, the liquidus temperature is very high and glass formation is limited by immiscibility in the melt; rapid quenching is needed to obtain glasses. The SiO_2–PbO system is of particular interest because of the low liquidus temperatures; these render glass formation easier and lead to heavy glasses due to the high atomic weight of lead.

The alkali silicate glasses are easily corroded by aqueous acids and the main reaction is an exchange between H_3O^+ of the solution with the alkali M^+ of the glass; the corrosion rate increases with the ionic radii of M^+, that is, $K^+ > Na^+ > Li^+$. The chemical durability is greatly increased by addition of divalent CaO or trivalent Al_2O_3 oxides, leading to commercial soda-lime–silica compositions.

The presence of modifier ions in silicate glasses make it possible to create optical guiding structure by ion exchange at

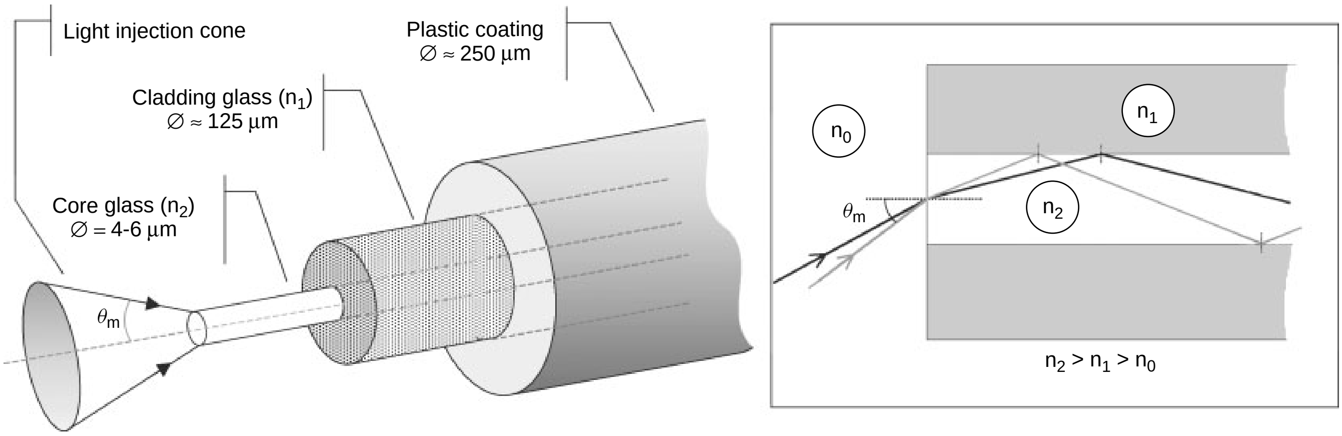

Figure 5 Typical structure of a silica fiber for telecommunication. Frame: Principle of light propagation in a multimode optical fiber

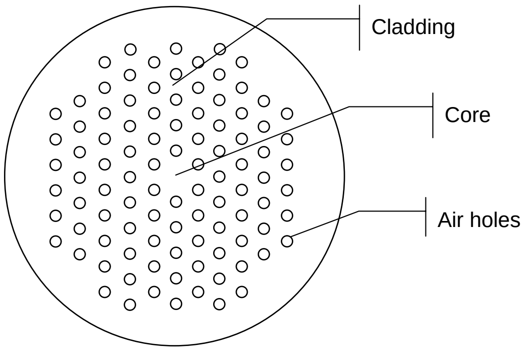

Figure 6 Cross section of a photonic crystal fiber

the glass surface. For example, Na^+ ions in the glass can be exchanged for more polarizable ions like Cs^+, Rb^+, K^+, or for small ions like Li^+ that generates collapsing and consequent densification of the glass matrix. Higher polarizability or material densification result in an increase of the refractive index.[8]

2.2.3 Commercial SiO_2-based Glasses

Commercial glass compositions change from one manufacturer to another, even for a given product. The selection given in Table 1 is taken from the article by Rawson[9] and indicates the general tendency in composition for a given application.

Glasses 1, 2, and 3 are, respectively, float glass for windows, container glass such as for bottles, and the glass used to make incandescent lamp bulbs. They have been optimized to achieve the viscosity–temperature characteristics required by the shaping process, and they are low cost. Glasses 4 and 5 are very rich in PbO and correspond to the traditional lead crystal composition having a high refractive index, $n = 1.6$, giving a brilliant appearance when cut. Glass 5 has the highest content of PbO and has a value of $n = 1.85$. These glasses are also strongly absorbing towards X ray and γ radiation.

Glasses 6, 7, and 8 represent the large and important group of borosilicate glasses including Pyrex, used for chemical apparatus and domestic cookwares.

Glass 9 is rich in alumina (Al_2O_3) and is a high-melting material suitable for glass fibers as used in composite reinforcement or thermal isolation. Glass 10 is used for cathode-ray tubes, glass 11 is an optical glass, and glass 12 is a solder glass used because of its high fluidity at about 550 °C to seal soda-lime glasses.

2.3 Boric Oxide and Borate Glasses

2.3.1 Boric Oxide Glass

B_2O_3 is very easily contaminated by OH and this significantly affects thermal properties, such as the melting point around 450 °C, leading to a melt with a rather low viscosity which vitrifies easily; the corresponding glass has a T_g close to 260 °C.

The building units in B_2O_3 glasses are triangular, owing to the three bonding electrons on the boron atom and sp^2 hybridization. Their association by corner sharing leads to a 2-D aperiodic network. As shown in Figure 7, the interchain connections generate boroxol groups, $B_3O_3O_{3/2}$.

2.3.2 Borate Glasses

Glass formation in the alkali borate system is characterized by an increase in the liquidus temperature, a high tendency to crystallize compared to B_2O_3 itself, and to give subliquidus immiscibility.[10,11] The phase separation phenomena can markedly affect the properties of borate glasses such as viscosity. The origin of this immiscibility can be found in the formation of two independent glassy networks during the addition of alkali oxides, M_2O.[12] The additional oxygen atoms brought by M_2O lead to a BO_4 tetrahedra-based

framework which is separated from the initial BO_3 triangular-based structure.

2.3.3 Borosilicate Glasses

While the practical applications of borate glasses are very limited, the glasses derived from Na_2O–B_2O_3–SiO_2 systems are of considerable technological importance. They include the glass commonly known as Pyrex, used for chemical apparatus and ovenware.

The addition of B_2O_3 to a silicate glass markedly reduces the thermal expansion coefficient and consequently enhances the resistance to thermal shock. At the same time, the chemical durability, especially the resistance to acid attack, is greatly improved.

Several borosilicate glass compositions exhibit immiscibility; they separate into two interconnecting phases, one rich in sodium borates, the other being almost pure silica. The first phase can be leached out by immersing the material in acid. The densified remaining glassy phase gives so-called Vycor® glass. The porous silica skeleton can also be used as a host for enzymatic and catalytic reactions.

2.4 Phosphate Glasses

The higher phosphorus oxide, P_2O_5, is a highly hygroscopic material. On melting it gives a very viscous liquid which can be readily supercooled to give a glass. This particular material has no practical interest owing to its rapid corrosion by water and moisture.

Information on binary phosphate glasses has to be regarded with some care owing to the variable amount of water retained in the glass and which varies with composition, time, and temperature of melting. The glass-forming ability and properties are very dependent on OH content, which introduces strong hydrogen bonds and which varies according to the equilibrium $2OH^- \rightleftharpoons O^{2-} + H_2O$.

The most interesting phosphate glasses for practical applications are multicomponent materials, often containing fluorides. They have been developed as optical glasses for laser applications; for instance, the Nd^{3+}-doped phosphate glasses of high optical quality used in large, high-power laser fusion have been selected because of their low nonlinear refractive index which attenuates the risk of beam self-focusing.

Er^{3+}-doped phosphate glasses are also very efficient lasers operating at 1.54 μm. In order to improve the resistance of the material to thermal shocks due to intense light pumping, phosphate glasses can be chemically strengthened by an ion-exchange process – Na^+ or K^+ for Li^+ – at the glass surface. Thus, laser output as high as 600 mJ at 1.54 μm could be achieved with 100 J pump energy.[13]

It must be noticed that Ca rich phosphate glasses and glass ceramics having a composition very close to apatite, the main component of bones are bioactive materials capable of bonding to natural bones and then used for surgery implantation.[14]

2.5 Miscellaneous Oxide Glasses

Several other oxides, such as GeO_2, Al_2O_3, TeO_2, and V_2O_5, containing small highly charged polarizing cations, are also able to form glasses when undercooling the melt. In these cases, the tendency for crystal formation upon cooling is very high and fast quenching is necessary.

GeO_2 is used in small quantities in the core of optical fibers for increasing the refractive index of SiO_2 in order to achieve the optical guiding conditions.

The only interest in this expensive oxide is its better IR transparency owing to a shift of the multiphonon edge; glasses of optical quality are therefore difficult to achieve even in multicomponent compositions. Addition of modified oxides such as alkali to GeO_2 contributes to the formation of GeO_6 octahedra in addition to the existing GeO_4 tetrahedra. Lead germanate glasses are commercial IR products.

The situation is very similar for Al_2O_3-based glasses. In the Al_2O_3–CaO system, where the two starting components have high-melting points, glasses can be prepared by fast quenching of the melt in the eutectic regions where the liquidus is around 1400 °C. The stability of Al_2O_3-based glasses is improved by making the composition more complex, but SiO_2 addition is detrimental to IR transparency.

A homogeneous TeO_2 glass is obtained only by quenching the melt when it is viscous above the melting point. The most stable tellurite glasses are formed in systems such as TeO_2–PbO, BaO, and so on. These glasses are of some interest because of their high refractive index, which can reach values up to 2.3. As far as phonon energies are concerned, tellurites are classified as intermediate glasses, between silicates and halides.[15]

V_2O_5 melts at 660 °C and forms a glass only by fast quenching. Therefore complex compositions belonging to the system V_2O_5–BaO–K_2O–ZnO enhance glass-forming ability. The most notable characteristic of these glasses is due to the easy mixed valence V^{4+}/V^{5+} situation, leading to semiconducting properties and coloration arising from charge transfer absorption.

The rigidity of the silicate or phosphate glass network can be markedly enhanced by substituting some oxygen atoms by nitrogen. The corresponding oxynitride glasses are characterized by a general modification of their thermal properties such as a sharp decrease in the expansion coefficient α and an increase in glass transition temperature. In the Y–Si–Al–O–N system,[16] when the nitrogen atomic percentage is increased from 0 to 6%, α varies from 70×10^{-7} to 35×10^{-7} °C^{-1} and T_g moves from 800 to 900 °C. Both observations indicate an increase in the degree of cross-linking when the trivalent N atoms substitute the divalent O atoms in the glass-forming skeleton.

The most effective way of making nitrogen-containing silicate glasses is to melt together mixtures of oxides and nitrides in a nitrogen or inert atmosphere. A maximum of 10% atomic substitution is generally attained and it has been observed that the nitrogen solubility is increased if the glass composition contains Al_2O_3. This is attributed to the fact that the $Si(O,N)_4$ and AlO_4 tetrahedra are of similar size.

2.6 Glasses from Ionic Salts

Vitreous materials can be formed by undercooling certain molten salts consisting of mixtures of nitrates, acetates, and sulfates, which contain discrete anions such as NO_3^-, $C_2O_4^{2-}$, SO_4^{2-}, and so on.

As discussed by Angell,[17] the conditions for glass formation in such unusual systems are not very well understood, especially because of a lack of information about contamination of these molten salt mixtures by water.

As expected, the absence of crystallization upon cooling is especially marked when the melt is close to the eutectic region, having a low liquidus temperature. For example, the region of glass formation in the binary system KNO_3–$Ca(NO_3)_2$ is for 60 mol % KNO_3, corresponding to a eutectic temperature of 146 °C, while the melting points of the two constituents are 337 °C (KNO_3) and 561 °C ($Ca(NO_3)_2$).

Several sulfate mixtures such as $KHSO_4$–$NaHSO_4$ are also glass formers with good resistance to crystallization.

The fact that many crystalline hydrates melt, such as $Ca(WO_3)_2{\cdot}4H_2O$, while more complex binary hydrated systems have a tendency to form glasses is an indication of the critical role of the water molecule and the hydrogen bond.

It is clear that the polymerization process in these low-melting melts involves strong hydrogen bonding between the OH^- group and the O^{2-} atom of the neighboring anions. Rotation as well as bending of the hydrogen bond is rather easy, making possible a system with a lack of periodicity.

There are no commercial applications for these unconventional glasses.

3 CHALCOGENIDE GLASSES

3.1 Introduction: Definition

Chalcogenides are compounds containing elements of group 6 of the periodic table, with the exception of oxygen. Chalcogens such as sulfur, selenium, and tellurium are characterized by the typical six-electron outer shell $s^2p_x{}^2p_y{}^1p_z{}^1$. In most of the vitreous combinations described in this article, the chalcogen atom will be divalent, using its two odd electrons in twofold coordination. The two remaining nonbonding pairs will be considered as localized lone pairs having a strong stereochemical effect around the chalcogen and introducing nonbonding atomic levels in the energy diagram.

Most of the metallic chalcogenides are found as crystalline materials, often with 2-D character and only a very limited number of them are able to form glasses from the melt.

Consequently, the chalcogenide glass family is essentially represented by polymer-type compounds in which the chemical bond is highly covalent. The chalcogen atom is then bonded to neighboring elements of the periodic table with similar electronegativity, such as As, P, Ge, Si, Cl, Br, and Bi. The conditions of glass formation and the physics of amorphous chalcogenides have been discussed and reviewed by Elliot.[18,19]

These materials are generally semiconductors with small band gaps in the range of 1–3 eV, owing to the specific character of the chemical bonds, that is, covalence plus nonbonding electrons. The band-gap edge is then located in the visible or near-IR region and most of those glasses are black. Owing to the high atomic weights of the constituent elements, these glasses have IR absorption edges located in the long wavelength region, which renders these materials very attractive for IR light transmission.

3.1.1 Classification of Chalcogenide Glasses

The noncrystalline chalcogen-containing materials can be distinguished according to the nature of the accompanying elements. As presented in Table 2, four general families of glasses can be identified.

Category 1 is represented by pure chalcogen, solid solutions of different chalcogens, or association with a pseudochalcogen such as As or P having a very similar electronegativity. Crystalline sulfur or selenium on melting give very viscous melts, indicating that the liquid phase is highly polymerized. Since the elemental chalcogens are twofold coordinated, the structural configuration of the resulting polymer is limited to rings or chains bonded together by van der Waals or dipole–dipole forces. A sulfur glass can be made by quenching the melt above a temperature of about 440 K, when the high viscosity is due to long polymeric chains.

In the case of Se, the chains already exist in the crystalline form and, just above the melting point ($T_m = 490$ K), the liquidus is viscous enough to lead to easy glass formation even with a moderate cooling rate.

Tellurium, which has more metallic character, is not able to support a polymeric arrangement in its liquid phase, which has a low viscosity like a molten metal. Glass formation is only possible from $Te_{1-x}Se_x$ solutions, and even then very fast quenching such as melt spinning is needed.

Table 2 Categories of chalcogen-based glasses[a]

No. Category	Examples of glass former
1. Pure chalcogen (6–6)	S, Se, Se_{1-x}, Te_x
or pseudochalcogen (5–6)	Se_{1-x}, S_x, As_2S_3, As_2Se_3
2. Semimetallic chalcogenides	$SiSe_2$, GeS_2
3. Metallic chalcogenides	Al_2S_3, Ga_2S_3
4. Chalcogen halides	Te–Cl, Te–Br

[a]5 and 6 represent elements from group 5, except N, or group 6, except O, of the periodic table.

The most interesting materials in this group of glasses are the arsenic sulfide and selenide, As_2S_3 and As_2Se_3. This combination of groups 15 and 16 elements gives rise to a very strong covalent 2-D framework, rendering these materials stable to devitrification and chemical attack. Glass formation has also been discovered in the $P_{1-x}Se_x$ system[20] close to $x = 0.2$ and $x = 0.75$, but the corresponding glasses have no application due to poor chemical durability.

Category 2 corresponds to chemical combinations of groups 4 and 6 elements. In this particular case the group 4 atoms, such as Si and Ge, will be fourfold coordinated and form SiS_4 or GeS_4 tetrahedra. From this elementary, symmetric module, a 3-D aperiodic framework is expected similar to that in SiO_2 glass, except that the large size of the tetrahedron will allow edge sharing in addition to corner sharing.

This classification is of course arbitrary, and it must be noted that the very stable chalcogenide glasses are often ternary or quaternary compounds corresponding to mixed complex compositions of categories 1 and 2. For instance, the commercial glass called AMTIR (Amorphous Materials Transmitting Infrared) is the multicomponent glass $As_{12}Ge_{33}Se_{55}$. Figure 8 represents the region of glass formation in the system As–Ge–Se.[20]

Category 3 corresponds to combinations of a real metal such as aluminum or gallium with a chalcogen such as S. The simple sulfides, Al_2S_3 or Ga_2S_3, cannot form glasses by themselves and need to be combined with glass modifiers such as rare earth sulfides La_2S_3. For some other glasses, stabilizers are also necessary and ternary glasses have been isolated in the system Ga_2S_3–MnS–La_2S_3,[21] for instance. The glass-forming units here are also tetrahedral AlS_4 or GaS_4, and probably octahedral MnS_6.

The last group of glasses, corresponding to category 4, are similar to those of class 1 in the sense that they have a Se-type chain structure. A decade ago, glasses were discovered[22] in the Te–X system (X = Cl, Br, I), leading to glassy polymeric materials with very low phonon energies and excellent IR-transmitting properties.

3.2 Structure and Bonding in Chalcogenides Glasses

3.2.1 The Building Units

For most of the chalcogenides in categories 1–4, three types of building unit (Figure 9) can be distinguished, giving rise to so-called short-range order.

1. The angular unit is illustrated by the Se atom: among the six outer electrons, only two are bonding, the two other pairs being localized and giving, by repulsion with the bonding pairs, a pseudotetrahedral arrangement around Se.
2. The distorted triangular unit observed around group 5 elements such as As: in this case the three bonding

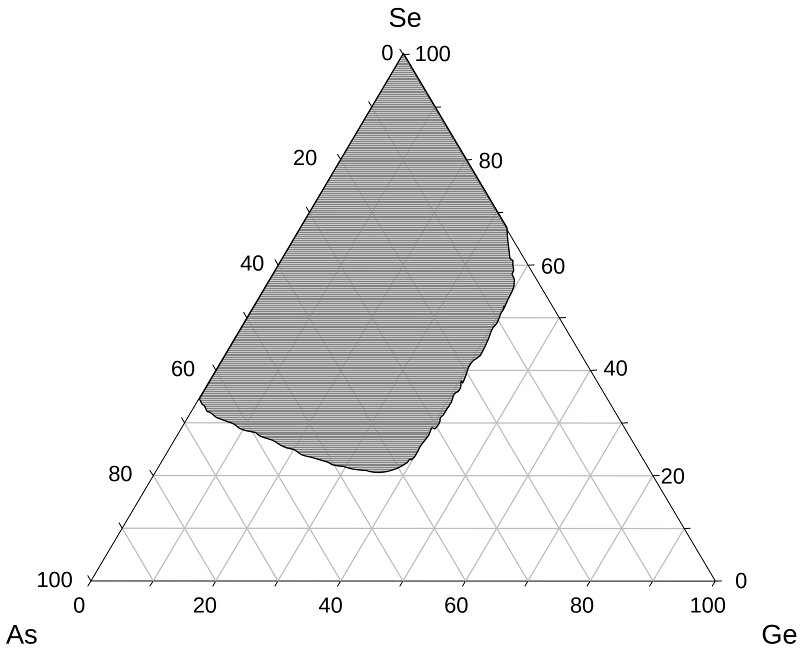

Figure 8 Glass-forming zone (approximate, since it depends on the quenching rate) in the Ge–Se–As system. The three components Se, $GeSe_2$, and As_2S_3 alone are able to form glasses

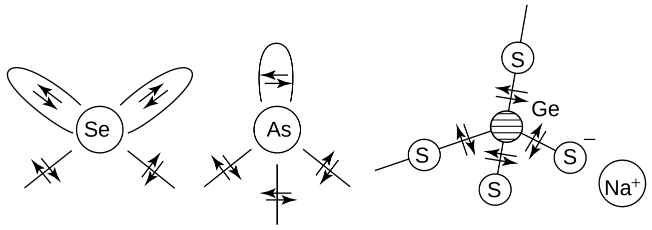

Figure 9 Building units found in most of the chalcogenide glasses: the angular unit existing in Se-type glasses; the pyramidal unit of the As-based glasses; and the tetrahedron of the GeS_2 glass

electrons lead to three bonding pairs which complement the remaining lone pair.

3. From the analysis of the corresponding crystalline materials the tetrahedron is the basic unit in the SiS_2-, $GeSe_2$-, Al_2S_3-, and Ga_2S_3-based glasses. When the glasses are stabilized by modifiers such as Na_2S, BaS, and La_2S_3, the tetrahedra are formed by bridging and nonbridging chalcogen.

3.2.2 The Nonperiodic Skeleton of Chalcogen-based Glasses

From the elementary units previously described, several 1-D, 2-D, or 3-D frameworks can be constructed, as shown in Figure 10. One-dimensional chains are found in Se by connecting the angular units. In sulfur, it has been observed that the unit can be rotated along the covalent σ-bond, giving rise to an equilibrium between chains and S_8 rings. The same situation occurs in SiS_2 glass, but here the chains are formed by connecting SiS_4 tetrahedra by sharing edges. In this $SiS_{4/2}$ chain, the distorted Si–S–Si bond reflects the strong stereochemical effect of the S electronic lone pairs.

In both 1-D-based glasses, the interactions between the chains being of the van der Waals type, are weak, and allow easy rotation or bending. Two-dimensional configurations, giving rise to distorted layer structures, are found in As_2S_3- or GeS_2-type glasses. The connection of pyramidal and angular units in As_2S_3 lead to an infinite distorted 2-D framework. The periodicity in this orpiment-related structure can be easily destroyed because the layers are bonded by van der Waals forces and because rotation and bending are possible around the S–As–S σ-bond without costing too much energy.

In GeS_2-based glasses, examination of the parent crystalline materials indicates that GeS_2 tetrahedra, connected by corner and edge sharing, also form a layered 2-D structure.

A 3-D framework analogous to the SiO_2 cristobalite structure is of course easy to build from elementary tetrahedra. Notice that, in the Ge/S system, the glass-forming ability is maximum for the composition GeS_4 which corresponds to tetrahedra connected by a S–S pairs bonds.

In all of these giant skeletons, the glassy state arises from the easy lack of periodicity. This means that a small rotation or bending of the bonds does not markedly affect the free enthalpy of the system because of framework flexibility.

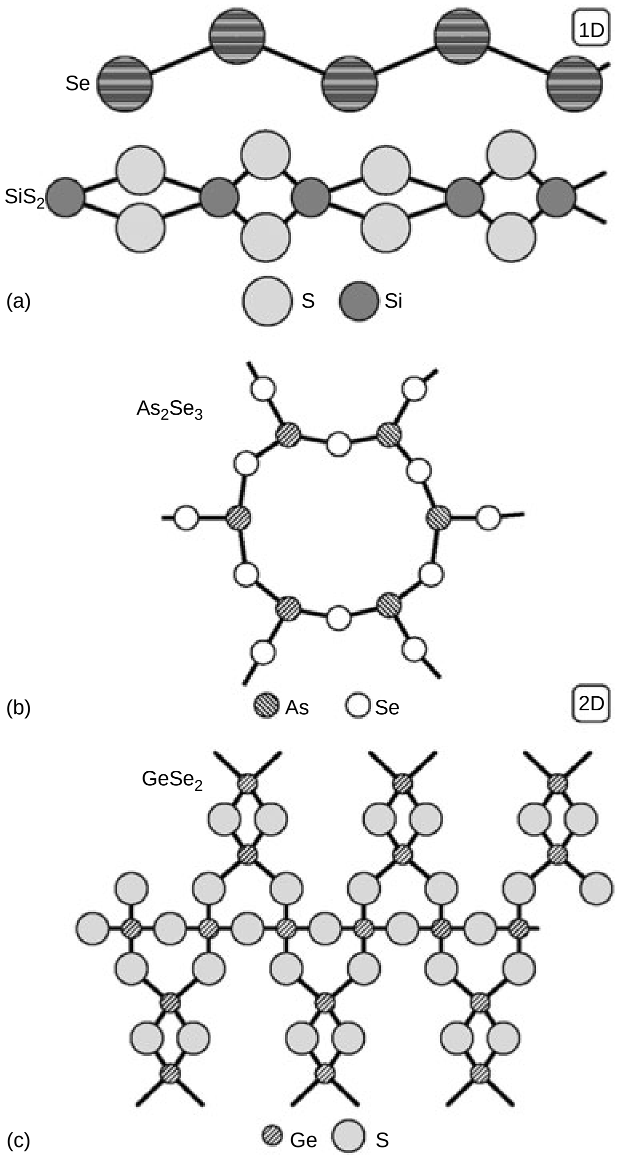

Figure 10 The different frameworks formed in chalcogen-based glasses: (a) a chain-like structure in Se or SiS_2; (b) 2-D skeleton in As_2S_3 formed by linking Se angular and As pyramidal units; (c) by sharing corners and edges, the tetrahedra of the GeS_2-based glasses also form a 2-D framework

3.3 Properties of Chalcogen-based Glasses

3.3.1 Thermal Properties

The glass transition temperatures give a good indication of the thermal stability of chalcogen-based glasses. Below T_g the glass is a real solid with infinite viscosity while above T_g the viscosity begins to decrease linearly, rendering the glass first plastic and then similar to a viscous liquid. Knowledge of these data is essential to allow comment on the thermal capabilities and for shaping the glass. Operations such as annealing, for relaxing the local stresses, and fibering, for optical waveguide preparation, need a precise determination of T_g. Table 3 gives T_g values for several glasses.

Table 3 Glass transition temperatures for several chalcogen-based glasses

Glass	T_g (°C)
S	−27
Se	35
Te_3Cl_2	82
As_2S_3	205
As_2Se_3	195
$As_{12}Ge_{33}Se_{55}$	362
$GeSe_2$	422
GeS_2	492

The glass transition temperature is directly related to the dimensionality of the glass and can be considered as an indication of the rigidity of the framework. For instance, the low T_g glasses are 1-D chain-like materials such as Se or Te_3Cl_2, while the high T_g glasses belong to families having a 2-D or 3-D configuration.

The same situation is found when wrong-bond[23] nonbridging anions are introduced in a glass by way of chalcogen–halogen substitution or sulfides are added as modifiers. For instance, T_g falls rapidly when xS atoms are substituted by $2x$I atoms to preserve electroneutrality in GeS_2 glass. The result of this substitution, when $x = 1$, is the formation of a chain-like glass $GeSI_2$, containing tetrahedral GeS_2I_2 units connected by corners and sharing only S atoms ($GeS_{2/2}I_2$), the I atoms being terminal.

When Na_2S is added to GeS_2 the same phenomenon is observed, the additional S atoms break the dimensionality of the skeleton by the transformation of the bridging bonds ···Ge–S–Ge··· into two nonbridging ···Ge–$S^-Na^+S^-$–Ge··· bonds, as indicated in Figure 9.

Chalcogen-based glasses can be deposited to form thin amorphous films by thermal evaporation or sputtering, owing to their low thermal characteristics. This technique is widely used in the deposition of Se-rich glasses on to cylindrical drums used as the photosensitive surface in Xerography.

3.3.2 Electrical and Optical Properties

A simplified picture of the density of states in a chalcogenide material comprises a low-energy σ valence bond and, at higher energy, the σ^* antibonding level corresponding to the conduction band. The novelty of chalcogen-based glasses comes from the existence of a nonbonding (nb) level arising from the lone pair electrons situated above the σ level, as depicted in Figure 11. The optical band gap E_g is due to the transition from the nb level to the σ^* level and it is observed that E_g varies from about 1 to 2.5 eV. The corresponding optical absorption edges follows Urbach-edge behavior and

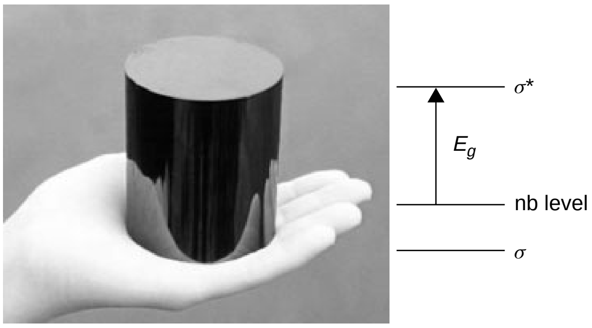

Figure 11 Optical band gap in chalcogen-based glasses. The optical band gap E_g is due to the transition from the nonbonding level to the antibonding level σ^*, which results in black-color glasses

give high values of the absorption coefficient α in the visible part of the spectrum. Consequently, most of the chalcogen-based glasses are black, as shown in Figure 11 except As_2S_3 that has a reddish color. (Recall the relationship λ_{max} (μm) E_g(eV) $= 1.24$ giving the correspondence between the band gap (electron volts) and the corresponding light wavelength and note that the optical absorption edge is not sharp but exhibits a long tail in the gap region.)

The chalcogenide glasses transmit light from the Urbach edge until the IR region where a second mechanism generates photon absorption. This phenomenon takes place in the low-energy region and arises from multiphonon processes associated with fundamental phonon vibrations of the material. In most of the chalcogen-derived glasses that contain heavy elements, the vibrational modes are at low energy and they exhibit excellent IR-transmitting properties. Most of the commercial chalcogen-based glasses such as AMTIR therefore have their IR cutoff after the 12 μm region and consequently cover the very strategic region 8–12 μm, corresponding to the second atmospheric window. This IR window is used for military and civil applications such as missile guidance, thermal imaging, and thermal detection, and so on. Chalcogen-based glasses can be shaped for making IR lenses and windows, and so on, as well as optical fibers used for carrying IR laser light from CO or CO_2 lasers and for local thermal imaging of room temperature black-body emitters.

Recently, chalcogenide glass IR fibers have been used as optical sensors for recording, in situ, the IR signatures of all kind of molecules in chemistry and biology. The principle is based on the absorption of the evanescent light circulating on the surface of the fiber, by the materials entering into contact with the fiber especially in the part which has been tapered.[24]
